If $\Delta = ad - bc = 0$, our mapping would be $z' = a/c$, a mapping of the whole inversive plane onto one point. If $c = 0$, the mapping is $z' = (az + b)/d$, which is a dilative rotation if $d \neq 0$. But if $\Delta = 0$ also, $ad = 0$. If $d = 0$, all points of the inversive plane are mapped onto the one point $z' = \infty$, and if $a = 0$, $z' = b/d$. If both $a = 0$ and $d = 0$, $z' = \infty$. Hence we see that there is a very sound reason for insisting that $\Delta \neq 0$, since we wish to consider non-degenerate mappings. Degenerate mappings, in which all points of the inversive plane are mapped onto one point, are of little interest.

We now see that the condition $\Delta \neq 0$ is sufficient for a Moebius transformation to be a one-to-one onto mapping of the inversive plane, a bijective mapping. In the first place $(az + b)/(cz + d)$ defines a unique z' unless $cz + d = 0$. But if $cz + d = 0$, so that $z = -(d/c)$, we cannot also have $az + b = 0$ for this value of z, since this would imply that $a(-d/c) + b = 0$, or $\Delta = ad - bc = 0$. Hence $cz + d = 0$ gives $z' =$ (non-zero constant)/0, and we have agreed that this gives $z' = \infty$.

The point $z = \infty$ has a unique image-point, since

$$\frac{az + b}{cz + d} = \frac{a + b/z}{c + d/z} = \frac{a}{c}$$

when $z = \infty$, by our rules. Hence every point of the inversive plane maps onto a uniquely defined point of the inversive plane.

The inverse mapping is given by $z = (-dz' + b)/(cz' - a)$, and this is again a Moebius transformation, since the determinant of this mapping is

$$(-d)(-a)-bc = ad-bc = \Delta\neq 0.$$

Hence the object-point z of an image-point z' is uniquely determined, and since every point z of the inversive plane has an image z', and every point z' of the inversive plane arises from a uniquely defined point z of the inversive plane, the mapping given by our Moebius transformation $z' = (az + b)/(cz + d)$ is one-to-one and onto, in other words, *a bijective mapping*.

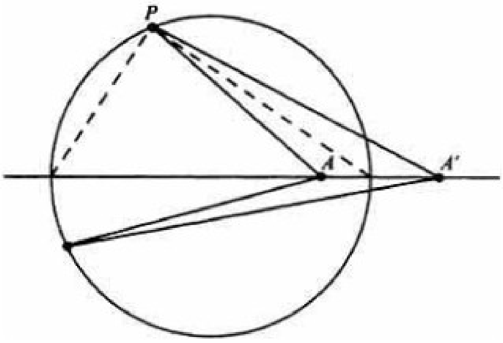

Fig. 52.2

By choosing special values of the constants a, b, c and d, we obtain a number of mappings which we have already encountered. But we can also *dissect* the given mapping into a product of familiar mappings. Before we do this, we examine the effect of a Moebius mapping on lines and circles.

52.3 The map of a circle or line under a Moebius transformation

Theorem *A Moebius transformation is a circular transformation, that is, it maps the set of circles and lines into the set of circles and lines.*

Proof. We can prove this theorem and an additional one by taking the equation of a circle or line in the z-plane in the form $|z - p| = k|z - q|$, where k is a real number (Fig.52.2). This is an expression of the theorem that any circle is the locus of a point which moves so that the ratio of its distances from two fixed points is a constant, these fixed points being inverse points for the circle. When the locus is a line, $k = 1$, and the points are mirror images in the line. The circle is called an Apollonius circle with respect to the two points (see §18.3). If we now transform this equation by the Moebius mapping $Z = (az + b)/(cz + d)$, we must write $z = (-dZ + b)/(cZ - a)$, and we obtain the equation

$$\left|\frac{-dZ+b}{cZ-a} - p\right| = k\left|\frac{-dZ+b}{cZ-a} - q\right|$$

and, after a little reduction this leads to

$$|Z(-d-pc)+b+pa| = k|Z(-d-qc)+b+qa|$$

or

$$\left|Z - \frac{ap+b}{cp+d}\right| = k\left|\frac{d+qc}{d+pc}\right|\left|Z - \frac{aq+b}{cq+d}\right|,$$

which is of the form

$$|Z-p'| = k'|Z-q'|,$$

where p', q' are the maps of the points p and q under the Moebius transformation, and $k' = k|d + qc|/|d + pc|$.

The form of the equation for Z shows that the transform is either a line or a circle, and we also have:

Corollary. The map of a circle and a pair of inverse points under a Moebius transformation is a circle and a pair of inverse points, where if the circle is a line, the points are mirror images in the line.

Other proofs of this theorem and Corollary are indicated in Exercises 52.1, 52.3.

52.4 Dissection of a Moebius transformation

We may write

$$z' = \frac{az + b}{cz + d} = \frac{a}{c} + \frac{(bc - ad)}{c(cz + d)} = \frac{a}{c} + \frac{(bc - ad)}{c^2}\left(\frac{1}{z + d/c}\right).$$

We now write

$$\text{(i)}\ T_{a/c}: z_1 = z + d/c,$$

$$\text{(ii)}\ N: z_2 = 1/z_1,$$

$$\text{(iii)}\ D: z_3 = \frac{(bc - ad)}{c^2} z_2,$$

$$\text{(iv)}\ T_{a/c}: z' = a/c + z_3.$$

The mapping (i) is a translation, (ii) is an inversion in the unit circle, center at the origin, followed by a reflexion in the real axis, (iii) is a dilative rotation, and (iv) is also a translation. If we give names to these familiar mappings as indicated, then

$$z' = \frac{az + b}{cz + d} = zT_{d/c}NDT_{a/c}.$$

In other words, a general Moebius transformation is the composition of a translation, an inversion in the unit circle followed by a reflexion in the *X*-axis, a dilative rotation and a translation. Many important consequences follow from this dissection, as the exercises following indicate.

Of course, a Moebius transformation is not, in general, a direct isometry, nor a direct similitude, although these mappings are included amongst Moebius transformations as special cases.

52.5 The group of Moebius transformations

Theorem *Moebius transformations form a group* $\mathscr{B}$ *under composition of mappings. If B and C are two Moebius mappings,* Δ_B *and* Δ_C *their determinants, then* $\Delta_{BC} = \Delta_B\Delta_C$ *is the determinant of the Moebius mapping BC.*

Proof. We have seen already that if B is a Moebius transformation, so is B^{-1}. The identity mapping $z' = z$ is a Moebius transformation. If $B: z' = (az + b)/(cz + d)$, $\Delta_B = ad - bc$, $C: z' = (a'z + b')/(c'z + d')$, $\Delta_C = a'd' - b'c'$ are two Moebius transformations, then the composition is

$$BC: z' = \frac{a'(az+b) + b'(cz+d)}{c'(az+b) + d'(cz+d)} = \frac{(aa' + b'c)z + a'b + b'd}{(ac' + cd')z + bc' + dd'},$$

and $\Delta_{BC} = (aa' + b'c)(bc' + dd') - (a'b + b'd)(ac' + cd') = (ad - bc)(a'd' - b'c')$, after some cancellation, so that $\Delta_{BC} = \Delta_B \Delta_C$, as we wished to prove, and since $\Delta_B \neq 0$, $\Delta_C \neq 0$, $\Delta_{BC} \neq 0$, and so the composition is also a Moebius transformation. The associative law holds for composition of bijective mappings, and therefore all the group axioms are satisfied, and the theorem is proved.

Exercises

52.1 By looking at the dissection of a Moebius transformation show that a Moebius transformation maps lines onto lines or circles, and circles onto lines or circles.

52.2 Show that the mapping $z' = 1/z$ maps the points 2, $1 + i$, $1 - i$ of the circle $|z - 1| = 1$ onto the collinear points $1/2$, $1/2 - i/2$, $1/2 + i/2$. Can you explain why this is so?

52.3 Give another proof of the Corollary to Thm 52.3, by examining the effect of the component parts of a Moebius transformation.

52.4 In the proof of Thm 52.3, the condition that the map of our circle or line be a line is $k' = k|d + qc|/|d + pc| = 1$. Show that an equivalent condition is that the point $z = -d/c$ which maps onto the point $Z = \infty$ lie on the circle $|z - p| = k|z - q|$. Why is this equivalence to be expected?

52.5 Show that the condition that $Z = (az + b)/(cz + d)$ should map the circle $|Z| = 1$ onto a line in the z-plane is $|a| = |c|$.

52.6 If a given Moebius transformation maps a circle $\mathscr{C}$ onto a circle $\mathscr{C}'$, show that a point P moving continuously on $\mathscr{C}$ is mapped onto a point P' which moves continuously on $\mathscr{C}'$, but that clockwise motion on $\mathscr{C}$ may be changed into anti-clockwise motion on $\mathscr{C}'$.

52.7 By Thm 52.5, the determinant of the mapping inverse to $z' = (az + b)/(cz + d)$ should be $(ad - bc)^{-1}$, whereas the mapping $z = (-dz' + b)/(cz' - a)$, which is the inverse mapping, has determinant $ad - bc$. Can you explain this?

53.1 Fixed points of a Moebius transformation

Theorem *If a Moebius transformation has more than two distinct fixed points, it is the identity mapping, $z' = z$.*

Proof. If w is a fixed point, then $w = (aw + b)/(cw + d)$. This leads to the quadratic equation $cw^2 + (d - a)w - b = 0$. If this equation has more than two distinct roots, it must be the identical equation $0 . w^2 + 0 . w + 0 = 0$, so that $c = d - a = b = 0$. Then the mapping is $z' = z$, since $\Delta = ad \neq 0$, and so neither a nor d is zero, and $z' = az/d = z$.

It is sometimes possible to say that a given mapping is uniquely determined when a certain number of distinct points and their images under the mapping are given. We came across theorems of this nature with isometries (Thm 43.5). A Moebius transformation depends on the ratios of four constants, a, b, c, d, subject to the conditions $ad - bc \neq 0$, and we expect such a transformation to be given if three distinct points and their images are assigned. But a stronger theorem is true.

53.2 The determination of a Moebius transformation

Theorem *A Moebius transformation is uniquely determined by the assignment of three distinct points z_j and their three distinct image points z_j'* ($j = 1, 2, 3$).

Proof. Consider the mapping $B{:}z' = (z - z_2)(z_1 - z_3)/(z - z_1)(z_2 - z_3)$. This is a Moebius transformation, since its determinant is

$$\Delta c = (z_2' - z_3')(z_1' - z_3')(-z_1' - z_2') \neq 0,$$

Under the mapping B, the image of $z = z_1$ is $z' = \infty$, the image of $z = z_2$ is $z' = 0$, and the image of $z = z_3$ is $z' = 1$.

Now define a mapping $C{:}z' = (z - z_2')(z_1' - z_3')/(z - z_1')(z_2' - z_3')$. Here the determinant is

$$\Delta c = (z_1' - z_3')(z_2' - z_3')(-z_1' - z_2') \neq 0,$$

so that this is also a Moebius transformation, and under this mapping the points z_1', z_2' and z_3' are mapped, respectively, onto the points ∞, 0 and 1. The composition of transformations BC^{-1} is again a Moebius mapping, and maps z_1 onto ∞ and then onto z_1', z_2 onto 0 and then onto z_2', and finally z_3 onto 1 and then onto z_3'.

Hence BC^{-1} is a Moebius transformation which maps z_1, z_2, z_3 onto the points z_1', z_2', z_3'. Is it unique? If A were a distinct Moebius mapping with the same properties, the Moebius mapping $(BC^{-1})A^{-1}$ would have three distinct fixed points, z_1, z_2 and z_3, and by Thm 53.1, the transformation $(BC^{-1})A^{-1} = \text{Identity}$, which means that $BC^{-1} = A$.

We are on ground familiar to those who know something about projective geometry (§69.1), and without saying so, we have been using the concept of *cross-ratio*.

53.3 The cross-ratio of four complex numbers

Definition. The cross-ratio of the four points (or complex numbers) z_j ($j = 1, 2, 3, 4$) is the complex number

$$(z_1, z_2; z_3, z_4) = \frac{(z_1 - z_3)}{(z_2 - z_3)} \Big/ \frac{(z_1 - z_4)}{(z_2 - z_4)}$$
$$= \frac{(z_1 - z_3)(z_2 - z_4)}{(z_2 - z_3)(z_1 - z_4)}.$$

It will be noticed that the order of the points is significant, and in fact there are, on the face of it, 4! = 24 different values of the cross-ratio of four given points, if the order of the points is not assigned. But these fall into six sets, since there are relations between the values which arise after a permutation of the points. The full details will be given later (§69.1). Here we need one property of the permutations:

Theorem $(z_1, z_2; z_3, z_4) = (z_2, z_1; z_4, z_3)$.

Proof. This is simple verification:

$$(z_2, z_1; z_4, z_3) = \frac{(z_2 - z_4)}{(z_2 - z_3)} \Big/ \frac{(z_1 - z_4)}{(z_1 - z_3)} = \frac{(z_1 - z_3)(z_2 - z_4)}{(z_2 - z_3)(z_1 - z_4)}$$
$$= (z_1, z_2; z_3, z_4).$$

Remark. The above is a special case of the theorem that *interchanging one pair* of the four numbers *and also the other pair* leaves the cross-ratio unchanged (compare Exercise 69.1).

One reason for the importance of the cross-ratio of four numbers is its *invariance* under any Moebius transformation. We prove this in the next section, but remark here that we proved in §23.2 that the cross-ratio of four collinear points is unchanged if we *invert* with respect to a center of inversion on the line. Now, inversion by itself is not a Moebius mapping, but *inversion followed by reflexion* in the line on which the points lie is a Moebius mapping, given by $z' = 1/z$, and the points are unchanged by the reflexion in the line. Hence we can regard the theorem of §23.2 as a very special case of the one we shall now prove.

53.4 An invariant under Moebius transformations

Theorem *The cross-ratio of four points is an invariant under Moebius* *transformations.*

Proof. This can be shown by direct verification. If the four points are $z_j (j = 1, 2, 3, 4)$, and these are mapped onto the points z_j', where $z_j' = (az_j + b)/(cz_j + d)$, then straightforward calculation shows that

$$\frac{(z_1 - z_3)(z_2 - z_4)}{(z_2 - z_3)(z_1 - z_4)} = \frac{(z_1' - z_3')(z_2' - z_4')}{(z_2' - z_3')(z_1' - z_4')}.$$

Alternatively, we may use the method of Thm 53.2. With the notations of that theorem, we have $z_j BC^{-1} = z_j'$, which means that $z_j B = z_j' C$. If we write out what this means in algebraic terms, we have

$$\frac{(z_j - z_2)(z_1 - z_3)}{(z_j - z_1)(z_2 - z_3)} = \frac{(z_j' - z_2')(z_1' - z_3')}{(z_j' - z_1')(z_2' - z_3')},$$

and writing $z_j = z_4$, and $z_j' = z_4'$, we have the desired result. Of course, the proof of Thm 53.2 was devised with a previous knowledge of the cross-ratio function in mind.

We now prove a very important geometric property of the cross-ratio.

53.5 The reality of the cross-ratio

Theorem *The cross-ratio of four distinct points is real if and only if the four points lie on a straight line or a circle.*

Remark. This theorem can be proved geometrically, more or less, by a method indicated in Exercise 53.3. The proof we give here is purely algebraic.

Proof. Let the four distinct points be $z_j (j = 1, 2, 3, 4)$, and suppose in the first instance that the cross-ratio $(z_1, z_2; z_3, z_4) = k$, where k is real. Let T be the unique Moebius transformation which maps z_1, z_2 and z_3 onto the three distinct points z_1', z_2' and z_3' of the real axis (Thm 53.2). Let $z_4 T = z_4'$. By the invariance of the cross-ratio (Thm 53.4), we have

$$\frac{(z_4 - z_2)(z_1 - z_3)}{(z_4 - z_1)(z_2 - z_3)} = \frac{(z_4' - z_2')(z_1' - z_3')}{(z_4' - z_1')(z_2' - z_3')} = k.$$

Hence

$$(z_4' - z_2')/(z_4' - z_1') = \mathrm{k}(z_2' - z_3')/(z_1' - z_3')$$

= a real number

Since z_1', z_2', z_3' are real, if we solve this equation for z_4', we find that z_4' = a real number, since the real numbers form a field. Hence $z_4T = z_4'$ also lies on the real axis. The four points z_1, z_2, z_3 and z_4 therefore lie on the image of (real line)T^{-1}. But we know that a Moebius transformation maps a line onto a circle or a line. Since T^{-1} is a Moebius transformation, and the real line is a line, it follows that the four points z_j ($j = 1, 2, 3, 4$) lie on a circle or a line when the cross-ratio of the four points is real.

Now let us assume that the four given points lie on a line or a circle. There is a unique Moebius transformation T which maps z_1, z_2 and z_3 into three given distinct points z_1', z_2', z_3' of the real axis, and since T maps circles and lines onto circles or lines the map of the line or circle which contains the four points z_j must be a line or circle through the three points z_1', z_2', z_3'. Since these points lie on a line, the real axis, the map must be this line. Hence the map of z_4 is also a point z_4' on the real axis. The cross-ratio of the four points z_j' on the real axis is a real number, and since cross-ratios are invariant under a Moebius transformation, it follows that the cross-ratio $(z_1, z_2; z_3, z_4)$ of the four points on a line or a circle is the same real number.

53.6 Lines in the inversive plane and the point ∞

The point ∞ was added to the Euclidean plane, considered as a representative of the complex line, as soon as we introduced inversion in §20.1. We then found that inversion is a one-to-one onto transformation of the completed plane, which we call the inversive plane. In §21.1 it was seen to be reasonable to consider all lines of the inversive plane to pass through this point ∞. The theorem that the inverse of a line which does not pass through the center of inversion is a curve (a circle, in fact) which does pass through the center of inversion is then an immediate deduction. When we consider Moebius transformations of the Gauss plane, inversion is the one component of the dissected Moebius transformation which is not one-to-one onto, and by adding the point ∞ to the Gauss plane, obtaining the inversive plane, we ensure that a Moebius transformation is one-to-one onto for the inversive plane.

We have already mentioned stereographic projection, which gives a one-to-one correspondence between the points of the Gauss plane and the points of a sphere from which one point has been removed. Adding the point ∞ to the Gauss plane is equivalent to patching the hole in the punctured sphere. We shall see later (Exercise 88.1) that circles in the Gauss plane project into circles on the sphere, if we project from the point *N* (Fig.52.1), the Gauss plane being regarded as the tangent plane at the point on the sphere diametrically opposite to *N*. If we join *N* to a line in the Gauss plane, the intersection of the resulting plane with the sphere is a circle which passes through *N*. The inversive plane can be regarded as the surface of a sphere, the point *N* being the point ∞. This was already remarked at the beginning of the Chapter. The further point made here is that lines in the inversive plane all pass through the point ∞.

Exercises

53.1 Show that any Moebius transformation with the two distinct fixed points p and q may be written in the form

$$\frac{z'-p}{z'-q}=k\,\frac{(z-p)}{(z-q)},$$

where k is a complex number.

53.2 Deduce from Thm 53.5 that a Moebius transformation maps the set of lines and circles into the set of lines and circles.

53.3 If the complex numbers z_1, z_2, z_3, z_4 are attached to the points A, B, C and D respectively of the real Euclidean plane, prove that the cross-ratio

$$(z_1,z_2;z_3,z_4) = \mathrm{k}(\cos\theta + \mathrm{i}\sin\theta),$$

where $k = |AC| \,.\, |BD|/|AD| \,.\, |BC|$, and $\theta = \alpha - \beta$, where α and β are the measures of the angles CAD and CBD respectively. Deduce Thm 53.5.

53.4 Show that the points of any given circle in the inversive plane may be represented thus:

$$z=(at+b)/(ct+d)\ (ad-bc\neq 0,)$$

where a, b, c, and d are complex numbers, and t is real.

53.5 Prove that if z_1, z_2, p, q and r are distinct complex numbers, the following relation between cross-ratios is true:

$$(z_1,z_2;p,r) = (z_1,z_1;P,q).(z_1,z_2;q,r).$$

53.6 Prove that

$$(z_1,z_2;z_3,z_4) = (z_2,z_1;z_3,z_4) = 1/(z_1,z_2;z_3,z_4)$$

53.7 Show that if the points z_1, z_2, z_3 and z_4 which lie on a circle are mapped by a Moebius transformation onto the points A, B, C and ∞ of a line, then

$$(z_1,z_2;z_3,z_4)=(A, B ;C, \infty) = \overline{AC}/\overline{BC}.$$

53.8 Prove the following theorem for cross-ratios:

$$\frac{(z_1, w_2; z_2, w_1)}{(z_2, w_3; z_3, w_2)} \cdot \frac{(z_3, w_4; z_4, w_3)}{(z_4, w_1; z_1, w_4)}.$$

53.9 Prove that if $\mathscr{C}_1,\mathscr{C}_2,\mathscr{C}_3$ and $\mathscr{C}_4$, are four circles (or lines), and $\mathscr{C}_1,\mathscr{C}_2$ intersect in P_1, Q_1, the circles $\mathscr{C}_1$ intersect in P_2, Q_2, the circles $\mathscr{C}_2,\mathscr{C}_3$ intersect in P_3, Q_3, and finally the circles $\mathscr{C}_4,\mathscr{C}_1$ intersect in P_4, Q_4, then if the four points P_i lie on a line or circle, so do the four points Q_i. (Use the preceding Exercise. This result appears again as Thm III of §94.1, with applications. Note that one point of the intersection of two circles, when the circles are lines, is always the point ∞.)

53.10 In the stereographic projection of the surface of a sphere onto the inversive plane (Fig.52.1), the lines in the plane arise from circles through the point N. What can you say about the two circles through N which arise from two parallel lines in the plane?

53.11 If $z_i = a + r(\cos \alpha_i + i \sin \alpha_i)$ ($i = 1, 2, 3, 4$), so that the four points z_i are points on a circle, center a, radius r, angular coordinates α_i, show that

$$(z_1, z_2; z_3, z_4) = \frac{\sin \frac{1}{2}(\alpha_1 - \alpha_3) \sin \frac{1}{2}(\alpha_2 - \alpha_4)}{\sin \frac{1}{2}(\alpha_1 - \alpha_4) \sin \frac{1}{2}(\alpha_2 - \alpha_3)}.$$

53.12 If the four points A, B, C, D represented by the complex numbers z_1, z_2, z_3, z_4 form a set of *orthocyclic points* (see Exercise 21.9), show that $(z_1, z_2; z_3, z_4)$ has modulus 1.

53.13 Prove that the triangles ABC and $A'B'C'$ are directly similar if and only if $(a, b; c, \infty) = (a', b'; c', \infty)$, where a, b, c are the complex numbers representing the points A, B, C, and a', b', c' the complex numbers representing the points A', B', C'.

54.1 The map of the inside of a circle

Theorem *If a circle $\mathscr{C}$ be mapped onto a circle $\mathscr{C}'$ by a Moebius mapping, then the interior of $\mathscr{C}$ is mapped onto the interior of $\mathscr{C}'$, or onto the exterior of $\mathscr{C}'$.*

Proof. We saw that a given Moebius transformation may be written as the composition of a translation, an inversion in the unit circle followed by a reflexion in the real axis, a dilative rotation and a translation. All these mappings, with the exception of the inversion, map the inside of a circle onto the inside of the mapped (image) circle. Inversion may map the inside of the object circle onto the inside of the image circle, or it may map the inside of the object circle onto the outside of the image circle. A simple example is the effect of inversion on the circle of inversion itself. Points on the circle of inversion map onto themselves, but points *inside* the circle are mapped onto points *outside* the circle. On the other hand, if the circle of inversion is *orthogonal* to the circle $\mathscr{C}$, points on $\mathscr{C}$ are merely interchanged by the inversion, and it is clear that the interior of $\mathscr{C}$ maps into the interior of $\mathscr{C}' = \mathscr{C}$.

Algebraic proofs of the theorem in inversion: The interior of a circle $\mathscr{C}$ inverts into the interior or the exterior of the image circle $\mathscr{C}'$, and this depends on whether the center of inversion is outside or inside $\mathscr{C}$, are indicated in the following Exercise (Exercise 54.3).

54.2 Map of a circle into itself

We are especially interested in those Moebius transformations which map a given circle $\mathscr{C}$ onto itself, and the inside of $\mathscr{C}$ onto the inside of $\mathscr{C}$. We take the unit circle, center at the origin, $|z| = 1$, as the circle $\mathscr{C}$.

There are, of course, Moebius transformations which map $|z| = 1$ onto $|z| = 1$, and the inside onto the inside. The identity mapping $Z = z$ is one such mapping, so the set of transformations is not empty. Another Moebius mapping which will serve is the rotation $Z = az$, where $|a| = 1$. This merely rotates the unit circle about the origin. If we take the composition of two such mappings, we have a mapping of the unit circle onto itself, inside mapping onto inside, and more generally we see that *under composition the set of Moebius transformations which map a circle and its interior onto themselves form a group*. This is merely a special case of the theorem discussed in §0.12: 'One-to-one onto mappings of a set form a group under composition.'

It is interesting to determine what form a Moebius transformation takes when it maps $|z| = 1$ onto $|Z| = 1$ and the interior onto the interior. If the transformation is $Z = (az + b)/(cz + d)$, we want $z^{\bar{z}} = 1$ to map onto $Z\overline{Z} = 1$, in the first instance. The map of $Z\overline{Z} = 1$ arises from

$$\frac{(az+b)}{(cz+d)}\frac{\overline{(az+b)}}{\overline{(cz+d)}} - 1 = 0,$$

which simplifies to

$$z\bar{z}(a\bar{a} - c\bar{c}) + z(a\bar{b} - c\bar{d}) + \bar{z}(\bar{a}b - \bar{c}d) + b\bar{b} - d\bar{d} = 0.$$

This is the same as the equation $z^{\bar{z}} - 1 = 0$ if

$$a\bar{b} - c\bar{d} = \bar{a}b - \bar{c}d = 0,$$

and

$$a\bar{a} - c\bar{c} + b\bar{b} - d\bar{d} = 0.$$

We therefore have only two conditions:

$$a\bar{b} - c\bar{d} = 0,$$

and

$$|a|^2 + |b|^2 = |c|^2 + |d|^2.$$

These are sufficient conditions. Write $c = k\bar{b}$. Then $\bar{c}d - \bar{a}b = 0$ leads to $\bar{k}bd - \bar{a}b = 0$, so that $d = \bar{a}/\bar{k}$. If we now substitute in the condition $|c|^2 + |d|^2 = |a|^2 + |b|^2$, this leads to $|k|^2|b|^2 + |a|^2/|k|^2 = |a|^2 + |b|^2$, and so we can take $|k| = 1$. Then $1/\bar{k} = k$, and so the form of the Moebius transformation is

$$Z = \frac{az + b}{k(\bar{b}z + \bar{a})}, \text{ where } |k| = 1,$$

and, of course, we may also write this as $Z = k(az + b)/(\bar{b}z + \bar{a})$, $|k| = 1$.

This mapping transforms $|z| = 1$ into $|Z| = 1$. The determinant of the mapping is $\Delta = k^2(a\bar{a} - b\bar{b}) = k^2(|a|^2 - |b|^2)$. If we choose $k = 1$, and $\Delta = 1$, then $|a|^2 - |b|^2 = 1$, and so $|b| < |a|$. The point 0 is then mapped onto the point $b/\bar{a}$, and since $|b| < |a|$, this point is *inside* the circle $|Z| = 1$. This is sufficient for us to be able to assert that the mapping $Z = (az + b)/(\bar{b}z + \bar{a})$, where $|a|^2 - |b|^2 = 1$, is a Moebius transformation which maps the circle $|z| = 1$ onto the circle $|Z| = 1$, and the inside of $|z| = 1$ onto the inside of $|Z| = 1$.

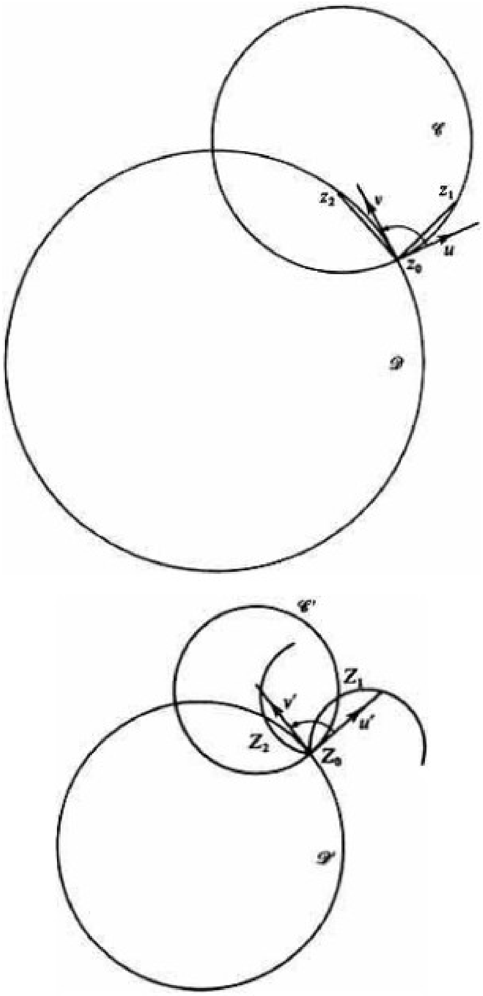
54.3 Conformal property of Moebius transformations

Theorem *The circles $\mathscr{C}$ and $\mathscr{D}$ intersect at the point z_0, and u is a unit tangent vector to $\mathscr{C}$ at z_0, v is a unit tangent vector to $\mathscr{D}$ at z_0. If $\mathscr{C}$ and $\mathscr{D}$ are mapped by a Moebius transformation onto the circles $\mathscr{C}'$ and $\mathscr{D}'$ intersecting at Z_0, and u is mapped on u', v is mapped on v', then u' and v' are tangent circles at Z_0 to $\mathscr{C}'$ and $\mathscr{D}'$ respectively, and the angle between u' and v' is equal to that between u and v both in measure and in sense*. (See Fig. 54.1.)

Proof. We assume that $cz_0 + d \neq 0$ in the Moebius mapping $Z = (az + b)/(cz + d)$. Let z_1 be a point on $\mathscr{C}$ distinct from z_0, and z_2 a point on $\mathscr{D}$ distinct from z_0. Then

$$Z_0 - Z_1 = \frac{az_0 + b}{cz_0 + d} - \frac{az_1 + b}{cz_1 + d} = \frac{(ad - bc)(z_0 - z_1)}{(cz_0 + d)(cz_1 + d)},$$

$$Z_0 - Z_2 = \frac{(ad - bc)(z_0 - z_2)}{(cz_0 + d)(cz_2 + d)}.$$



$\mathscr{C}$
z_2
v
z_1
z_0
u
$\mathscr{D}$
$\mathscr{C}'$
Z_1
v'
u'
Z_2
Z_0
$\mathscr{D}'$

Fig. 54.1

Hence, since $ad - bc \neq 0$,

$$\frac{Z_0 - Z_1}{Z_0 - Z_2} = \frac{(z_0 - z_1)}{(z_0 - z_2)} \cdot \frac{(cz_2 + d)}{(cz_1 + d)}.$$

As z_1 approaches z_0 on $\mathscr{C}$, Z_1 approaches Z_0 on $\mathscr{C}'$, and since the *line* joining z_0 to z_1 is mapped onto a circle through Z_0 and Z_1 (which may be a line), the unit tangent vector u to $\mathscr{C}$ at z_0 is mapped onto a circle tangent to $\mathscr{C}'$ at Z_0. Similarly, the unit tangent vector v to $\mathscr{D}$ at z_0 is mapped onto a circle tangent to $\mathscr{D}'$ at Z_0. As z_2 and z_1 both approach z_0 on the circles $\mathscr{C}$ and $\mathscr{D}$ respectively, we have, in the limit

$$\frac{Z_0 - Z_1}{Z_0 - Z_2} = \frac{z_0 - z_1}{z_0 - z_2},$$

and comparison with Thm 47.9 shows us that the triangles $Z_0Z_1Z_2$ and $z_0z_1z_2$ are *directly similar*, and therefore the angle between u' and v' is equal to that between u and v both in measure and sense.

Another proof of this theorem is suggested in Exercise 54.1.

Exercises

54.1 From the dissection of a Moebius transformation (§52.4) prove Thm 54.3, by examining the effect of the component transformations on the measure and the sense of the angle between two circles.

54.2 Prove directly that the mappings $Z = (az + b)/(\bar{b}z + \bar{a})$, where $a\bar{a} - b\bar{b} = 1$, map the circle $|z| = 1$ onto the circle $|Z| = 1$, and the interior onto the interior, and that the set of mappings form a group under composition.

54.3 The *inside* of the circle $\mathscr{C}$, given by the equation

$$C(X, Y) = X^2 + Y^2 - 2pX - 2qY + r = 0$$

may be characterized as the set of points (x, y) for which the *power* $C(x, y)$ of (x, y) with respect to the circle $\mathscr{C}$ is not positive. Using the formula of §21.1, show that, after inversion in the circle $X^2 + Y^2 = k^2$,

$$C(x, y) = r\left\{X^2 + Y^2 - \frac{2k^2}{r}(pX + qY) + \frac{k^4}{r}\right\}\Big/(X^2 + Y^2),$$

where the point (x, y) is mapped onto the point (X, Y) by the inversion, so that if the circle $\mathscr{C}$ is mapped onto the circle $\mathscr{C}'$, we have

Power of (x,y) with respect to $\mathscr{C}$=r(Power of(X,Y) with respect to $\mathscr{C}'$)/$(X^2 + Y^2)$.

Deduce that if the center of inversion $(0, 0)$ is *inside* $\mathscr{C}$, the inside of $\mathscr{C}$ inverts into the *outside* of $\mathscr{C}'$, and that if the center of inversion is *outside* $\mathscr{C}$, the inside of $\mathscr{C}$ inverts into the *inside* of $\mathscr{C}'$.

55.1 Special Moebius transformations

We now concentrate on the subgroup of Moebius transformations which map the unit circle onto itself, and the inside onto the inside. We know that these transformations do form a subgroup of the group of all Moebius transformations (§54.2), and we shall call these special Moebius mappings *M*-transformations.

We also give the boundary of the unit circle $|z| = 1$ a special name, ω, and we call the inside of the unit circle Ω. The points of ω are not included among the points of Ω, which is regarded as an open disk.

Our aim is to set up a geometry in Ω, defining points and lines and incidence properties in the first instance. Our points are ordinary Euclidean points in Ω, but our lines are circles orthogonal to ω, and since we are only considering the space Ω, our lines are the arcs of circles orthogonal to ω which lie in Ω. We shall show that we can obtain a geometry in Ω which marches step by step alongside Euclidean geometry, until there is a dramatic parting of ways when we arrive at the concept of parallel lines in the two geometries. In Euclidean geometry there is a unique parallel to a given line l through a given point P. We shall find in our space Ω that there are *two* parallels. This geometry is called *hyperbolic geometry*, and is an example of a *non-Euclidean* geometry.

We shall show that the group of M-transformations corresponds to the group of direct isometries of the Euclidean plane, in the sense that similar theorems are true for each group in the respective geometries. We begin our study of Ω by proving some theorems on M-transformations.

55.2 Theorems on *M*-transformations

Theorem *Let X and A be two points of* Ω, ξ *and* α *directions through X and A respectively. Then there is a unique M-transformation which maps X on A, and the direction* ξ *onto the direction* α. (See Fig. 55.1.)

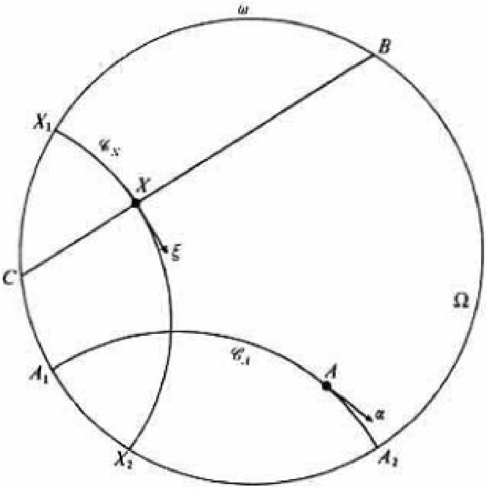


Fig. 55.1

transformations reverse orientation. We list those properties of M_--transformations which differ from M_+-transformations as Exercises (Exercises 57.7, 57.9).

We must now redefine p-congruence. If we call the elements of our extended group M^*-*transformations*, we say that $AB \overset{p}{=} A'B'$ if there is an M^*-transformation which maps A on A' and B on B'. Angles, if congruent in the Euclidean sense are congruent under M^*-transformations, and we now have *the general SAS theorem*, which is independent of the orientation of the triangles ABC and $A'B'C'$: the formulation is as in Thm 57.1, but the phrase 'with equal orientation' is omitted.

Theorem II *Given two p-triangles ABC and A'B'C', the congruences* $AB \overset{p}{=} A'B'$ $AC \overset{p}{=} A'C'$ *and* $\sphericalangle CAB \overset{p}{=} \sphericalangle C'A'B'$ *imply the p-congruence of the triangles, so that* $\sphericalangle ABC \overset{p}{=} \sphericalangle A'B'C'$, $\sphericalangle ACB \overset{p}{=} \sphericalangle A'C'B'$ *and* $BC \overset{p}{=} B'C'$.

57.2 The parallel axiom

As far as we have gone, there seems to be a complete correspondence between our p-geometry and that part of Euclidean geometry which is developed before the introduction of the parallel axiom. This axiom, in one form, (shown by Playfair to be equivalent to Euclid's formulation), says:

Through a given point P which does not lie on a given line l there passes a unique line which is parallel to l.

In Euclidean geometry, of course, two coplanar lines are said to be *parallel* if they do not intersect.

We could say that two p-lines in our p-geometry are p-parallel if they do not intersect.

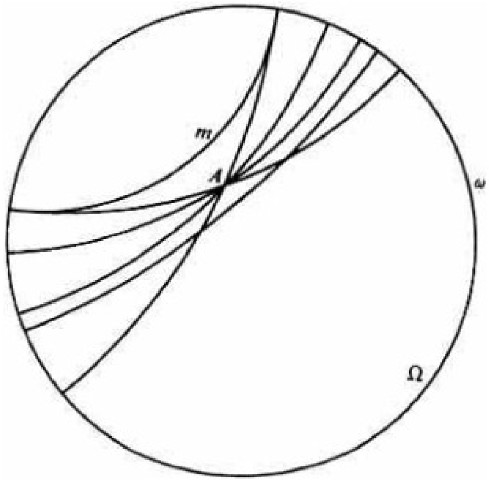

Fig. 57.3

Let A be a point in Ω (Fig.57.3), and let m be a given p-line which does not contain A. Then we see that through A there is an infinity of p-lines which do not intersect m in Ω. This property is independent of whether m is convex or concave to A. We could say, therefore, that there is *an infinity* of p-lines through A which are p-parallel to the given p-line m.

But we notice (see Exercise 57.1) that there are exactly *two* p-lines through A which touch the given p-line m, the points of contact lying on ω. These two p-lines through A separate the p-lines through A into two classes: the p-lines which cut the p-line m are in one class, and those which do not intersect m are in the second class.

We reserve the term *p-parallel* for *the two p-lines through A which touch the given p-line m at points of* ω. We now have, in our geometry, instead of the Euclidean parallel axiom, the theorem:

Theorem *Through any given p-point A which does not lie on a given p-line m there pass exactly two p-lines p-parallel to the given p-line.*

Hence our p-geometry is not Euclidean geometry, and it is naturally called *non-Euclidean geometry*. Our p-plane is a *model* for such a geometry. If Euclidean geometry is an internally consistent system, without contradictions, then so is the model, and its existence shows that the parallel axiom in Euclidean geometry is *independent* of the other axioms, that is *it cannot be deduced from them*.

Exercises

57.1 Prove that through any given point A in Ω which does not lie on a given p-line m there pass just two p-lines which touch m, and these do so on ω.

57.2 Show that through any given p-point A there exists a unique p-line l' perpendicular to a given p-line l, and that if m, n be the p-lines through A which are p-parallel to l (it is assumed that A does not lie on l), then m and n make equal angles with l'.

57.3 Prove that two distinct p-lines which are perpendicular to the same p-line have no intersection.

57.4 If we allow the vertices A, B and C of a p-triangle to lie on ω, what can we say about the angles of this triangle?

57.5 Prove that two distinct p-lines which have no intersection have a unique p-line perpendicular to both of them.

57.6 Prove that the totality of M_+ and M_- transformations, with composition as group multiplication, form a group, which is a subgroup of the group of all Moebius and conjugate Moebius transformations.

57.7 If z_1, z_2, z_3 and z_4 are mapped by a conjugate Moebius transformation into z_1', z_2', z_3' and z_4', prove that the cross-ratio of the object set is equal to the conjugate of the cross-ratio of the image set:

$$(z_1, z_2; z_3, z_4) = \overline{(z_1', z_2'; z_3', z_4')}$$

57.8 Show that the composition of the two mappings

$$Z' = (\bar{a}\bar{z} + \bar{b})/(\bar{c}\bar{z} + \bar{d}), \quad Z = \bar{Z}' \, (\bar{a}\bar{d} - \bar{b}\bar{c} \neq 0)$$

produces the mapping

$$Z = (az + b)/(cz + d), \quad (ad - bc \neq 0).$$

Deduce that Thm 52.3 and its Corollary are true for conjugate Moebius transformations.

57.9 Show that Thm 54.3 continues to hold for conjugate Moebius transformations, except that the sense of an angle is changed by the transformation.

57.10 Show that if z_1, z_2, z_3, z_4 are four points on a p-line, and z_1', z_2', z_3', z_4' are their images under a Moebius *or* a conjugate Moebius transformation, then

$$(z_1, z_2; z_3, z_4) = (z_1', z_2'; z_3', z_4').$$

57.11 Show that inversion in the circle $cz\bar{\bar{z}} - z\bar{\bar{p}} - \bar{\bar{z}}p - b = 0$, where b and c are real, the center is the complex number p/c, the square of the radius is given by $r^2 = (p\bar{\bar{p}} + bc)/c^2$, can be obtained by writing

$$(Z - p/c)\overline{(z - p/c)} = r^2 = (p\bar{p} + bc)/c^2,$$

which leads to the conjugate Moebius transformation

$$Z = \frac{p\bar{z} + b}{c\bar{z} - \bar{p}} \quad (p\bar{p} + bc > 0).$$

57.12 Show that the circles $cz\bar{\bar{z}} - z\bar{\bar{p}} - \bar{\bar{z}}p - b = 0$, $ez\bar{\bar{z}} - z\bar{q} - \bar{\bar{z}}q - d = 0$ are orthogonal if and only if $be + cd + q\bar{\bar{p}} + \bar{q}p = 0$.

57.13 Show that the composition of inversion in two circles is equivalent to a Moebius transformation.

57.14 Show that if the Moebius transformation of the preceding Exercise is of the form $Z = (az + b)/(cz + d)$, then if the circles are orthogonal we find that $a + d = 0$.

57.15 Verify that a Moebius transformation $Z = (az + b)/(cz + d)$, where $a + d = 0$ is an involutory transformation, that is, if the map of any point z is Z, then the map of Z is z. (Compare Exercise 25.2. Since $(T_{\mathscr{C}})^{-1} = T_{\mathscr{C}}$, and $(T_{\mathscr{D}})^{-1} = T_{\mathscr{D}}$, $T_{\mathscr{C}}T_{\mathscr{D}} = T_{\mathscr{D}}T_{\mathscr{C}}$ leads to $(T_{\mathscr{C}}T_{\mathscr{D}})^2 =$ Identity. See also Thm I, §76.2, and Appendix III, on *the complex line*.)

58.1 The angle-sum of a *p*-triangle

Theorem *The sum of the angles of a p-triangle ABC is less than π.*

Proof. If C is the center of ω (Fig.58.1), then the p-lines CA and CB are diameters of ω, and the p-line AB is an arc of a circle which is orthogonal to ω. If two circles are orthogonal, their centers do not both lie inside one of the circles. The center of the p-line AB therefore lies outside ω, and the center C of ω lies outside the circle which determines the p-line AB. Hence the p-line AB is *convex* to C, as shown in Fig. 58.1, and the angles of the curvilinear triangle ABC at A and at B are less than the angles of the Euclidean triangle ABC at A and at B. Since the angle-sum of the Euclidean triangle ABC is equal to π, the angle-sum of the p-triangle ABC is less than π.

If no vertex of the p-triangle ABC is the center of ω (Fig.58.2), let V be the other intersection of the circles which determine the p-lines AC and BC. Then V and C are inverse points in ω, being the intersection of two circles orthogonal to ω. Choose as circle of inversion the circle $\mathscr{C}$ which has V as center and which is orthogonal to ω.

If we invert in this circle, ω inverts into itself, circles through V invert into lines, and since C is the intersection of two circles orthogonal to ω, C inverts into the center of ω, and the circles through V invert into diameters of ω. Hence the p-triangle ABC inverts into a p-triangle $A'B'C'$, where C' is the center of ω, and so we are back in the case we examined first. Since angles are unchanged by inversion, the angle-sum of p-triangle ABC = the angle-sum of triangle $A'B'C'$, and this is less than π.

58.2 The exterior angle is greater than either of the interior and opposite angles

Theorem *In any p-triangle, if one of the p-sides be produced, the exterior angle is greater than either of the interior and opposite angles.*

Proof. This follows directly from the proof of Thm 58.1, since angles of p-triangle ABC are unchanged by inversion, and if we are considering p-line CB produced, say, the exterior angle at B of p-triangle ABC is equal to the exterior angle at B' of p-triangle $A'B'C'$. Since the p-line $B'A'$ is convex to C', the exterior angle at B' of p-triangle $A'B'C'$ is greater than the same angle for the Euclidean triangle $A'B'C'$, and the angle at A' for the p-triangle $A'B'C'$ is less than the same angle for the Euclidean triangle $A'B'C'$. Since, for the Euclidean triangle $A'B'C'$

the exterior angle at B' exceeds the angle A', this is even more the case for the *p*-triangle $A'B'C'$.

58.3 Non-Euclidean distance

We have shown how to compare two *p*-segments for *p*-congruence. We now obtain a *distance-function* for any two *p*-points A and B. This function will satisfy the usual conditions:

$$d(A,B) = d(B,A) \geqq 0:$$

$$d(A,B) = 0 \text{ if and only if } \mathrm{B} = \mathrm{A}:$$

$$d(A,B) + d(B,C) \geqq d(A,C),$$

with equality if and only if B lies in the *p*-segment connecting A and C. This last inequality is called *the triangle inequality*.

Our M^*-transformations are equivalent to the isometries of the Euclidean plane, and these, of course, are distance-preserving, and we hope that our distance-function will be invariant under M^*-transformations. We shall see that this is the case.

Our distance-function is to be defined in terms of the cross-ratio $(\alpha, \beta; A, B)$, where the *p*-line cuts ω in the points α and β (Fig.58.3). We therefore begin by obtaining some further properties of this cross-ratio.

We know that there is a unique Moebius transformation which maps the points α, A and β onto three given distinct points α', A' and β' of the real line, where we choose A' to lie between α' and β'. A point moving continuously on the *p*-segment $\alpha\beta$ is mapped by this Moebius transformation onto a point which moves continuously on the segment of the real line defined by α' and β'. (Compare Exercise 52.6.) Since we are considering a pair of points A, B on the *p*-line whose terminal points on ω are α and β, all points A', B' will lie on the segment of the real line $\alpha'\beta'$. We also know that cross-ratios are invariant under a Moebius transformation, and so

$$(\alpha,\beta A,B) = (\alpha',\beta';A',B'),$$

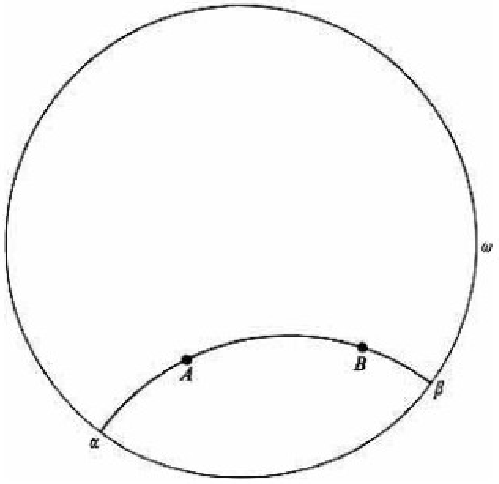

Fig. 58.3

which is a real number. We found this result in Thm 53.5. But we now obtain a stronger result. The order α, A, B, β on the p-line is the same as the order α', A', B', β' on the real line, and the cross-ratio of the real numbers is equal to $\frac{\alpha'A'}{A'\beta'}\Big/\frac{\alpha'B'}{B'\beta'}$. As A' moves on the real line from α' towards β', the ratio $\alpha'A'/A'\beta'$ increases from 0 to $+\infty$, in a continuous manner. It therefore follows, that if B' is *between* A' and β', the ratio $\alpha'B'/B'\beta'$ is *greater* than the ratio $\alpha'A'/A'\beta'$. We have therefore proved that *if the points* α, A, B, β *are in this order on a p-line*, *the cross-ratio* $(\alpha, \beta\, A, B)$ *is a positive real number less than* 1.

If α, β be interchanged, the cross-ratio is the reciprocal of this (Ex. 53.6), and similarly if A, B be interchanged: so that interchanging either α, β or A, B produces a positive real number greater than 1.

Definition. Let the p-line ab cut ω in the points α, β. Then

$$d(A,B) = |\log(\alpha,\beta A,B)|.$$

We have just seen that the cross-ratio in the definition is a positive real number, so that the logarithm exists, and the logarithm is positive if the cross-ratio exceeds 1, and negative if the cross-ratio is less than 1. Since we define $d(A, B)$ to be the modulus of the cross-ratio, we have

$$d(A,B) \geqq 0.$$

Again,

$$d(B,A) = |\log(\alpha,\beta B,A)| = |\log 1/(\alpha,\beta A,B)|$$

$$= |-\log(\alpha,\beta A,B)| = d(A,B).$$

Furthermore, if $d(A, B) = 0$, then we must have $(\alpha, \beta; A, B) = 1$, and since α, β are distinct points, this leads to $A = B$. Hence $d(A, B) = 0$ if and only if $B = A$.

We note also that interchanging α and β leaves $d(A, B)$ unchanged, the proof being similar to the proof that $d(A, B) = d(B, A)$.

Theorem I *If A, B and C are p-points, in this order, on a p-line then*

$$d(A,C)= d(A,B) + d(B,C)$$

Proof. Suppose that α, A, B, C, β lie, in this order, on a p-line, α, β being the intersections of the p-line with ω. Then we know that the cross-ratios $(\alpha, \beta; A, B)$, $(\alpha, \beta; B, C)$ and $(\alpha, \beta; A, C)$ are all positive real numbers less than 1. Their logarithms are therefore all negative real numbers. From Exercise 53.5 we may write

$$(\alpha,\beta A,C) = (\alpha,\beta A,B).(\alpha,\beta B,C)$$

(this result is independent of the order of A, B and C). Taking logarithms,

$$\log(\alpha,\beta A,C) = \log(\alpha,\beta A,B) + \log(\alpha,\beta B,C),$$

and since these three logarithms are all negative numbers, we now have

$$|\log(\alpha,\beta A,C)| = |\log(\alpha,\beta A,B)| + |\log(\alpha,\beta B,C)|$$

and so

$$d(A,C) = d(A,B) + d(B,C)$$

Before proving the general triangle inequality, we remark that our distance-function $d(A, B)$ is, in fact, invariant under an M^*-transformation. We know that an M_+-transformation leaves cross-ratios unchanged (Thm 53.4), and an M_--transformation maps a cross-ratio onto its conjugate complex value (Exercise 57.7). But when the four points under consideration are on a p-line, the cross-ratio is a real number (Thm 53.5), and so both M_+ and M_--transformations leave the cross-ratio invariant. Hence, if the points α, β, A and B on a p-line are mapped onto the points α', β', A' and B' by an M^*-transformation, these points are again on a p-line, α' and β' lie on ω, and since

$$(\alpha,\beta A,B) = (\alpha',\beta';A',B'),$$

we have

$$\mathrm{d}(A,B) = d(A',B').$$

Conversely, if we are given that $d(A, B) = d(A', B')$, we can prove that there is an M_+-transformation which maps A on A' and B on B'. It will be recalled that our original definition of *p*-congruence between *p*-segments (§56.2) involved the existence of an M_+-transformation which mapped A on A' and B on B'. The result we prove now ties the concepts of *p*-congruence and *p*-distance together.

We assume that the *p*-line AB cuts ω in the points α and β, and that the *p*-line $A'B'$ cuts ω in the points α' and β'. We name the points of intersection of the *p*-lines with ω so that the order α, A, B, β on the one *p*-line corresponds to the order α', A', B', β' on the other *p*-line. We know there is a unique M_+-transformation which maps α on α', A on A' and β on β'; the proof is exactly as in that of Thm 55.2. We assert that this M_+-transformation also maps B on B'.

We are given that $|\log(\alpha, \beta; A, B)| = |\log(\alpha', \beta'; A', B')|$, and because of our method of choosing α' and β' we know that each cross-ratio is a positive real number less than 1. Hence we can say that the two logarithms are equal, dropping the modulus signs, and that therefore the cross-ratios are equal. Since α is mapped on α', A on A' and β on β', this means that B is mapped on B'.

The proof that the cross-ratio $(\alpha, \beta; A, B)$ is a positive real number less than 1 also shows that if C is a *p*-point in the *p*-segment $B\beta$, the cross-ratio $(\alpha, \beta; A, C)$ is also positive, real and less than 1 but *less than the value of the cross-ratio* $(\alpha, \beta; A, B)$. Since the logarithms of a sequence of steadily decreasing positive real numbers less than 1 tend steadily towards $-\infty$, and the distance-function is the modulus of the logarithm of this cross-ratio, we see that:

The distance-function $d(A, B)$ *for fixed* A *is a monotone increasing function of the position of the p-point* B *on the p-line* $A\beta$. *As* B *moves from* A *towards* β, $d(A, B)$ *increases steadily from* 0 *to* $+\infty$.

Of course, a similar result is true if A moves steadily from B towards α.

It follows that if we have four *p*-points A, B, C and D (Fig.58.4), and we know that

$$d(A,B)>d(C,D)$$

and we find the unique M-transformation which maps A on C, and the direction along the *p*-line AB at A onto the direction along the *p*-line CD at C (Thm 55.2), the point B will be mapped onto a *p*-point on the *p*-segment $D\beta'$; that is, it will fall on a point *outside* the *p*-segment CD.

Hence, there is an exact equivalent in our *p*-geometry to the Euclidean construction: ‘Mark off from the segment CD, or CD produced, a length equal to a given length AB.’

Suppose now that A, B and C are *p*-points (Fig.58.5), and we consider the *p*-lines through *B* which intersect the *p*-line *AC* in *p*-points which lie between *A* and *C*. The *p*-line *BA* intersects the *p*-line *AC* at *A*, and if *B′* be the *p*-point of intersection of a *p*-line through *B* and the *p*-line *AC*, we see that as *B′* moves continuously towards *C* from *A*, the *p*-angle *ABB′* increases continuously. We also note that if *B′* be any *p*-point in the *p*-segment *AC*, the *p*-line *BB′* lies inside the *p*-angle *ABC* and the *p*-angle *ABB′* is less than the *p*-angle *ABC*.

With these preparatory remarks *we may now prove theorems in our p-geometry with the terminology and the diagrams of Euclidean geometry*.

We shall not, of course, use the Euclidean parallel axiom!

Theorem II *In a p-triangle ABC, if d*(*A*, *B*) = *d*(*A*, *C*), *then the p-angles ABC and ACB are congruent.*

Proof. By the General SAS Theorem of §57.1, if we consider the two triangles *ABC* and *ACB*, we have $AB \overset{p}{=} AC$, $AC \overset{p}{=} AB$,, and $\sphericalangle BAC \overset{p}{=} \sphericalangle CAB$. The two triangles are therefore *p*-congruent, and so $\sphericalangle ABC \overset{p}{=} \sphericalangle ACB$.

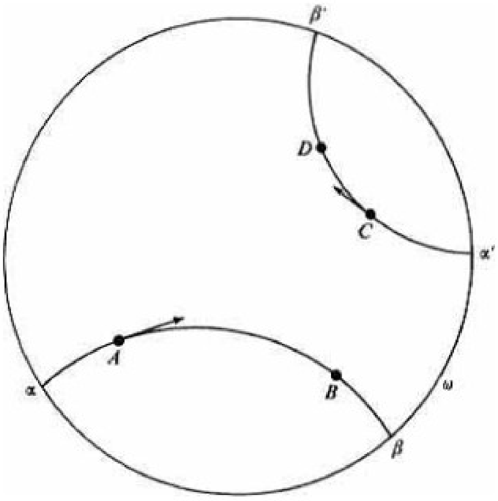

Fig. 58.4

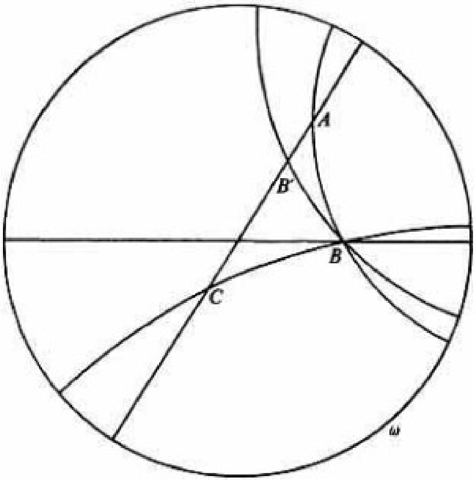

Fig. 58.5

Note that triangles *ABC* and *ACB* have opposite orientation, so that we must use the General SAS Theorem. A direct proof is indicated in Exercise 58.4.

Theorem III *In any p-triangle ABC, the greatest side is opposite the greatest angle*

Proof. Suppose that $d(A, C) > d(A, B)$ (see Fig. 58.6), and mark off a *p*-segment AB' on *p*-line *AC* equal to *AB*, so that $d(A, B') = d(A, B)$. Then B' lies in the segment *AC*, and the *p*-line BB' lies inside the angle *ABC*. Since $d(A, B') = d(A, B)$, the angles ABB' and $AB'B$ are equal. Therefore angle *ABC* is greater than angle $AB'B$, since angle *ABC* is greater than angle ABB'. But angle $AB'B$ is the exterior angle to angle $BB'C$ in *p*-triangle $BB'C$, and therefore exceeds the interior angle $B'CB$ which is the angle *ACB* (Thm 58.2). Hence angle *ABC* is greater than angle *ACB*.

Corollary. In a right-angled *p*-triangle, the longest side is that opposite the right angle.

Proof. Since the angle-sum of a *p*-triangle is less than two right angles, (Thm 58.1), the right angle is the largest angle.

We can now prove the triangle inequality for *p*-triangles and *p*-distances.

Theorem IV *In any p-triangle ABC*, $d(A, B) + d(B, C) > d(A, C)$.

Proof. If $d(A, C) \geq d(A, B)$ and $d(A, C) \geq d(B, C)$, then

$$d(A,C) + d(C,B) > d(A,B) \text{ and } d(A,C) + d(A,B) > d(B,C),$$

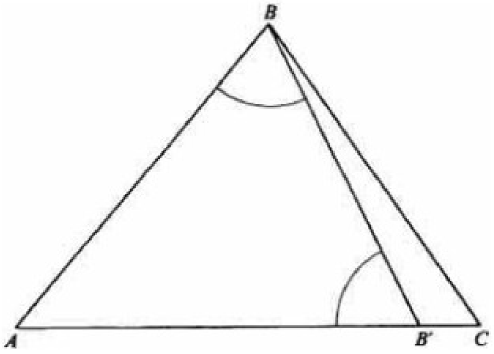

Fig. 58.6

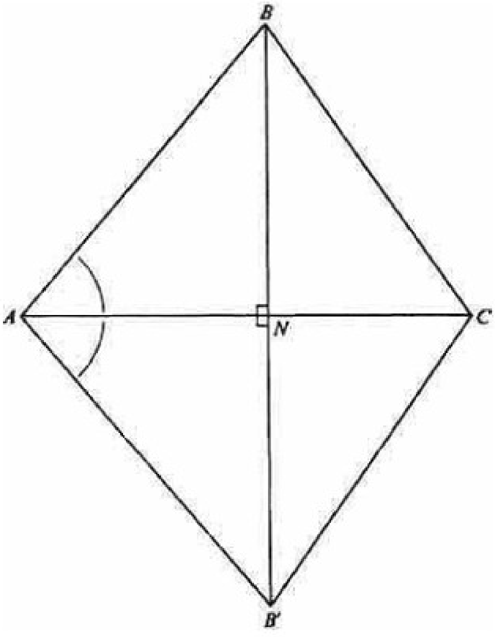

Fig. 58.7

so that if *AC* is the longest side of the *p*-triangle *ABC* (Fig.58.7), the proof of the theorem is only necessary with this assumption for the general inequality to be true. On the opposite side of the *p*-line *AC* to *B* mark off angle *B′AC* = angle *BAC*, where $d(A, B') = d(A, B)$. Let the intersection of the *p*-lines *BB′* and *AC* be *N*. The *p*-triangles *ANB* and *ANB′* are *p*-congruent, by the S A S theorem (Thm

57.1, II), and since the sum of the angles BNA, $B'NA$ is two right angles, both BNA and $B'NA$ are right angles. Therefore $d(A, B) > d(A, N)$, and $d(B, C) > d(N, C)$. Hence, *if N lies in the segment AC*,

$$d(A,B) + d(B,C) > d(A,N) + d(N,C) = d(A,C)$$

(by Thm I, above).

If N lay outside the p-segment AC, we still have $d(A, B) > d(A, N)$, and since in this case $d(A, N) > d(A, C)$, we should have $d(A, B) > d(A, C)$, which is a contradiction to our initial hypothesis.

Exercises

58.1 Show that the stronger form of the triangle inequality is: If A, B and C are three p-points, then $d(A, B) + d(B, C) \geq d(A, C)$, with equality if and only if A, B and C lie, in this order, on a p-line.

58.2 Does Thm III of §58.3 imply Thm II of the same Section? (Examine the proofs of both Theorems carefully before answering.)

58.3 If A is at the center of ω, and B, C are p-points such that $d(A, B) = d(A, C)$, show that the line-segments AB and AC are equal in length from the Euclidean point of view, and deduce that $\sphericalangle ABC = \sphericalangle ACB$. .

58.4 Using the preceding Exercise, prove that if in a p-triangle ABC we have $d(A, B) = d(A, C)$, then the p-angles ABC and ACB are equal.

58.5 Prove the ASA Theorem: (If for two triangles ABC, $A'B'C'$ (p-triangles, of course) $AB \overset{p}{=} A'B'$, $\sphericalangle BAC \overset{p}{=} \sphericalangle B'A'C'$ and $\sphericalangle ABC \overset{p}{=} \sphericalangle A'B'C'$, then the triangles are p-congruent).

58.6 Prove the SSS Theorem: (If for two p-triangles ABC, $A'B'C'$ we have $AB \overset{p}{=} A'B'$, $BC \overset{p}{=} B'C'$ and $CA \overset{p}{=} C'A'$ then the corresponding angles of the two triangles are also p-congruent). (Hint: Copy triangle $A'B'C'$ onto triangle ACQ, where $AQ \overset{p}{=} A'B'$, $\sphericalangle CAQ \overset{p}{=} \sphericalangle C'A'B'$, and Q is on the opposite side of AC to B. Prove triangles ABC, AQC are p-congruent, and deduce the theorem.)

58.7 Prove the SAA Theorem: (If for two p-triangles ABC, $A'B'C'$ we have $AB \overset{p}{=} A'B'$, $\sphericalangle CAB \overset{p}{=} \sphericalangle C'A'B'$ and $\sphericalangle ACB \overset{p}{=} \sphericalangle A'C'B'$, then the two triangles are p-congruent.)

59.1 Similar *p*-triangles are *p*-congruent

We have already seen (Thm 58.1) that in our p-geometry the sum of the angles of a p-triangle is always less than π, whereas in Euclidean geometry the angle-sum is always equal to π. Perhaps an even more surprising difference is the fact that a p-triangle is completely determined by its angles.

Theorem *Two p-triangles are p-congruent if the three angles of the one are respectively equal to the three angles of the other.*

Remark. We have established above that we may prove theorems in our p-geometry with the terminology and diagrams of Euclidean geometry, and have

57.1, II), and since the sum of the angles BNA, $B'NA$ is two right angles, both BNA and $B'NA$ are right angles. Therefore $d(A, B) > d(A, N)$, and $d(B, C) > d(N, C)$. Hence, *if N lies in the segment AC*,

$$d(A,B) + d(B,C) > d(A,N) + d(N,C) = d(A,C)$$

(by Thm I, above).

If N lay outside the p-segment AC, we still have $d(A, B) > d(A, N)$, and since in this case $d(A, N) > d(A, C)$, we should have $d(A, B) > d(A, C)$, which is a contradiction to our initial hypothesis.

Exercises

58.1 Show that the stronger form of the triangle inequality is: If A, B and C are three p-points, then $d(A, B) + d(B, C) \geq d(A, C)$, with equality if and only if A, B and C lie, in this order, on a p-line.

58.2 Does Thm III of §58.3 imply Thm II of the same Section? (Examine the proofs of both Theorems carefully before answering.)

58.3 If A is at the center of ω, and B, C are p-points such that $d(A, B) = d(A, C)$, show that the line-segments AB and AC are equal in length from the Euclidean point of view, and deduce that $\sphericalangle ABC = \sphericalangle ACB$. .

58.4 Using the preceding Exercise, prove that if in a p-triangle ABC we have $d(A, B) = d(A, C)$, then the p-angles ABC and ACB are equal.

58.7 Prove the SAA Theorem: (If for two p-triangles ABC, $A'B'C'$ we have $AB \overset{p}{=} A'B'$, $\sphericalangle CAB \overset{p}{=} \sphericalangle C'A'B'$ and $\sphericalangle ACB \overset{p}{=} \sphericalangle A'C'B'$, then the two triangles are p-congruent.)

59.1 Similar *p*-triangles are *p*-congruent

We have already seen (Thm 58.1) that in our p-geometry the sum of the angles of a p-triangle is always less than π, whereas in Euclidean geometry the angle-sum is always equal to π. Perhaps an even more surprising difference is the fact that a p-triangle is completely determined by its angles.

Theorem *Two p-triangles are p-congruent if the three angles of the one are respectively equal to the three angles of the other.*

Remark. We have established above that we may prove theorems in our p-geometry with the terminology and diagrams of Euclidean geometry, and have taken advantage of this freedom in the proofs of Theorems II and III and IV in §58.3. We continue in the same vein in the following proof.

Proof. In Fig. 59.1 suppose that $\sphericalangle A = \sphericalangle A'$, $\sphericalangle B = \sphericalangle B'$, $\sphericalangle C = \sphericalangle C'$ but that the p-triangles ABC and $A'B'C'$ are not p-congruent. Then we may assume that $d(A, B) \neq d(A', B')$, and that in fact $d(A, B) > d(A', B')$. On AB and AC mark off lengths equal to $A'B'$ and $A'C'$ respectively, calling the endpoints on AB and AC the points D and E. Then D certainly lies in the segment AB, but E may lie on C, or on AC produced, or in the segment AC. If E falls on C, then by the SAS Theorem (§57.1) the triangles ADC and $A'B'C'$ are congruent, so that the angle ADC = angle $A'B'C'$ = angle ABC. But by Thm 58.2, angle ADC > angle ABC, Hence E cannot fall on C. If E falls on AC produced then again triangles ADE and $A'B'C'$ are congruent, and angle AED = angle $A'C'B'$ = angle ACB, and by Thm 58.2 we should have angle ACB > angle AED. Hence E can only fall between A and C. If we now consider the quadrilateral $BCED$, the sum of the angles is 2π. But this contradicts Thm 58.1, since a quadrilateral can be divided into two triangles, and the angle-sum of one of the triangles would be $\geq \pi$. Hence the original triangles ABC, $A'B'C'$ are p-congruent.

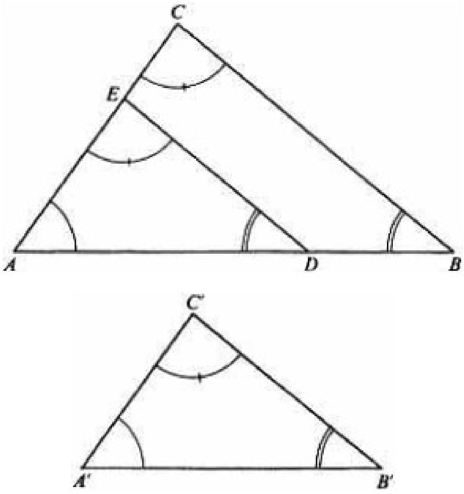

Fig. 59.1

59.2 *p*-circles in the *p*-plane

There are some obvious constructs in our p-geometry which merit investigation.

The definition of a *p*-circle is evidently as follows:

Definition. The locus of a *p*-point which moves so that its *p*-distance from a given *p*-point A is a constant r is a *p*-circle, center (*p*-center) A and *p*-radius r.

Theorem I *A p-circle, center A is a Euclidean circle orthogonal to the family of p-lines which pass through A.*

Proof. The *p*-lines through A all pass through the fixed point A' (Fig.59.2), where A' is the inverse of A in ω. Let P be the point whose locus we are considering, and $\mathscr{C}$ the *p*-line through P and A. This passes through A'. We wish to find the locus of P, subject to the condition $|\log(\alpha, \beta: A, P)| = r$, for a constant r, where α, β are the points in which $\mathscr{C}$ intersects ω. If we invert with respect to a circle, center A', orthogonal to ω, ω inverts into itself, the inside of ω inverts into the inside of ω, and A inverts into the center O of ω. The circle $\mathscr{C}$ inverts into the line OP', where P' is the inverse of P. Let the diameter OP' meet ω in the points α', β', which are the inverses of α, β. We know that although the inversion is a conjugate Moebius transformation, the cross-ratios $(\alpha, \beta; A, P)$ and $(\alpha', \beta'; O, P')$ are equal (Exercise 57.10). Hence

$$|\log(\alpha',\beta';o,P')| = |\log(\alpha,\beta A,P)| = r$$

This is readily seen to imply that P' is at a given distance from O, on either side of O, and therefore the locus of P' is a circle in the Euclidean sense, center O. This circle is orthogonal to the pencil of lines through O, and therefore arises from the Euclidean circle which is orthogonal to the family of circles through A and A' in the original figure.

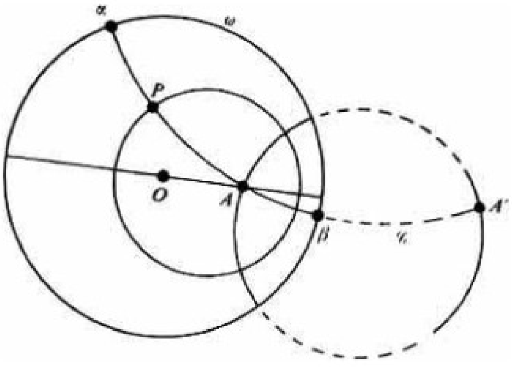

Fig. 59.2

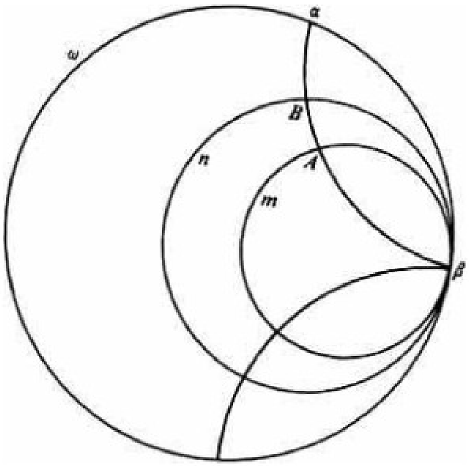

Fig. 59.3

We note that the Euclidean center of this circle only coincides with the p-center A in one case. We leave the elucidation of this happening as an Exercise. (Exercise 59.3.)

Again, as the center A moves towards ω, and we keep P fixed, the p-distance $d(AP)$ tends towards infinity, and the p-circle center A tends towards a Euclidean circle which touches ω internally. Such a circle is called a *horocycle*.

Theorem II *Two horocycles tangent to* ω *at the same point* β *cut off equal p-distances on the p-lines through* β.

Proof. Let m and n be two horocycles touching ω at the point β (Fig.59.3), and suppose that a p-line through β meets ω again in the point α, and intersects m in the p-point A and n in the p-point B. We know (Exercise 57.11) that inversion is a conjugate Moebius transformation. We also know (Exercise 57.10) that p-lengths are unaffected by a conjugate Moebius transformation. Let us therefore invert the given configuration in a circle center β (Fig.59.4). The circles ω, m and n invert into parallel lines ω', m' and n', the p-line AB inverts into a line $\alpha'B'A'$, where α' is the point where it meets ω', B' is the point where it meets n', and A' is the point where it meets m'. The point β itself has inverted into the point ∞. What has happened to the cross-ratio $(\alpha, \beta; A, B)$? It has become the cross-ratio $(\alpha', \infty; A', B')$, and this is simply the ratio $\overline{\alpha'A'}/\overline{\alpha'B'}$. But for fixed parallel lines we know that this is constant. Hence $d(A, B)$ is independent of the particular p-line through β which cuts A and B on the given horocycles.

An alternative proof is indicated in Exercise 59.1.

It has been made clear that to the possible two-dimensional inhabitants of our space Ω, the boundary circle ω is unattainable, and corresponds to the line at infinity in the real Euclidean plane. Poincaré suggested physical conditions which might obtain in Ω which would make ω unattainable. He imagined a variation of temperature in Ω which would make the dimensions of the two-dimensional inhabitants shrink to zero as they approach ω, the Great Divide. As they shrink, their steps also shrink, and the law of shrinkage can be so chosen that the geodesic, or shortest path, in the Euclidean sense, between two points in Ω is precisely the *p*-line through the two points. The Poincaré model is an illustration of Hamlet's: 'I could be bounded in a nutshell and count myself a king of infinite space, were it not that I have bad dreams'.

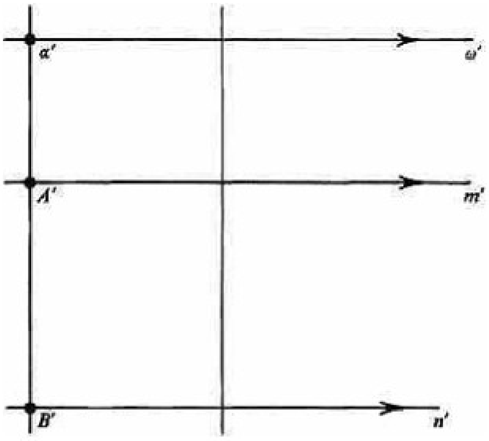

Fig. 59.4

We have seen that in our hyperbolic non-Euclidean geometry there are two *p*-parallels through a given *p*-point to a given *p*-line. It is possible to have a non-Euclidean geometry in which there are *no* parallels through a given point to a line.

We shall not investigate other types of non-Euclidean geometry. The Poincaré model, which we now leave, is a model of *hyperbolic* non-Euclidean geometry, and a non-Euclidean geometry with no parallels through a point to a given line is called an *elliptic* non-Euclidean geometry. In Exercise 59.2 a model for such a geometry is introduced. The invention of non-Euclidean geometries in the nineteenth century was one of the great leaps forward of the human mind. We can well understand the excitement of Janos Bolyai, one of the inventors of non-Euclidean geometry, when he wrote to his father, who first taught him mathematics: 'Out of nothing I have created a new, different, world!' For further explorations of this different world we refer the interested reader to other books (**4, 19, 20, 23**).

We have listed the axioms of Euclid in an Appendix (p. 432) so that the reader may be able to refer to them, and compare the Euclidean theorems deduced from them with those we have obtained. It is hoped that the impact of a non-Euclidean geometry may serve to interest the reader in the foundations of geometry.

In our next chapter we discuss *projective geometry*. In this geometry two lines in a plane always intersect, and so this geometry also ranks as a non-Euclidean geometry.

Exercises

59.1 Let m and n be two horocycles touching ω at the point β, and suppose that one p-line through β meets m again in A, and n again in B, and that another p-line through β meets m again in A', and n again in B'. Show that, by an inversion in a suitable circle of the coaxal system defined by the two p-lines, the p-line βAB can be inverted into the p-line $\beta A'B'$, and that this inversion maps ω and the horocycles onto themselves, ω onto ω, m onto m and n onto n, so that A is mapped onto A' and B onto B'. Deduce, that since an inversion is a conjugate Moebius transformation, $d(A, B) = d(A', B')$.

59.2 S is the surface of a sphere in real three-dimensional Euclidean space, and O is the center. Show that we have a model of an elliptic non-Euclidean geometry if we take S as our Plane, and identify a *pair* of points on S which are diametrically opposed (that is, their join passes through the center) as a Point in the Plane. The Lines in our Plane are to be given by the intersections with S of Euclidean planes through O. Show that two distinct Points determine a unique Line, and that two distinct Lines always intersect in a unique Point, so that there are no parallels to a given Line through a given Point which does not lie on it.

59.3 The points A and A' are inverse in a circle ω, A lying inside ω, and $\mathscr{C}$ is a circle of radius >0 which lies inside ω and is a member of the coaxal system polar to the coaxal system defined by circles which pass through A and A'. Show that if A' is a finite point, the center of $\mathscr{C}$ is never at A. When is the center of $\mathscr{C}$ at A?

59.4 Consider a Euclidean half-plane Ω bounded by the line ω, and all (semi-) circles in Ω which have their centers on ω, together with the set of all lines in Ω perpendicular to ω. Show how to set up a model of a hyperbolic geometry with this arrangement. What is the connexion with the model discussed in § 56.1?

VII

THE PROJECTIVE PLANE AND PROJECTIVE SPACE

We shall now investigate a geometry which is more fundamental than Euclidean geometry, in the sense that there will be no mention of metrical properties, distances or angle-measure, and the only concept we shall make use of at first is that of *incidence*. This geometry is called *projective geometry*, since its properties are invariant under *projection*, which is a geometrical transformation we shall investigate later. We shall enquire into the properties of projective space of n dimensions, after a special study of the cases $n = 2$ and $n = 3$, and since our treatment will be algebraic (non-algebraic treatments are also possible), we must say what kind of algebraic construct our numbers are to be taken from.

We shall work in a *commutative field*, although some of our theorems are also valid in a *skew* (non-commutative) field. For most of our purposes it will suffice to assume that our field is that of *the complex numbers*.

The outstanding property of this field which we may want to use is sometimes called *the fundamental theorem of algebra*: any polynomial with coefficients in the field of complex numbers splits into linear factors with coefficients which are complex numbers.

60.1 The complex projective plane

We must define the points of our geometry. A *point* is defined as an ordered triad of complex numbers (y_0, y_1, y_2) *not all zero*, with the understanding that the ordered triad (y_0k, y_1k, y_2k), where k is *any non-zero complex number*, represents the same point.

We must show that this relation is *an equivalence relation*, which is easily done, but this becomes evident if we remark that the ordered triad (y_0, y_1, y_2) represents a point distinct from the origin in three-dimensional complex affine space, and the set of points (y_0k, y_1k, y_2k) as k varies is the *ray*, or line through the origin joining the origin to the point. We are therefore defining a *line* or *ray* through the origin to be a *point* in our geometry, which is that of the complex projective plane.

The coordinates (y_0, y_1, y_2) we are using are usually called *homogeneous coordinates*, since only the ratios $y_0{:}y_1{:}y_2$ of the coordinates are significant, these being the same for the point (y_0k, y_1k, y_2k).

A *line* in our complex projective plane is defined to be the subset of points in the plane whose coordinates satisfy a linear homogeneous equation

$$u^0X_0 + u^1X_1 + u^2X_2 = 0,$$

where not all the u^i $(i = 0, 1, 2)$ are zero. Since, multiplying on the right by $k \neq 0$ we also have

$$u^0(X_0k) + u^1(X_1k) + u^2(X_2k) = 0,$$

it follows that if one member of the equivalence class representing a point of our projective plane satisfies the equation, so does every member.

We note that in three-dimensional affine space the equation above is that of *a plane through the origin*. Hence rays through the origin are to be points of the projective plane, and *planes* through the origin are to be *lines* of the projective plane. A *point* of the projective plane is *incident* with, or *lies on* a *line* of the projective plane if and only if the *ray* corresponding to the point lies in the *plane* corresponding to the line.

We now prove two incidence theorems which explain why our algebraic formulation is chosen in what may appear, at first sight, to be a curious manner.

Theorem I *In the projective plane, two distinct points determine a unique line with which they are incident.*

Theorem II *In the projective plane two distinct lines intersect in a unique point.*

Remark. It is the second theorem which distinguishes this geometry from ordinary Euclidean geometry, where lines which are distinct may not intersect. In this geometry distinct lines *always* intersect.

Proof. We prove the second theorem first. Let

$$u^0X_0 + u^1X_1 + u^2X_2 = 0 = \upsilon^0X^0 + \upsilon^1X_1 + \upsilon^2X_2.$$

be the equations of the two lines. Since they are distinct, we do *not* have

$$u^0:u^1:u^2 = \upsilon^0:\upsilon^1:\upsilon^2.$$

Solving the two homogeneous equations for the point of intersection of the two lines gives us as point of intersection:

$$(u^1\upsilon^2 - u^2\upsilon^1, u^2\upsilon^0 - u^0\upsilon^2, u^0\upsilon^1 - u^1\upsilon^0).$$

This triad could only fail to be a point if *each* of the elements of the triad displayed above were zero. This could only be the case if

$$[u^0:u^1:u^2] = k[\upsilon^0,\upsilon^1,\upsilon^2]\ (k\neq 0),$$

which would mean that the two lines are identical, and this possibility is contrary to hypothesis.

To prove Thm I we remark that if the two distinct points are

$$(x_0,x_1,x_2) \text{ and } (y_0,y_1,y_2),$$

then we do *not* have

$$(x_0,x_1,x_2) = (y_0k,y_1k,y_2k)\ (k\neq 0),$$

and the line

$$u^0X_0 + u^1X_1 + u^2X_2 = 0$$

contains both points, where

$$u^0 = x_1y_2 - x_2y_1,\ u^1 = x_2y_0 - x_0y_2,\ u^2 = x_0y_1 - x_1y_0,$$

as can be immediately verified. This line exists, since we do not have $u^0 = u^1 = u^2 = 0$, the two points (x_0, x_1, x_2) and (y_0, y_1, y_2) being distinct points. Hence there is *a* line through the two points. There cannot be more than one, since we should then have two distinct lines intersecting in more than one point, contrary to Thm II.

To Theorems I and II we add a third, designed to ensure that the geometry we are considering is not trivial.

Theorem III The projective plane contains at least four distinct points, no three of which are collinear.

Proof. The points (1, 0, 0), (0, 1, 0), (0, 0, 1) and (1, 1, 1) are easily seen to satisfy this condition over the field of the complex numbers, since the first three points lie, in pairs, on the lines $X_2 = 0$, $X_0 = 0$ and $X_1 = 0$ respectively, and the fourth point does not lie on any of these lines.

It will be noticed that we use capital letters for the variables in an equation, lowercase letters for actual coordinates of points, and also for what we may evidently call *the coordinates of a line*: $[u^0, u^1, u^2]$, the line being

$$u^0X_0 + u^1X_1 + u^2X_2 = 0.$$

We note, that just as with points, the ordered triad $[ku^0, ku^1, ku^2]$ $(k \neq 0)$ represents the same line as does the ordered triad $[u^0, u^1, u^2]$.

60.2 The principle of duality in the projective plane

The symmetrical nature of the incidence relation

$$u^0y_0 + u^1y_1 + u^2y_2 = 0.$$

which expresses the fact that the line $[u^0, u^1, u^2]$ *contains* the point (y_0, y_1, y_2), or equivalently, that the point (y_0, y_1, y_2) *lies on* the line $[u^0, u^1, u^2]$ gives rise to the *Principle of Duality* in the projective plane. This asserts that by an automatic interchange of the terms *point* and *line*, *lying on* and *passing through*, *join* and *intersection*, *collinear* and *concurrent*, and so on, any theorem in the projective plane which involves only incidence properties of points and lines becomes, on transliteration with the help of the dictionary of interchanges we have just listed, a theorem involving lines and points.

To give an immediate example, the theorem of Desargues, which we have already encountered (§5.2) and which is essentially a theorem of the projective plane, says that if ABC, $A'B'C'$ are two triangles in the projective plane which are such that the lines AA', BB' and CC' are concurrent (that is, pass through the same point), then the three points of intersection of corresponding sides, $BC \cap B'C'$,$CA \cap C'A'$ and $AB \cap A'B'$are collinear (lie on a line).

The theorem obtained by applying the Principle of Duality says that if abc, $a'b'c'$ are triangles (we should change the term *triangle*, which refers to a configuration formed by three *points*, to *triline*, to be precise, since we now consider two configurations formed by triads of lines, a, b and c and a', b' and c', these not being concurrent: but we shall not do this) in the projective plane which are such that the points aa', bb' and cc' are collinear (lie on a line) then the lines joining corresponding vertices, $bc \cup b'c'$,$ca \cup c'a$and $ab \cup a'b'$ are concurrent (pass through a point).

We shall see, in fact, that exactly the same algebra which we shall use to establish the Desargues Theorem will establish the dual theorem, which is the converse of the Desargues Theorem (§62.2).

It will be noted that we are using the symbol AB to denote the *line* joining two distinct points A and B, and dually the symbol ab to denote the *point* of intersection of the two distinct lines a and b. Since we use the symbol $\cap$ for the intersection of two point-sets, the point of intersection of two lines AB and $A'B'$ is written as $AB \cap A'B'$, and therefore dually we write $ab \cup a'b'$ for the line joining the points ab and $a'b'$, although the $\cup$ symbol here does *not* stand for the join of two point-sets. Another symbol, if used, would also create difficulties. Some authors use the symbol $A + B$ for the set of points on the line joining A to B. We shall not do this, and we do not think that there will be any misunderstanding in interpreting our symbolism.

The reader may wonder why we talk of the Principle of Duality, when our statement describing it amounts to a proof. Historically the statement was put in the form of a Principle. For us it is almost a self-evident theorem.

Exercises

60.1 Show that the equation of the line joining the two points (x_0, x_1, x_2) and (y_0, y_1, y_2) is the result of eliminating U^0, U^1, U^2 from the three equations $U^0X_0 + U^1X_1 + U^2X_2 = 0$, $U^0x_0 + U^1x_1 + U^2x_2 = 0$, $U^0y_0 + U^1y_1 + U^2y_2 = 0$, and is therefore the determinantal equation

$$\begin{vmatrix} X_0 & X_1 & X_2 \\ x_0 & x_1 & x_2 \\ y_0 & y_1 & y_2 \end{vmatrix} = 0.$$

60.2 Write out the dual of the Exercise above, changing the phrase ‘equation of the line’ to ‘equation of the point’. (Note that the equation of a *line* is the condition that a point (X_0, X_1, X_2) lie on a line $[u^0, u^1, u^2]$. The equation of a *point* is the condition that a line $[U^0, U^1, U^2]$ pass through a point (x_0, x_1, x_2).)

60.3 Four distinct points A, B, C and D, no three of which are collinear, are said to form a complete quadrangle (or four-point), with *sides* formed by joining the points in pairs, and with *diagonal triangle* formed by the *diagonal points*, which are the intersections of the sides, other than A, B, C and D. Write down the dual of this definition, drawing a diagram in each case.

60.4 The Pappus Theorem says that if A, B, C are three distinct points on a line l, and A', B', C' three distinct points on a distinct line m, then the three points $BC' \cap B'C, CA' \cap C'A$ and $AB' \cap A'B$ are collinear. Write down the dual of this theorem, drawing a diagram in each case.

60.5 A set of points $(P, Q, R, \ldots,)$ on a line l is said to be *in perspective* with a set of points $(P', Q', R', \ldots)$ on a line l', if the joins PP', QQ', RR', . . . all pass through a point V. Formulate a dual concept for lines $(p, q, r, \ldots)$ on a point L, and lines $(p', q', r', \ldots)$ on a point L'.

60.6 The points on the surface of a given sphere which are diametrically opposed are identified as Points, and great circles cut on the surface of the sphere by planes through the center are identified as Lines. Show that these Points and Lines satisfy Theorems I, II and III of §60.1, the ground field being that of the real numbers.

60.7 Show that the points $A = (1, 0, 0)$, $B = (0, 1, 0)$, $C = (0, 0, 1)$, $D = (0, 1, 1)$, $E = (1, 0, 1)$, $F = (1, 1, 0)$ and $G = (1, 1, 1)$, where the field is that of the integers, mod 2 (that is $1 + 1 = 0$) form a finite projective geometry, with three points on every line and three lines through every point (See Pedoe, **12,** p. 85).

60.8 If all the elements involved, with the exception of the symbol ∞, are real numbers, show that the set of points and lines described satisfy Thms. I, II and III of §60.1. The points are: (*i*) ordinary points with coordinates (a, b); (*ii*) infinite points (m), together with the point ∞. The lines are given by the equations $X = c$, and $Y = mX + b$, and there is also the line at infinity ω. The line at infinity contains the point ∞ and all points (m), the line $X = c$ contains the point ∞ and all points (c, d), and the line $Y = mX + b$ contains the point (m) and all the points $(a, ma + b)$.

61.1 A model for the projective plane

We have already associated a *ray* through the origin of a three-dimensional space with a *point* of our projective plane. We pursue this further. Let V_3 be the complex vector space of vectors $y = (y_0, y_1, y_2)$, where the y_i are complex numbers. If $y \neq (0, 0, 0)$, the zero vector, then we may define a *ray* of V_3 as the set of vectors $yk = (y_0k, y_1k, y_2k)$ $(k \neq 0)$. We say that a *point* of our complex projective plane is a *ray* of V_3.

Two vectors $y = (y_0, y_1, y_2)$ and $z = (z_0, z_1, z_2)$ of V_3 are said to be *linearly dependent* if there exist complex numbers λ and μ, not both zero, so that

$$y\lambda + z\mu = 0$$

where 0 is the zero vector. If such a relation necessarily implies that $\lambda = \mu = 0$, we say that y and z are *linearly independent*. Since a point of the complex projective plane is defined to be a ray of V_3, we see that if two non-zero vectors y and z are linearly dependent, so that they define the same ray of V_3, then they also define the same point of our complex projective plane.

If y and z are *independent*, and therefore neither is the zero vector, each defines a ray of V_3, and the set of vectors linearly dependent on y and z form a subspace of V_3. In fact, if $x = y\lambda + z\mu$, and we write down the three equations for the coordinates of the vectors on each side of this equation, we have

$$\begin{aligned} y_0\lambda + z_0\mu - x_0 &= 0, \\ y_1\lambda + z_1\mu - x_1 &= 0, \\ y_2\lambda + z_2\mu - x_2 &= 0, \end{aligned}$$

and on eliminating λ and μ from these equations we have the determinantal equation

$$\begin{vmatrix} X_0 & X_1 & X_2 \\ y_0 & y_1 & y_2 \\ z_0 & z_1 & z_2 \end{vmatrix} = 0.$$

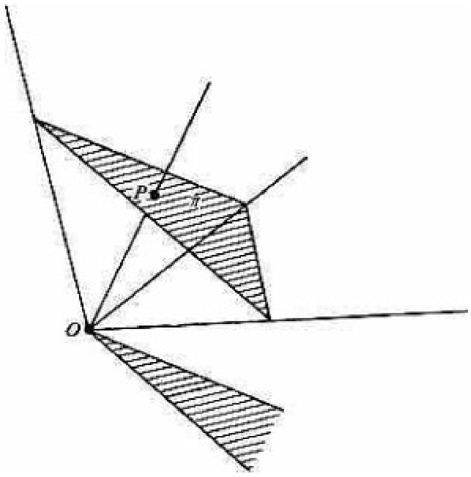

Fig. 61.1

This is a linear homogeneous equation in (X_0, X_1, X_2), and represents both the *plane* in V_3 defined by two distinct rays $y\lambda$ and $z\mu$, and the *line* in our projective plane which joins the two distinct points y and z.

It is clear that we may use a single symbol such as y or z for a point in our projective plane, with the understanding that $y\lambda$ represents the same point as y. We have seen that the set of points linearly dependent on the points y and z is the set $y\lambda + z\mu$. This gives the set of points on the *line* joining y and z.

If we assume that we are perfectly familiar with vector spaces V_3 over the complex number field, we have set up a *model* for the complex projective plane, since all the mathematical properties of the projective plane can be described or verified for V_3, and we assume that the mathematical properties of V_3 are free from contradiction. If we wish to *see* something, and this is what a model is for, let us consider how to set up homogeneous coordinates in a plane in real affine space. Call the plane π, and choose a system of three-dimensional coordinates for which the origin $O = (0, 0, 0)$ does not lie in π (Fig.61.1). Then a ray through O which is not parallel to π intersects π in a unique point P, and if the ray is the set of points (y_0k, y_1k, y_2k), where k varies over the real number field, the point P can be assigned the coordinates (y_0, y_1, y_2), where (y_0k, y_1k, y_2k) are also the coordinates of the same point P. This is precisely the development already given.

Here there is a difference, since rays through O may be parallel to π. If such a ray is $(z_0, z_1, z_2)k$, we say that the point (z_0, z_1, z_2) is *an ideal point* in π, or *a point at infinity*. If the equation of the plane π is $u^0X_0 + u^1X_1 + u^2X_2 = \text{constant}$, in our system of three-dimensional coordinates, the equation of the plane through O which is *parallel* to π is simply the equation $u^0X_0 + u^1X_1 + u^2X_2 = 0$, and we may take this same equation as *the equation of the line at infinity in the plane* π.

By introducing ideal points into the plane π, we have made it into a projective plane, in which all points have equal status, and two distinct lines always intersect.

Returning to our complex projective plane, which we shall also label π, we know that the vector space V_3 contains sets of 3 linearly independent vectors. One such set is $E_0 = (1, 0, 0)$, $E_1 = (0, 1, 0)$, $E_2 = (0, 0, 1)$. Vectors are, of course, linearly independent if there is no non-trivial linear homogeneous relation between them; that is, if the vectors be x, y and z, they are linearly independent when any linear relation $x\lambda + y\mu + z\nu = 0$ necessarily implies $\lambda = \mu = \nu = 0$. The vectors E_0, E_1 and E_2 are clearly independent. Since we may write any vector $y = (y_0, y_1, y_2)$ in V_3 as

$$y = E_0y_0 + E_1y_1 + E_2y_2,$$

and this same expression holds for points in π, we have shown that:

The system of homogeneous coordinates in π arises from the expression of a point P being linearly dependent on three fixed points which form a proper triangle in π.

We know that any three independent vectors in V_3 form *a basis* for the vectors of V_3: that is, any vector of V_3 can be expressed linearly in terms of three independent vectors. If the three independent vectors be named E_0^*, E_1^*, E_2^* then any vector y of V_3 has a unique expression in the form

$$y = E_0^*\lambda + E_1^*\mu + E_2^*\nu.$$

Independent vectors in V_3 correspond, if there are two vectors, to two distinct points of π, and if there are three vectors, to three non-collinear points of π, forming a proper triangle. The theory of the basis for vectors in V_3 shows us that if any three non-collinear points be chosen in π, with coordinates E_0^*, E_1^* and

E_2^*, then any point in π may be expressed in the form

$$P = E_0^*\lambda + E_1^*\mu + E_2^*\nu,$$

where the ordered triad (λ, μ, ν) is any one of an equivalence class $(\lambda k, \mu k, \nu k)$ $(k \neq 0)$ (Fig.61.2.)

If we call the triangle we have chosen *the triangle of reference*, we may call (λ, μ, ν) *the coordinates of the point P with respect to the given triangle of reference*.

We shall investigate, in §64.1 the effect of a change of triangle of reference on the coordinates of a given point. But for a given triangle of reference we now have enough apparatus to prove theorems on points, lines, their joins and intersections in the projective plane π.

Since we shall be investigating the projective geometry of n dimensions in §66.1, we have introduced a suffix notation (y_0, y_1, y_2) for our coordinates, but we may now revert to a simpler notation, calling the triangle of reference ABC, and the coordinates of a point in π: (x, y, z).

We note that the coordinates of A, B and C are respectively $(1, 0, 0)$, $(0, 1, 0)$ and $(0, 0, 1)$ referred to ABC as triangle of reference. Any point on BC is $(0, 1, 0)y + (0, 0, 1)z = (0, y, z)$, and in fact the equation of the line BC is $X = 0$.

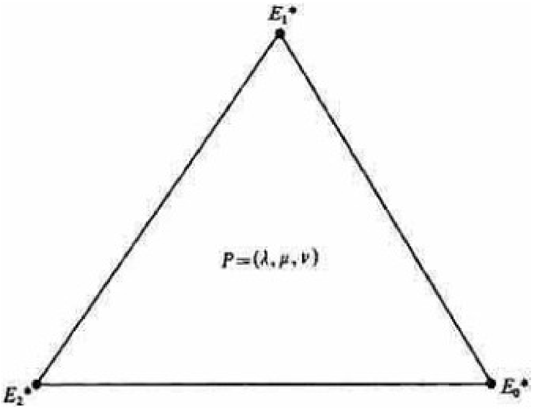

Fig. 61.2

If A' is the point $(0, q, r)$ on BC, any point on the line AA' is given by $(1, 0, 0)p + (0, q, r) = (p, q, r)$. Conversely, if the point (p, q, r) be joined to the vertex A, the intersection of this line with the side BC is the point $(0, q, r)$, and the equation of the line joining A to the point (p, q, r) is simply $rY - qZ = 0$.

The reader will find it interesting to compare the treatment of points and lines given here with that of points and lines in the real Euclidean plane given in Chapter I. Some of the results appear to be similar, but we do not deal with metrical results in the projective plane. We have a greater freedom, since our coordinates are not normalized (for instance, if A, B and C are three non-collinear points, any point P may be expressed as $P = Ax + By + Cz$, without having $x + y + z = 1$, as in Thm 4.2), but we do not have a metrical interpretation.

On the other hand, some theorems, such as the Theorem of Ceva, do have a corresponding theorem in the projective plane, since the metrical interpretation is not fundamental to the theorem.

Example. The lines AP, BP and CP cut the opposite sides of triangle ABC in the points L, M and N respectively. If $L = xB + x'C$, $M = yC + y'A$, $N = zA + z'B$, then

$$xyz = x'y'z'.$$

If $P = (p, q, r)$ with respect to ABC as triangle of reference, then $L = (0, q, r)$, $M = (p, 0, r)$ and $N = (p, q, 0)$, Since we are given that $L = (0, x, x')$, $M = (y', 0, y)$ and $N = (z, z', 0)$, we have

$$x{:}x' = q{:}r,\ y{:}y' = r{:}p,\ z{:}Z' = p{:}q,$$

and therefore

$$(x{:}x')(y{:}y')(z{:}z') = (q{:}r)(r{:}p)(p{:}q) = 1.$$

Example. Theorem of Menelaus (compare Thm 4.1). A line cuts the sides BC, CA and AB of a triangle ABC in the points L, M and N respectively. If $L = Bx + Cx'$, $M = Cy + Ay'$ and $N = Az + Bz'$, then $xyz = -x'y'z'$.

Let the equation of the line be $eX + fY + gZ = 0$. Then L is given by the equation $fY + gZ = 0$, so that $L = (0, -g, f) = B(-g) + C(f)$. Hence $x{:}x' = -g{:}f$. Similarly $y{:}y' = -e{:}g$, and $z{:}z' = -f{:}e$, and the theorem follows immediately.

Exercises

61.1 Prove that if $A' = B + Ck$ is a point on BC, and if M be taken on AA' distinct from A or A', then if BM intersects CA in Q and CM intersects AB in R, the line QR will intersect BC in the point $B - Ck$.

61.2 The sides BC, CA and AB of the triangle of reference have coordinates $[1, 0, 0]$, $[0, 1, 0]$ and $[0, 0, 1]$ respectively. If we write

$$a = [1,0,0],\ b = [0,1,0],\ c = [0,0,1],$$

show that $a' = b + kc$ is a line through the point bc. Write down the theorem dual to that given in Exercise 61.1, and prove it, using essentially the same algebra.

61.3 If ABC be the triangle of reference, show that the equation $lX + nZ = 0$ represents a line through the point B, and the equation $pX + qY = 0$ represents a line through the point C. If the first line intersects the side AC in the point E, and the second line intersects the side AB in the point F, show that the equation of the line EF is $lpX + lqY + npZ = 0$.

61.4 If the lines $uX + \upsilon Y + wZ = 0$, $u'X + \upsilon'Y + w'Z = 0$ intersect at the point P, show that the equation

$$(uX + \upsilon Y + wZ)\gamma + (u'X + \upsilon'Y + w'Z)\mu = 0$$

represents a line which always passes through P, for all values of λ and μ except $\lambda = \mu = 0$. Find the equation of the line which joins P to the vertex A of the triangle of reference.

62.1 The normalization theorem for points on a line

Theorem *If P, Q and R are three distinct collinear points in π, then a coordinate system may be set up in which the homogeneous coordinates of P, Q and R, written as vectors y, z and t, satisfy the equation*

$$t = y + z.$$

Remark. We use a single symbol to represent a vector. When we use a single symbol to represent a point in π, this means that we have chosen a specific representative from the equivalence class of ordered triads which represent the point.

Proof. In any system of homogeneous coordinates where P, Q and R are represented by the vector symbols y', z' and t' respectively, we have a relation

$$y'\lambda + z'\mu + t'\nu = 0,$$

since the three points are linearly dependent. The λ, μ, υ are not all zero. In fact, none of the multipliers is zero, since this would involve two of the points under consideration being identical, and this is excluded. Hence $\nu \neq 0$, and we may write

$$t' = y'\rho + z'\sigma,$$

where neither ρ nor σ is zero. Now write

$$y'\rho = y,\ z'\sigma = z \text{ and } t' = t,$$

so that y is a specific representative of the point P, z a specific representative of the point Q and t a specific representative of the point R, and we have

$$t = y + z.$$

Remark. If we set up a coordinate system on the line for which P and Q are base points, any point on the line being $X = Px_0 + Qx_1$, our procedure assigns the unit point, with coordinates (1, 1), to R.

This tidying-up process enables us to prove the Desargues Theorem very simply.

62.2 The Desargues theorem

Theorem *If two triangles ABC, $A'B'C'$ in π are such that the lines AA', BB' and CC' pass through a point V, then the three points $BC \cap B'C'$, $CA \cap C'A'$ and $AB \cap A'B'$ all lie on a line.*

Proof. We assume that the seven points V, A, B, C, A', B', C' are distinct (Fig.62.1). In a system of homogeneous coordinates let $^{\varepsilon}$ denote the point V, and let $A = \alpha$, $B = \beta$, $C = \gamma$, $A' = \alpha'$, $B' = \beta'$, and $C' = \gamma'$.

By the Normalization Theorem of §62.1, we may write

$$\varepsilon = \alpha + \alpha' = \beta + \beta' = \gamma + \gamma'$$

simultaneously for the three pairs of points with which V is collinear. Let us write:

$$\rho = \beta - \gamma = \gamma' - \beta', \sigma = \gamma - \alpha = \alpha' - \gamma', \tau = \alpha - \beta = \beta' - \alpha'.$$

Then the point represented by ρ is linearly dependent on B and C, and therefore lies on the line BC, and it is also linearly dependent on B' and C', and therefore also lies on the line $B'C'$. If these lines are distinct, ρ is therefore the symbol for the point of intersection $BC \cap B'C'$. Similarly,

$$\sigma = CA \cap C'A' \text{ and } \tau = AB \cap A'B'$$

But

$$\rho + \sigma + \tau = \beta - \gamma + \gamma - \alpha + \alpha - \alpha = 0.$$

Therefore ρ, σ and τ are linearly dependent, and represent three collinear points. Hence the points

$$BC \cap B'C', CA \cap C'A' \text{ and } AB \cap A'B'$$

are collinear.

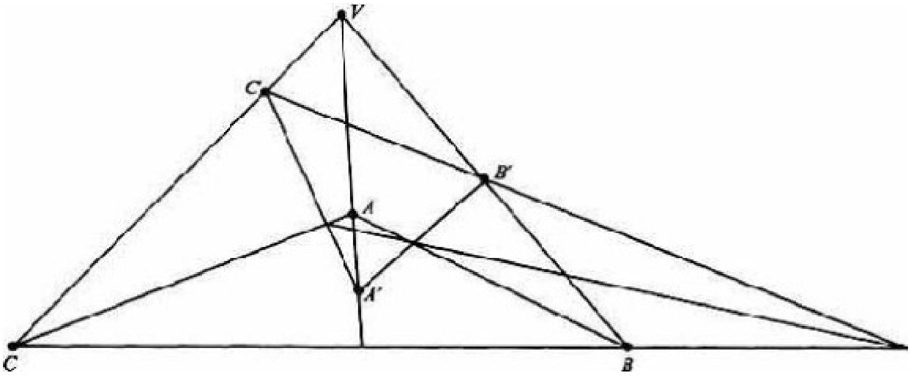

Fig. 62.1

Remark. With a similar definition of homogeneous coordinates to that we have given, and with lines defined to be sets of points linearly dependent on pairs of given distinct points, the projective plane can be defined over a skew field. The Normalization Theorem holds for such a field, and so does the Theorem of Desargues. It will be observed that commutativity under multiplication has not been used in the two proofs above.

When projective geometry is built up from incidence axioms, the Desargues Theorem for the plane is often invoked as an axiom. We can prove the Theorem here because we have assumed a system of homogeneous coordinates for our projective plane. It can be shown that the assumption of the Desargues Theorem leads to the possibility of the construction of a system of homogeneous coordinates over a skew field.

Finally, we note that when two triangles ABC, $A'B'C'$ are such that the lines AA', BB' and CC' pass through a point V, they are said to be *in perspective* from the point V, which is called *the center of perspective*. The line which contains the points $BC \cap B'C'$ $CA \cap C'A'$ and $AB \cap A'B'$ is called *the axis of perspective*. We may also say that the two triangles are *in perspective* from the axis of perspective, and the Desargues Theorem says that two triangles in perspective from a point are also in perspective from a line. The dual, or converse, reverses the order of these statements.

Exercises

62.1 State and prove the dual to the Normalization Theorem (§62.1).

62.2 State and prove the dual of the Desargues Theorem.

62.3 Show that the dual of the Desargues Theorem is implied by the Desargues Theorem, without the intervention of the Principle of Duality. (Hint: we wish to show that three certain lines pass through a point.

This can be shown to be equivalent to three certain points lying on a line. Choosing two triangles which satisfy the Desargues Theorem, this follows.)

62.4 If the sides of a variable triangle pass through three fixed collinear points, while two vertices move along fixed lines, prove that the third vertex must move along a third fixed line concurrent with the other two.

62.5 Three triangles $A_iB_iC_i$ ($i = 1, 2, 3$) are such that any two of them are in perspective, the center of perspective of $A_iB_iC_i$ and $A_jB_jC_j$ being V_{ij}. If V_{12}, V_{23} and V_{31} are collinear, prove that the three triangles have a common axis of perspective l, and that any two of the triangles $A_1A_2A_3$, $B_1B_2B_3$ and $C_1C_2C_3$ are in perspective, the three centers of perspective lying on l.

62.6 A, B, C, D is a quadrangle. P is a point on BD, Q, R are points on AB, AD, and S, T are points on CB, CD. Prove that if P, Q, R are collinear, and also P, S, T, then the lines QS, RT and AC are concurrent.

62.7 D is a fixed point on the side AB of a given triangle ABC, H and K are fixed points which do not lie on any side of the triangle. P is a variable point on CD, and AP intersects DH in Q, and BP intersects DK in R. Prove that QR meets AB in a fixed point. (If P' be another position of P, and Q', R' the corresponding constructed points, we wish to show that QR, AB, and $Q'R'$ are concurrent. Application of the converse of Desargues' Theorem to two suitable triangles produces the result.)

62.8 D is a point on the side BC of triangle ABC, and P, Q are points on AB. The line PD meets AC in H, the line QD meets AC in K, and CP meets AD in M, while CQ meets AD in N. Prove that KM and HN meet on AB. (For a geometrical proof, not using coordinates, see Exercise 63.6.)

63.1 The normalization theorem for points in a projective plane

Theorem I *If A, B, C and P are four distinct points in a projective plane π, and no three are collinear, then a system of homogeneous coordinates can be set up so that the symbols x, y, z* and *t for the respective points satisfy the relation $t = x + y + z$.*

Proof. Since four points in π are linearly dependent, if x', y', z' and t' are the vector symbols for A, B, C and P in our system of homogeneous coordinates, we have a relation $x'\lambda + y'\mu + z'\nu + t'\tau = 0$, where not all of the multipliers λ, μ, ν, τ are zero. In fact, none of them can be zero since if, say, $\lambda = 0$, this would imply the linear dependence, and therefore collinearity of the points B, C and P. Hence we may write

$$t' = x'\lambda' + y'\mu' + z'\nu',$$

where none of the multipliers λ', μ', ν' is zero. We may now *absorb* the multipliers λ', μ' and ν', and write

$$x = x'\lambda', y = y'\mu', z = z'\nu'$$

where x is a definite symbol for A, y for B and z for C, and writing $t = t'$ we have

$$t = x + y + z$$

Remark. If A, B and C are chosen as vertices of the triangle of reference in π, our theorem asserts that any point P *not on the sides* of ABC can be taken to have the coordinates (1, 1, 1). This is called *fixing the unit point* of the coordinate system.

Care has to be taken in applying this theorem, so that we do not assign the same coordinates to two distinct points in the plane. Students tend to do this at first, and are therefore able to prove all true and untrue theorems they set their minds to!

The dual of the above theorem is also important, and we state it without proof.

Theorem II *If a, b, c and p are four distinct lines in a projective plane π, and no three are concurrent, then a system of homogeneous coordinates may be set up so that the symbols l, m, n and q for the respective lines satisfy the relation*

$$q = l + m + n$$

Remark. If a, b and c are chosen as sides of the triangle of reference, the fourth line p, which does not pass through any vertex, can be written as

$$X + Y + Z = 0.$$

Example. ABC is a triangle, and O is a point in the plane of the triangle which does not lie on any side. The line AO meets BC in A', the line BO meets CA in B', and the line CO meets AB in C'. We prove that the points

$$L = B'C' \cap BC, M = C'A' \cap CA, N = A'B' \cap \mathrm{AB}$$

are collinear, and that a coordinate system may be chosen so that the equation of the line LMN is $X + Y + Z = 0$.

Remark. The line LMN is called *the polar line* of the point O with respect to the triangle ABC.

We choose ABC as triangle of reference (Fig.63.1), and O as unit point, as we may do, by Thm I above. Then $A' = (0, 1, 1)$, $B' = (1, 0, 1)$ and $C' = (1, 1, 0)$. To find L, we consider the set of points $(1, 0, 1)\lambda + (1, 1, 0)\mu$, which is the set of points on $B'C'$, and choose λ, μ so that the resulting point lies on BC, which means that its first coordinate is zero. This is evidently done by taking $\lambda = 1$ and $\mu = -1$, so that $L = (1, 0, 1) - (1, 1, 0) = (0, -1, 1)$.

Similarly $M = (1, 0, -1)$ and $N = (-1, 1, 0)$, and these three points satisfy the equation $X + Y + Z = 0$.

Theorem III *The Pappus Theorem. If D, A, E are distinct points on a line l, and C, F, B are distinct points on another line m, coplanar with l, then the three points $DF \cap AC = v$,$DB \cap CE = U$ and $EF \cap AB = W$ are collinear*. (See Fig.

;. *11 $

63.2.)

Remark. The Pappus Theorem appeared in §9.5, when the line of collinearity *UVW* is the line at infinity. Our naming of the points here is not the standard one, since we wish to name the triangle of reference we intend to use to prove the theorem as *ABC*, and the unit point as *U*.

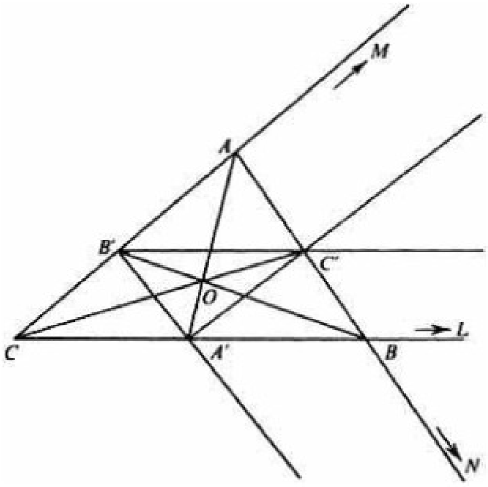

Fig. 63.1

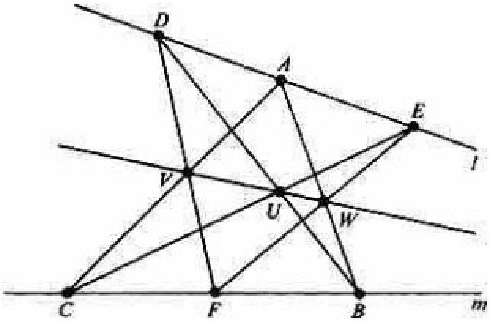

Fig. 63.2

Proof. We choose *ABC* as triangle of reference, and *U* as the unit point, so that $U = A + B + C$. We then take *E*, which is on *UC* as $E = U + Ck$. We now find $D = AE \cap BU$. Since $E = A + B + C(1 + k)$, we see that

$$\begin{aligned} E + AK &= A(1+\mathrm{k}) + B(1+\mathrm{k}) + C(1+\mathrm{k}) - Bk \\ &= U(1+\mathrm{k}) - Bk, \end{aligned}$$

and therefore the point represented, lying on AE and BU, must be D. Hence

$$D = E + Ak = A(1+k) + B + C(1+k)\, Bk$$

The point F is not yet defined, and we take

$$F = B + Ck'$$

V lies on AC and FD, and we find that

$$v = -F + D = A(1+\mathrm{k}) + C(1+\mathrm{k}-\mathrm{k}').$$

Finally, W lies on AB and EF, and to find W we have to eliminate C from

$$E = A + B + C(1+\mathrm{k}). \text{ and } F = B + Ck'$$

and

$$Ek' - F(1+\mathrm{k}) = Ak' + B(k' - 1 - k) = W$$

We note that in obtaining this result we assumed that $k'(1 + k) = (1 + k)k'$, that is, we assumed the commutativity of multiplication for the symbols of our ground field. Since we began by assuming that it is the field of complex numbers, we may do this.

We now have

$$\begin{gathered} U = A + B + C \\ V = A(1+k) + B.0 + C(1+k-k') \\ W = Ak' + B(k' - 1 - k) + C.0, \end{gathered}$$

and evidently

$$U(1+k-k') - V + W = 0.$$

so that the points U, V and W are collinear.

The proof is not as elegant as that of the Desargues Theorem, and algebraically we expect this, since it can be shown that the Pappus Theorem is equivalent to the ground field being commutative, and so at some stage of the proof this assumption enters. No such assumption, as we saw, entered into the proof of the Desargues Theorem. Both theorems will appear again later, when we shall have the means to prove them without using algebra (Thm V, §71.2, Exercise 71.5).

Exercises

63.1 In the proof of the Pappus Theorem (Thm III above) we tacitly assumed, in choosing U as unit point with respect to triangle ABC, that U does not lie on any side of ABC. Show that if U does lie on a side of

ABC the initial assumptions of the theorem are invalidated, or the theorem becomes trivial.

63.2 The line *LMN* is the polar line of the point *O* with respect to the triangle *ABC*, and $A'AO \cap BC, B' = BO \cap CA, C' = CO \cap AB$. The point *P* does not lie on a side of the triangle *ABC*, and *AP*, *BP* and *CP* intersect the polar line in the points *F*, *G* and *H* respectively. Prove that the lines *FA'*, *GB'* and *HC'* are concurrent. (With the notation of the preceding Example, p. 254, take *P* as (p, q, r), and show that the equation of the line *FA'* is $(q - r)(X + Y + Z) + 2rq(Y/q - Z/r) = 0$. If the lines *FA'*, *GB'* and *HC'* are $u = 0$, $v = 0$ and $w = 0$ respectively, we have

$$pu + qv + rw = 0.$$

which proves that the lines are linearly dependent, that is, concurrent.)

63.3 *ABC* is a given triangle, and *D*, *E* and *F* are fixed non-collinear points on *BC*, *CA* and *AB* respectively. A variable line through *A* meets *DE* and *DF* in *P* and *Q* respectively. Prove that the intersection *R* of *BP* and *CQ* lies on a fixed line.

63.4 *L*, *M* and *N* are collinear points on the sides *BC*, *CA* and *AB* of a triangle *ABC*, and *A'*, *B'* and *C'* are chosen on *AL*, *BM* and *CN* respectively. *B'C'*, *C'A'* and *A'B'* meet *BC*, *CA* and *AB* respectively in the points *P*, *Q* and *R*. Prove that *A'P*, *B'Q* and *C'R* are concurrent.

63.5 If *ABC* and *DEF* are two coplanar triangles such that *AD*, *BE*, *CF* are concurrent, and also *AE*, *BF*, *CD* are concurrent, prove that *AF*, *BD* and *CE* are concurrent. (With *ABC* as triangle of reference, and the points *D*, *E*, *F* as $(1, p, p')$, $(q', 1, q)$ and $(r, r', 1)$, the first condition gives $pqr = p'q'r'$. Proceed from this result. The problem can also be solved by applying the Pappus Theorem.)

63.6 *D* is a point on the side *BC* of a triangle *ABC*, and *P*, *Q* are points on *AB*. The line *PD* meets *AC* in *H*, the line *QD* meets *AC* in *K*, and *CP* meets *AD* in *M*, while *CQ* meets *AD* in *N*. Prove that *KM* and *HN* meet on *AB*. (This can be proved by using the Pappus Theorem, noting that the line *AB* is also the line *PQ*. For a proof involving only the Desargues Theorem, see Exercise 69.8.)

64.1 Change of triangle of reference

Since we wish to introduce matrix notation, we now switch back to the suffix notation for coordinates. Let *ABC* and *A'B'C'* be two triangles in the projective plane π, and suppose that a point *P* has coordinates (y_0, y_1, y_2) with respect to *ABC* as triangle of reference, and coordinates (y_0', y_1', y_2') with respect to *A'B'C'* as triangle of reference. This means that we may write

$$P = Ay_0 + By_1 + Cy_2 \text{ and } P = A'y'_0 + B'y'_0 + C'y'_2.$$

Now suppose that *A* has coordinates (a_{00}, a_{10}, a_{20}) with respect to triangle *A'B'C'*, so that

$$A = A'a_{00} + B'a_{10} + C'a_{20},$$

and similarly suppose that

$$B = A'a_{01} + B'a_{11} + C'a_{21},$$
$$C = A'a_{02} + B'a_{12} + C'a_{22}.$$

Then

$$\begin{aligned} P &= (A'a_{00} + B'a_{10} + C'a_{20})y_0 + (A'a_{01} + B'a_{11} + C'a_{21})y_1 \\ &\qquad\qquad\qquad\qquad\qquad\qquad + (A'a_{02} + B'a_{12} + C'a_{22})y_2 \\ &= A'(a_{00}y_0 + a_{01}y_1 + a_{02}y_2) + B'(a_{10}y_0 + a_{11}y_1 + a_{12}y_2) \\ &\qquad\qquad\qquad\qquad\qquad\qquad + C'(a_{20}y_0 + a_{21}y_1 + a_{22}y_2) \\ &= A'y_0' + B'y_1' + C'y_2'. \end{aligned}$$

Since A', B' and C' are linearly independent, any linear relation between them must be trivial, with zero multipliers. Hence we may equate the multipliers of A', B' and C' on both sides of our last equation, and we have

$$\begin{aligned} y_0' &= a_{00}y_0 + a_{01}y_1 + a_{02}y_2, \\ y_1' &= a_{10}y_0 + a_{11}y_1 + a_{12}y_2, \\ y_2' &= a_{20}y_0 + a_{21}y_1 + a_{22}y_2. \end{aligned}$$

so that, in matrix form

$$y' = (y_0' + y_1' + y_2')^{\mathrm{T}} = Ay,$$

where $y = (y_0, y_1, y_2)^T$, and $\mathbf{A} = [a_{ij}]$ $(i, j = 0, 1, 2)$.

Of course, an equivalent equation is

$$y'k = Ay \ (k \neq 0),$$

since we are dealing with homogeneous coordinates.

We can make an immediate statement about the square matrix **A.** Since we may also express y in terms of y', *the matrix* **A** *has an inverse*, and the expression of y in terms of y' must be

$$y = A^{-1}y'$$

We have therefore proved

Theorem I *A change of triangle of reference in the projective plane is equivalent to a non-singular linear transformation of coordinates.*

We consider the effect of a change of triangle of reference on the equation of a line. If the equation of a line is $u^0\ Y_0 + u^1\ Y_1 + u^2\ Y_2 = 0$, we saw that we may talk of *line coordinates* $[u^0, u^1, u^2]$, and designate line coordinates by a single symbol $u = [u^0, u^1, u^2]$. Now suppose that the equation of a line is $v^0\ Y_0' + v^1\ Y_1' + v^2\ Y_2' = 0$ in the primed system of coordinates. Then its original equation in the unprimed system was

$$v^0(a_{00}Y_0 + a_{01}\ Y_1 + a_{02}Y_2) + v^1(a_{10}Y_0 + a_{11}Y_1 + a_{12}Y_2) + v_2(a_{20}Y_0 + a_{21}Y_1 + a_{22}Y_2) = 0,$$

that is

$$(v^0a_{00} + v^2\ a_{10} + v^2\mathrm{a}_{20})Y_0 + (v^0a_{01} + v^1a_{11} + v^2a_{21})Y_1 + (v^0a_{02} + v^1a_{12} + v^2a_{22}Y_2) = 0.$$

Hence, if $y' = \mathbf{A}y$ is the matrix transformation of coordinates,

$$[u^0, u^1, u^2] = [v^0, v^1, v^2]\begin{bmatrix} a_{00} & a_{01} & a_{02} \\ a_{10} & a_{11} & a_{12} \\ a_{20} & a_{21} & a_{22} \end{bmatrix}$$

is the matrix transformation between the original and the new line coordinates. Once more, if $y' = \mathbf{A}y$ gives the new point-coordinates y' in terms of the original point-coordinates y, then $u' = u\mathbf{A}^{-1}$ gives the new line-coordinates u' in terms of the original line-coordinates u.

We note that a point is written as a *column*-vector, and a line as a *row*-vector in these computations. Of course, the calculations may be considerably simplified by using matrix notation. The equation of a line is $uy = 0$, and in the new coordinates it is $vy' = 0$. If we substitute $y' = \mathbf{A}y$, the equation becomes $v\mathbf{A}y = 0$, so that $u = v\mathbf{A}$, or if we call the new line coordinates u', then $u = u'\mathbf{A}$, which is the result obtained above, with the working given in detail.

We therefore have

Theorem II *If we change to a new triangle of reference by the non-singular transformation of point coordinates* $y' = \mathbf{A}y$, *then the corresponding transformation in line-coordinates is given by* $u' = u\mathbf{A}^{-1}$.

Example. Let O be a point not on the sides of a triangle ABC. Let $AO \cap BC = A'BO \cap CA = B'$ and $CO'AB = C'$. We have proved in the Example of §63.1 that we may choose the coordinates so that the equation of the line on which the points $L = B'C' \cap BC$, $M = C'C' \cap CA$and $N = A'B' \cap AB$ lie is given by the equation $X_0 + X_1 + X_2 = 0$. We now show that with respect to $A'B'C'$ as triangle of reference, the equation of this line can also be taken as $X_0' + X_1' + X_2' = 0$, and we shall deduce *that O has the same polar line with respect to the triangles ABC* and $A'B'C'$.

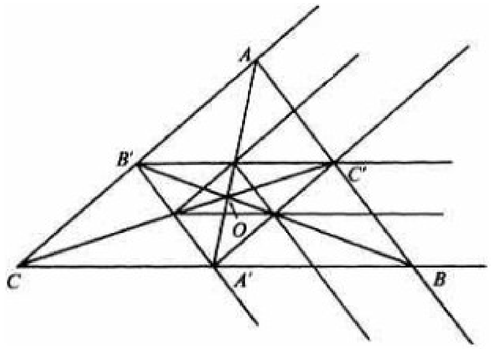

Fig. 64.1

Once again we take O as unit point with respect to triangle ABC (Fig.64.1), so that $A' = (0, 1, 1)$, $B' = (1, 0, 1)$ and $C' = (1, 1, 0)$.

Since A', B' and C' form a proper triangle, we may take $A'B'C'$ as a new triangle of reference, and express the points A, B and C linearly in terms of A', B' and C'. Clearly

$$\begin{aligned}-2A &= (-2,0,0) = (0,1,1) - (1,0,1) - (1,1,0),\\ -2B &= (0,-2,0) = -(0,1,1) + (1,0,1) - (1,1,0),\\ -2C &= (0,0,-2) = -(0,1,1) - (1,0,1) + (1,1,0),\end{aligned}$$

and the above theory tells us that it is the transpose of this matrix, which gives A, B and C in terms of A', B' and C' which is the matrix $\mathbf{A}$ we are looking for. The matrix is symmetric, and it is

$$\mathbf{A} = \begin{bmatrix} 1 & -1 & -1 \\ -1 & 1 & -1 \\ -1 & -1 & 1 \end{bmatrix}.$$

The point $O = (1, 1, 1) = (A' + B' + C')/2$, and so its coordinates are still $(1, 1, 1)$ with respect to the triangle $A'B'C'$. Now let us see what happens to the equation $X_0 + X_1 + X_2 = 0$, which has line coordinates $[1, 1, 1]$. The new line coordinates u' are connected with the original ones by the transformation $u' = [1, 1, 1]\mathbf{A}^{-1}$.

Since so that the new line-coordinates of the polar line may also be taken as $[1, 1, 1]$. But these are the line coordinates of the polar line of O with respect to the triangle $A'B'C'$, since O has coordinates $(1, 1, 1)$ with respect to this triangle. Hence *O has the same polar line with respect to triangles ABC and $A'B'C'$.*

$$\begin{bmatrix} 0 & -1 & -1 \\ -1 & 0 & -1 \\ -1 & -1 & 0 \end{bmatrix}\begin{bmatrix} 1 & -1 & -1 \\ -1 & 1 & -1 \\ -1 & -1 & 1 \end{bmatrix} = 2\begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix},$$

$$u' = [1, 1, 1]\begin{bmatrix} 0 & -1 & -1 \\ -1 & 0 & -1 \\ -1 & -1 & 0 \end{bmatrix} = [-2, -2, -2]$$

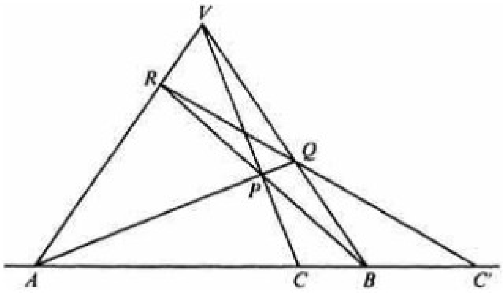

Fig. 64.2

The geometric meaning of this result is left as an exercise for the reader, and the explanation is simple in terms of harmonic ranges and pencils, with which we end this discussion of the projective geometry of the plane, leaving many other important matters to be dealt with later.

64.2 Harmonic ranges

A, B and C are three distinct collinear points, and V is any point not on the line AB. We take any point P on VC distinct from V and from C, and call the intersection of BP and VA the point R and let Q be the intersection of AP and VB. Then if the line QR intersects AB in C', we show that C' depends only on A, B and C, and not on the choice of V and P (Fig.64.2).

In fact, we show that if $C = A + B\lambda$, then $C' = A - B\lambda$.

Since P is on VC, we may write

$$P = C + V\mu = A + B\lambda + V\mu.$$

Therefore

$$P - A = B\mu + V\mu = Q,$$

since the point represented by each term of this equation lies on AP and also on BV. Again

$$P - B\lambda = A + V\mu = \mathrm{R}.$$

Also, C' is on RQ and also on AB, and since

$$R - Q = P - B\lambda - (P - A) = A - B\lambda$$

this must be the point C', so that we have obtained

$$C' = A - B\lambda.$$

We call C' *the harmonic conjugate* of C with respect to A and B. Our algebraic result shows that if we start with C', A and B, and perform the above construction, we arrive at C, since $-(-\lambda) = \lambda$. Hence C and C' are paired, just as A and B are, to start with. But the pairing is in the same sense, since

$$2B\lambda = B = (A+B\lambda) - (A - B\lambda) = C - C'$$

shows that if we begin with C and C' instead of A and B, and B instead of C, the harmonic construction leads to

$$C + C' = (A + B\lambda) + (A - B\lambda) = 2A = A.$$

Hence, *if we say that C and C′ are harmonic conjugates with respect to A and B, we have also proved that A and B are harmonic conjugates with respect to C and C′*. The points A, B and C, C' are said to form *a harmonic range*.

Metrically, we encountered harmonic ranges in §19.1. Points which divide a segment AB internally and externally in the same numerical ratio are harmonic conjugates with respect to A and B. This is indicated by the symbols $A + B\lambda$ and $A - B\lambda$ for C and C'.

There is a dual theory for harmonic pencils, and an important connecting link which asserts that *the range of points given by the intersections of a line with the four rays of a harmonic pencil is a harmonic range*, but we leave the proof of this until §69.1.

Here we remark that the point of intersection, in the construction above, of VC and RQ can be written as $R + Q = 2V\mu + (A + B\lambda)$, and since $R - Q = C'$, this shows that *the harmonic conjugate of* C' with respect to R and Q *is the point* $VC \cap RQ$. Hence, if $BR \cap QC = R'$ and $AQ \cap CR = Q'$, the line $Q'R'$ passes through C'.

We now see why the polar line of O, in the Example of §64.1, with respect to both triangles, ABC and $A'B'C'$, is the same. Another method of proof is indicated in Exercise 64.1.

64.3 Abstract projective planes

As we have already indicated in Exercises 60.7 and 60.8, the concept of *projective plane* can be generalized. Suppose that we have a finite or infinite set S of elements $P_1, P_2, \ldots$ together with a finite or infinite collection of *special subsets* $l_1, l_2, \ldots$ of S, and the concept of *inclusion*. Thus, if P is an element of S which is in a special subset l of S, we shall write $P \in I$. Then an *abstract projective plane* is a set S, which with its special subsets l satisfies the following three properties:

I. If P and Q are any two distinct elements of S, there is a unique special subset l of S such that $P \in I$ and $Q \in I$.

II. If l_1 and l_2 are any two distinct special subsets of S, there is a unique element P of S such that $P \in I_1$ and $P \in I_2$.

III. There are at least four distinct elements of S such that no three of them are elements of a special subset l of S.

In §60.1, these properties were written as Theorems I, II and III, our complex projective plane being a special case of an abstract projective plane. In Exercise 60.7 a finite projective plane with seven points was introduced, the ground field being that of the integers modulo 2, and in Exercise 60.8 it was indicated that once coordinates have been introduced into the real affine plane, further 'ideal' points and lines can be added so that we obtain a projective plane.

The subject of finite projective planes is a most important one. It will not be discussed here. Further discussion can be found in Pedoe (**12**), Chapter V. But we give some Exercises which indicate some consequences of the three axioms which are to be satisfied by the elements (points) and special subsets (lines) of an abstract projective plane.

Exercises

64.1 Prove the result of the Example in §64.1 by considering the triangles ABC and $A'B'C'$ as perspective triangles, and then the triangles $A'B'C'$ and $A''B''C''$ as perspective triangles, where $A'' = B'C' \cap AA'$,$B'' = C'A' \cap BB'$and $C'' = A'B' \cap CC'$.

64.2 Show that if we have a harmonic range A, B, $A + B\lambda$, $A - B\lambda$ referred to one system of coordinates, and with respect to another triangle of reference A becomes A' and B becomes B', then $A + B\lambda$ becomes $A' + B'\lambda$ and $A - B\lambda$ becomes $A' - B'\lambda$.

64.3 If A, B, C, D are four points in a plane, no three of which are collinear, prove that their coordinates a, b, c, d may be so chosen that $a + b + c + d = 0$. If $P = AB \cap CD$,$Q = AC \cap BD$ and $R = AD \cap BC$, so that P, Q and R are the diagonal points of the quadrangle formed by A, B, C and D, show that the coordinates p, q and r of P, Q and R satisfy the equations

$$\begin{aligned} p &= a + b = -c - d, \\ q &= a + c = -b - d, \\ r &= a + d = -b - c. \end{aligned}$$

64.4 Deduce from the preceding Exercise that any two diagonal points of a complete quadrangle are harmonic conjugates with respect to the points in which their join meets the two sides of the quadrangle which do not contain the two diagonal points.

64.5 State and prove the dual theorems corresponding to the two preceding Exercises.

64.6 OA, OB, OC are given lines. Variable lines MPQ, $MP'Q'$ meet OA in M, OB in P, P' and OC in Q, Q'. Finally PQ' meets $P'Q$ in R. Prove that R lies on a fixed line.

64.7 Let the diagonal triangle of a complete quadrangle be LMN, and let P be a given point in the plane. Prove that the harmonic conjugates of LP, MP and NP relative to the pairs of opposite sides of the quadrangle which meet in L, M and N respectively are concurrent.

64.8 ABC is a triangle, and P, Q are given points. A', B' and C' are the harmonic conjugates relative to P, Q of the points in which PQ meets BC, CA and AB respectively. Prove that AA', BB' and CC' are concurrent.

64.9 Consider the non-singular linear mapping given by the equations

$$(X_0', X_1', X_2') = (3X_0 - X_1 + 2X_2, -2X_0 - 2X_1 - 2X_2, 2X_0 - X_1 + 3X_2),$$

and let the transforms of P and Q be P' and Q'. Prove that PP' passes through the point $(1, -1, 1)$, that the line PP' is mapped onto itself, and that the lines PQ and $P'Q'$ intersect on the line $2X_0 - X_1 + 2X_2 = 0$.

64.10 Prove that in an abstract projective plane at least three points lie on every line, and at least three lines pass through every point.

64.11 A tennis match is played between two teams, each player playing one or more members of the other team. We are told that:

(i) any two members of the same team have exactly one opponent in common,

(ii) no two members of the same team play all the members of the other team between them. Prove that two players who do not play each other have the same number of opponents. Deduce that any two players, whether in the same or different teams, have the same number of opponents.

64.12 Let $n \geq 2$ be any integer, and suppose that we are considering an abstract projective plane with a finite number of points. Show that the following properties are equivalent:

(1) One line contains exactly $n + 1$ points.

(2) One point is on exactly $n + 1$ lines.

(3) Every line contains exactly $n + 1$ points.

(4) Every point is on exactly $n + 1$ lines.

(5) There are exactly $n^2 + n + 1$ points.

(6) There are exactly $n^2 + n + 1$ lines.

65.1 Projective space of three dimensions

We now introduce homogeneous coordinates into what we call a *three-dimensional projective space*. We consider a four-dimensional vector space V_4 over the complex field, and define *a point of three-dimensional projective space*, which we shall call S_3, to be *a ray*, which arises from *a vector* of V_4. That is, a point of S_3 is to be the equivalence class (y_0k, y_1k, y_2k, y_3k) $(k \neq 0)$, where $y = (y_0, y_1, y_2, y_3)$ is *a non-zero vector* of V_4.

Once again, linear dependence of points in S_3 is defined in the obvious way, and the points in S_3 linearly dependent on two distinct points of S_3 determine a line. If y and z are any representatives of the two points, the set of points $y\lambda + z\mu$ determine a line which contains the two points. But now that we obtain S_3 from a V_4, we may consider the set of points linearly dependent on three points, not already linearly dependent, which means that they are not collinear. If the points be denoted by the symbols y, z and t, the set is $y\lambda + z\mu + t\nu$, and we say this set of points determines *a plane* in S_3, the plane (yzt).

In V_4 there are sets of four independent vectors, but any five vectors are dependent. Hence in S_4 there are sets of four independent points, but any set of five points is a dependent set. Suppose that we now let A, B, C, D and E be the symbols for five points in S_3. Then we have a relation

$$Aa + Bb + Cc + Dd + Ee = 0,$$

where not all of the multipliers are zero. If we now write

$$Aa + Bb + Cc= -Dd - Ee,$$

the left-hand side represents a point in the plane ABC, and the right-hand side a point on the line DE. Hence we have one of the Propositions of Incidence in S_3:

A plane either contains a given line, or intersects it in one point.

Suppose now that we have two distinct planes, the one defined by the points A, B, C and the other by the points D, E, and F. Then the line DE either lies in the plane ABC or intersects it in a point, and the line EF either lies in the plane ABC or intersects it in a point. Since the planes are distinct, we do not have both lines, DE and EF in the plane ABC. If one of these lines lies in the plane ABC, the two planes ABC and DEF already intersect in a line. If neither lies in the plane ABC, we have two points in the plane DEF which lie in the plane ABC, and therefore the line joining the two points lies in ABC. Hence

Two planes which are distinct always intersect in the points of a line.

We note that there are no exceptions to the Propositions of Incidence in S_3, since planes are never parallel.

We have not written all the Propositions of Incidence in a form which would indicate that the Principle of Duality (§60.2) also applies to S_3. It does, of course, but in S_3 the fundamental interchange is between point and plane. Algebraically this is seen as soon as we show that a plane can also be given by homogeneous coordinates. If

$$(X_0,X_1,X_2,X_2,X_3) = (a_0,a_1,a_2,a_3)\lambda + (b_0,b_1,b_2,b_3)\mu + (c_0,c_1,c_2,c_3,)\nu,$$

the elimination of the parameters λ, μ, and ν leads to the determinantal equation

$$\begin{vmatrix} X_0 & X_1 & X_2 & X_2 \\ a_0 & a_1 & a_2 & a_3 \\ b_0 & b_1 & b_2 & b_3 \\ c_0 & c_1 & c_2 & c_3 \end{vmatrix} = 0,$$

which is of the form

$$u^0X_0 + u^1X_1 + u^2X_2 + u^3X_3 = 0,$$

a homogeneous linear equation. Hence a plane can be assigned homogeneous coordinates $[u^0, u^1, u^2, u^3]$, and belongs to an equivalence class $k[u^0, u^1, u^2, u^3]$ $(k \neq 0)$. Two distinct planes intersect in a unique line, and the equation of a line is often given by the assignment of two distinct planes which contain it. We may use matrix notation, and write the equation of a plane as

$$uX = 0,$$

where $u = [u^0, u^1, u^2, u^3]$ and $X = (X_0, X_1, X_2, X_3)^T$, so that once again we write *plane-coordinates* as *row-vectors* and *point-coordinates* as *column-vectors*. Then the equation of a line may be written

$$uX = 0 = vX$$

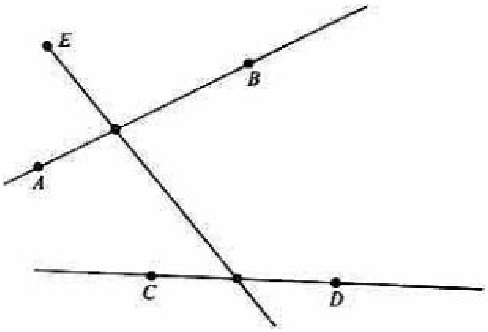

Fig. 65.1

where u and v are two distinct planes through the line.

The condition that a given plane u should contain a given point x is

$$uX = 0,$$

and this is a symmetrical relation between the plane-coordinates u and the point-coordinates x. Hence we have a Principle of Duality for S_3, in which *point* and *plane* and *plane* and *point* are interchanged. Since a line is determined by two points, and also by two planes, *lines remain unchanged* in the transliteration which produces a dual theorem from a given theorem.

We may prove easily, or regard the Proposition as an application of the Principle of Duality, that since three distinct points determine a unique plane, provided the points are linearly independent, so *three distinct planes determine a unique point*, provided they are linearly independent, *which lies in each of them*.

We consider some applications of the Propositions of Incidence.

(*a*) From a point which does not lie on either of two skew (non-intersecting) lines in S_3 one and only one line can be drawn to intersect each line. (Such a line is called a *transversal* of the two lines).

Take points A, B on one line, and C, D on the other (Fig.65.1), and let E be the symbol for the given point. Since five points are always linearly dependent, we have a relation

$$Aa + Bb + Cc + Dd + Ee = 0$$

between the symbols for the five points, where not all of a, b, c, d and e are zero. Writing this as

$$-Ee = (Aa + Bb) + (Cc + Dd),$$

we see that the point E is collinear with the point $Aa + Bb$ on the one line and the point $Cc + Dd$ on the other.

If there were two distinct transversals to the two lines, through E, the two lines would lie in the plane determined by the two transversals, which intersect at E, and therefore the given lines, being coplanar, would intersect, whereas we are told that they are skew.

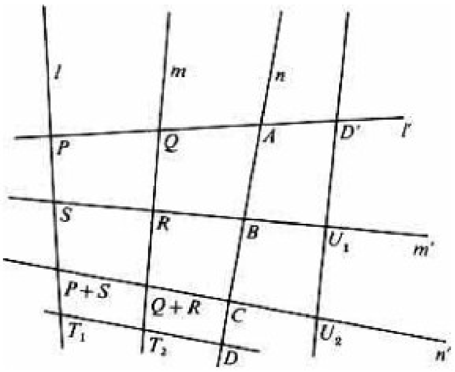

Fig. 65.2

Another way of obtaining this result is suggested in Exercise 65.2.

(*b*) We investigate the set of lines which are transversal to *three* given mutually skew lines in S_3 (Fig.65.2). Let l, m and n be mutually skew lines, and draw the transversals l', m' and n' from three distinct points A, B and C lying on n to l and m. From the point D on n, distinct from A, B and C, we draw a fourth transversal to l and m, and from D', any point on l' which is not on l, m or n we draw the unique transversal to m' and n'. We prove that, subject to certain conditions, the transversal from D to l and m intersects the transversal from D' to m' and n'.

We take the four points shown in the diagram as base-points, P, Q, R and S. They are independent, since dependence would involve l and m being coplanar, and we have assumed that they are skew. By the Normalization Theorem, §62.1, we may choose $A = P + Q$, where $A = n \cap l'$, and $B = R + S$, where $B = n \cap m'$. With A and B determined except for a multiplying constant, we may also choose $C = A + B$, where $C = n \cap n'$. (This possibility should be examined carefully.) We then take $D = A + B\lambda$, for some λ, and $D' = P + Q\mu$, for some μ, where D is the point chosen on n distinct from A, B and C, and D' is the point chosen on l' distinct from A, P and Q.

Since $C = A + B = P + Q + R + S = (P + S) + (Q + R)$, the transversal from C to l and m intersects these lines at the points $P + S$ and $Q + R$ respectively. Similarly $D = A + B\lambda = P + Q + (R + S)\lambda = (P + S\lambda) + (Q + R\lambda)$, and therefore the transversal from D to l and m intersects these lines in the points $T_1 = P + S\lambda$ and $T_2 = Q + R\lambda$.

Finally, we note that $D' = P + Q\mu = -(S + R\mu) + (P + S) + (Q + R)\mu$, and therefore the transversal from D' to m' and n' intersects these lines in the points

$$U_1 = -(S + R\mu) \text{ and } U_2 = (P + S) + (Q + R)\mu.$$

We have now obtained the coordinates of the points we are considering. We wish to show that there is a point on the line U_1U_2 which is the same point as one on the line T_1T_2: that is, we require that for some values of v, v' and k,

$$\begin{aligned}(T_1 + T_2\nu)k = [(P + S\lambda) + (Q + R\lambda)\nu]k &= U_2 - U_1\nu' \\ &= (P + S) + (Q + R)\mu + (S + R\mu)\nu'.\end{aligned}$$

Since P, Q, R and S are independent, the multipliers of P, Q, R and S on each side of this equation are proportional, and therefore

$$1 : v : \lambda\ v\lambda = 1 : \mu : \mu + \mu v' : 1 + v'$$

are equations to be solved, if possible, for v and v'. Taking $v = \mu$, then we want both

$$\lambda\mu = \mu + \mu v'$$

and

$$\lambda = 1 + v'$$

If we assume commutativity for our multipliers, we have

$$\lambda\mu = \mu\lambda = \mu + \mu v'\ \mu[\lambda - (1 + v')] = 0,$$

and since $\mu \neq 0$, we may take

$$v' = \lambda - 1,$$

and the final equation is also satisfied.

In this case the point of intersection of the transversals through D and D' is

$$\begin{aligned}T_1 + T_2\nu &= (P + S\lambda) + (Q + R\lambda)\nu \\ &= P + Q\nu + R\nu\lambda + S\lambda \\ &= P + Q\mu + R\mu\lambda + S\lambda,\end{aligned}$$

so that the coordinates of the point may be taken as

$$(y_0, y_1, y_2, y_3) = (1, \mu, \mu\lambda, \lambda)$$

and this always lies on the surface

$$X_1X_3 - X_0X_2 = 0.$$

Such a surface is called *a quadric surface*, and it is one of the fundamental constructs in S_3. We shall investigate quadric surfaces in more detail in §81.1.

We remark that the surface contains two systems of *generators*, or lines which lie in the surface, one system containing the lines l, m and n, and the other containing the lines l', m' and n'. The lines in a system are mutually skew, but any line in one system intersects any line in the other system. The reader is asked to prove this result in Exercise 65.5.

We have already mentioned that the assumption of commutativity of our coordinates is equivalent to the assumption of the Pappus Theorem, and in some texts the intersection of the lines $U_1\ U_2$ and T_1T_2 is derived directly from that theorem [Baker, (2), Vol. 1]. Another proof is suggested in Exercises 71.16, 17, 18, using the Fundamental Theorem of Projective Geometry, which is also equivalent to the Pappus Theorem. This theorem is proved in §71.1.

65.2 Moebius tetrahedra

Theorem *If two tetrahedra $ABCD$, $A'B'C'D'$ are such that $A' \in (BCD)$,$B' \in (CDA)$,$C' \in (DAB)$,$D' \in (ABC)$ so that the first tetrahedron is* escribed *to the second), and also $A \in (B'C'D')$,$B \in (C'D'A')$ and $C \in (D'A'B')$, then necessarily $D \in (A'B'C')$.*

Such mutually inscribed and escribed tetrahedra are called *Moebius* tetrahedra, after their discoverer. They are a surprising phenomenon, since it is not possible in S_2 to have two triangles which are mutually inscribed and escribed (Exercise 65.7). We leave the proof of the theorem as stated for an Exercise (65.6), and demonstrate the existence of Moebius tetrads by remarking that if we take $ABCD$ as tetrad of reference, and

$$\begin{gathered}A' = (0, q_1, r_1, s_1)\\ B' = (-q_1, 0, r_2, s_2)\\ C' = (-r_1, -r_2, 0, s_3)\\ D' = (-s_1, -s_2, s_3, 0)\end{gathered}$$

then we have a tetrad which is inscribed in $ABCD$. To show that it is also escribed, we have to show that the plane $A'B'C'$ contains the point $D = (0, 0, 0, 1)$, the plane $B'C'D'$ contains the point $A = (1, 0, 0, 0)$, the plane $C'D'A'$ contains the point $B' = (0, 1, 0, 0)$, and the plane $D'A'B'$ the point $C' = (0, 0, 1, 0)$. If we prove that the plane $A'B'C'$ contains D, this will indicate the method. Since $(0, q_1, r_1, s_1)r_2 - (-q_1, 0, r_2, s_2)r_1 + (-r_1, -r_2, 0, s_3)q_1 = (0, 0, 0, k)$, where $k = s_1r_2 - s_2r_1 + s_3q_1$, this is so. We also remark that the matrix of entries for A', B', C', D' is skew-symmetric. Another proof of our last result arises from the theorem that the determinant of a skew-symmetric matrix of odd order is zero. We shall see in §85.4 that Moebius tetrads and skew-symmetric matrices are linked.

This section on S_3 has been kept short since we shall obtain results in S_n, projective space of n dimensions, which naturally apply to the case $n = 3$, and the methods are not essentially different. The Exercises which follow indicate what a fuller treatment of the case $n = 3$ would imply. We must stress a point which is often not clear to students when the properties of S_3 are first studied: a line in S_3 is not different from a line in S_2, and a plane in S_3 is a projective plane, so that properties in S_2 continue to hold in any plane in S_3. For example, if we have any three distinct collinear points in S_3, which we denote by A, B and C, and if $C = A + B\lambda$, then the harmonic conjugate of C with respect to A and B can be constructed, as in §64.2, in any plane which contains the line ABC, and we find that the harmonic conjugate $C' = A - B\lambda$, and therefore it is independent of the particular plane chosen through the line.

Exercises

65.1 Show that in S_3 a plane is determined by the assignment of a point and a line which does not contain the point, if the plane is to contain both the point and the line. Show also that two intersecting lines determine a plane, which is to contain them.

65.2 Give another proof that from a point which does not lie on either of two skew lines in S_3 there is a unique transversal to the two lines, by considering the intersection of the one line with the plane defined by the point and the other line.

65.3 State and prove a Normalization Theorem for five points A, B, C, D and E in S_3, where E does not lie in any face of the tetrahedron formed by A, B, C and D.

65.4 Show that in Fig. 65.2 the point C does not lie in any face of the tetrahedron formed by P, Q, R and S, so that, by the Normalization Theorem, we could have taken $C = P + Q + R + S$ to start with, and then deduced that $A = P + Q$ and $B = R + S$, since there is a unique transversal through C to the lines l' and m'.

65.5 Show that the quadric surface $X_1X_3 - X_0X_2 = 0$ contains the line of intersection of the two planes $\lambda X_1 - X_2 = 0 = \lambda X_0 - X_3$ for any value of λ, and the line of intersection of the two planes $\mu X_0 - X_1 = 0 = X_2 - \mu X_3$ for any value of μ. If we call the first set of lines the λ-system, and the second set the μ-system, show that the λ-system consists of mutually skew lines, as does the μ-system, but that every line of the λ-system intersects every line of the μ-system. Finally, show that the point of intersection of a line of the λ-system and a line of the μ-system is the point $(1, \mu, \mu\lambda, \lambda)$ of the surface. Do any more lines in the surface pass through this point?

65.6 Prove the theorem on Moebius tetrads of §65.2. (Begin with A' as given, and show that if we take $B' = (-q_1, 0, r_2, s_2)$, $C' = (-r_1, q_3, 0, s_3)$, and $D' = (-s_1, q_4, r_4, 0)$, as we may, then we obtain $q_3 = -r_2$, $r_4 = -s_3$ and $q_4 = -s_2$, so that $(A'B'C')$ contains D.)

65.7 Show that it is impossible to find two proper triangles in S_2 which are mutually inscribed and escribed.

65.8 AB, CD are given skew lines in S_3. The transversal of AB, CD through a variable point P meets AB, CD in R, S. The point P' is the harmonic conjugate of P with respect to R, S. Find the locus of P' if P moves on (i) a given plane, (ii) a given line.

65.9 If ABC, $A'B'C'$ are two triangles in S_3, which are not coplanar, and the lines AA', BB' and CC' are concurrent at a point V (so that the triangles are perspective from a point), show that the points $BC \cap B'C'$,$CA \cap C'A'$ and $AB \cap A'A'B'$ exist and are collinear, using only the Propositions of Incidence.

65.10 Prove the converse of the Desargues Theorem in S_3, that if two non-coplanar triangles are perspective from a line, then they are also perspective from a point.

65.11 Given five mutually skew lines p, a, b, c, d in S_3, a transversal is drawn to a and c from a point P on p, intersecting a in A and c in C, and another transversal is drawn to b and d, intersecting b in B and d in D. Prove that the intersection Q=$AB \cap CD$ of AB and CD describes a line as P describes p.

65.12 Show that a change of tetrad of reference in S_3 is equivalent to a non-singular transformation $y' = \mathbf{A}y$ between coordinates. Show that plane-coordinates change in the manner indicated by the matrix equation $u = u'\mathbf{A}$, where $y' = \mathbf{A}y$ is the relation between point-coordinates.

65.13 Restate the Normalization Theorem (Exercise 65.3) as a theorem on non-singular linear transformations in S_3.

65.14 Let A_i (i = 1, 2, 3, 4) be a tetrad of points in S_3 which are not coplanar. If P be any given point, and PA_1 meet the plane $A_2A_3A_4$ in the point P_1, let P_1' be the harmonic conjugate of P with respect to the points A_1 and P_1. Let us write $PT_1 = P_1'$, where the transformation T_1 is called *harmonic homology* (see §39.1). Show that T_1 is represented by a non-singular matrix. Prove further that if T_2, T_3 and T_4 be defined in a similar way,

$$(P)T_1T_2T_3T_4 = P.$$

(Compare Exercise 25.3, and the link to this Exercise provided by §39.1.)

65.15 If A, B, C and D be four non-coplanar points in S_3, and

$$P = Ax_0 + Bx_1 - Cx_2 - Dx_3$$

show that the harmonic conjugate of P with respect to the pair of points in which the transversal from P to AB and CD intersects them is

$$P' = Ax_0 + Bx_1 - Cx_2 - Dx_3$$

and that the relation between P and P' is represented by a non-singular matrix. What can we say about the square of this matrix?

65.16 $ABCD$ is a tetrahedron, A' an arbitrary point not lying in a face. The transversal is drawn from A' to AB, CD, and B' is the harmonic conjugate of A' with respect to the intersections of this transversal with AB and CD. Points C' and D' are defined similarly, with regard to AC and BD and AD and BC. Prove that the two tetrads $ABCD$, $A'B'C'D'$ are such that each edge of either meets a pair of opposite edges of the other, and is divided harmonically by them.

Prove also that AA', BB', CC' and DD' meet in a point A'', that AB', BA', CD' and DC' meet in a point B'', that AC', BD', CA', DB' meet in a point C'', and that AD', BC', CB', DA' meet in a point D''. Finally, show that the three tetrads $ABCD$, $A'B'C'D'$ and $A''B''C''D''$ form a completely symmetrical system, in the sense that the edge of any one of the tetrads meets a pair of opposite edges of each of the others and is divided harmonically by them. (Such a set of tetrahedra is called a *desmic* system. Begin with $A' = A + B + C + D$, and then $B' = (A + B) - (C + D)$, *etc.* The solution is shorter than the enunciation of the problem! For a real, and simple model of a set of desmic tetrads, see Exercise 88.6.)

65.17 π and π' are distinct planes in S_3, and V is a point not in either plane, W a distinct point not in either plane. The points P in π' are projected into points Q in π from V, and into points Q' in π from W,($VP \cap$

$\pi = Q, WP \cap \pi = Q'$) Show that the mapping $Q \rightarrow Q'$ in π is a collineation, that the joins of corresponding points, QQ', pass through a fixed point, and that the intersection of corresponding lines, $m \cap m'$, where m' is the map of m, always lies on a fixed line. After doing this geometrically (without the use of coordinates) set up the equations for the collineation $Q \rightarrow Q'$ in π, and verify your results.

11

The Axiom on Parallels

Euclidean geometry is distinguished from neutral geometry by one axiom, one that describes the nature of parallel lines. There are many formulations of the parallel axiom for Euclidean geometry, but the one that gets right to the heart of the matter is *Playfair's axiom*, named after the Scottish mathematician John Playfair.

> *(Playfair's axiom) Let ℓ be a line, and let P be a point that is not on ℓ. Then there is exactly one line through P that is parallel to ℓ.*

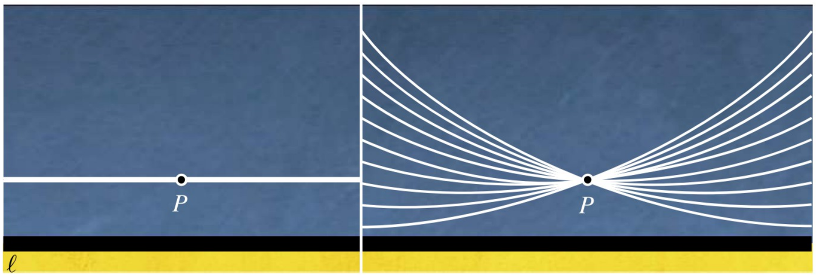

Figure 1. On the left, Euclidean geometry: a single line through P parallel to ℓ. On the right, more than one line through P parallel to ℓ.

In this chapter, we look at a small collection of theorems that are almost immediate consequences of Playfair's axiom, and as such are at the very core of Euclidean geometry. The first of these is Euclid's fifth postulate. This is the controversial postulate in the *Elements*, but also the one that guarantees the same parallel behavior that Playfair's axiom provides. Euclid's fifth is a little unwieldy, particularly when compared to Playfair's axiom, but it is the historical impetus for much of what followed. So let's use Playfair's axiom to prove Euclid's fifth postulate.

Theorem 11.1 *(Euclid's fifth postulate) If lines ℓ_1 and ℓ_2 are crossed by a transversal t, and the sum of adjacent interior angles on one side of t measure less than 180°, then ℓ_1 and ℓ_2 intersect on that side of t.*

Proof First some labels.

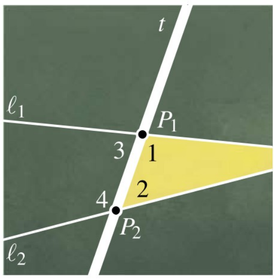

Figure 2. The labels.

Start with lines ℓ_1 and ℓ_2 crossed by transversal t. Label P_1 and P_2, the points of intersection of t with ℓ_1 and ℓ_2 respectively. On one side of t, the two adjacent interior angles should add up to less than 180°. Label the one at P_1 as $\angle 1$ and the one at P_2 at $\angle 2$. Label the supplement of $\angle 1$ as $\angle 3$ and label the supplement of $\angle 2$ as $\angle 4$.

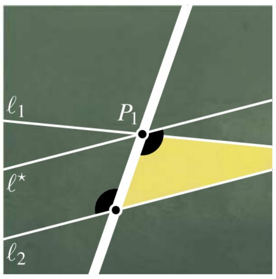

Figure 3. Constructing the unique parallel.

This theorem asserts that the lines intersect, and says where the intersection occurs. We will tackle those two statements in that order. Note that $\angle 1$ and $\angle 4$ are alternate interior angles, but they are not congruent: if they were, their supplements $\angle 2$ and $\angle 3$ would be too, and then

$$(\angle 1) + (\angle 2) = (\angle 1) + (\angle 3) = 180^\circ.$$

There is, however, another line $\ell^\star$ through P_1 that forms an angle congruent to $\angle 4$ (because of the angle construction axiom), and by the alternate interior angle theorem, $\ell^\star$ must be parallel to ℓ_2. Because of Playfair's axiom, $\ell^\star$ is the only parallel to ℓ_2 through P_1. Therefore ℓ_1 intersects ℓ_2.

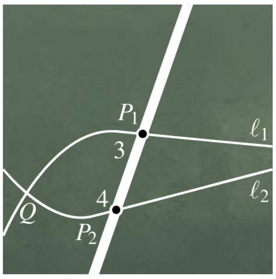

Figure 4. An impossible triangle on the wrong side of t.

The second part of the proof is to figure out on which side of t that ℓ_1 and ℓ_2 cross. Let's see what would happen if they intersected at a point Q on the wrong side of t, the side with $\angle 3$ and $\angle 4$. Then $\triangle P_1P_2Q$ would have two interior angles, $\angle 3$ and $\angle 4$, whose measures add up to more than 180°. This would violate the Saccheri-Legendre theorem. So ℓ_1 and ℓ_2 cannot intersect on the side of t with $\angle 3$ and $\angle 4$ and so they must intersect on the side with $\angle 1$ and $\angle 2$.

□

One of the truly useful theorems of neutral geometry is the alternate interior angle theorem. In fact, we just used it in the last proof. You may recall from high school geometry that the converse of the theorem is often even more useful. The problem is that the converse of the alternate interior angle theorem can't be proved using just the axioms of neutral geometry. It depends on the Euclidean behavior of parallel lines.

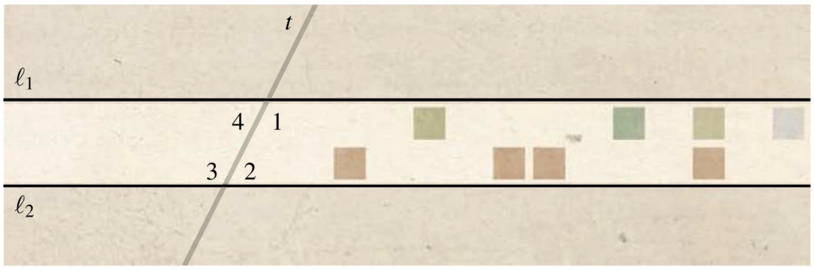

Figure 5. The converse of the alternate interior angle theorem: if $\ell_1 \parallel \ell_2$, then $\angle 1 \simeq \angle 3$ and $\angle 2 \simeq \angle 4$.

Theorem 11.2 *(Converse of the alternate interior angle theorem) If ℓ_1 and ℓ_2 are parallel, then the pairs of alternate interior angles formed by a transversal t are congruent.*

Proof Consider two parallel lines crossed by a transversal. Label adjacent interior angles: $\angle 1$ and $\angle 2$, and $\angle 3$ and $\angle 4$, so that $\angle 1$ and $\angle 4$ are supplementary and $\angle 2$ and $\angle 3$ are supplementary. That means that the pairs of alternate interior angles are $\angle 1$ and $\angle 3$, and $\angle 2$ and $\angle 4$. Now, we just have to do a little arithmetic. From the two pairs of supplementary angles:

(i): $(\angle 1) + (\angle 4) = 180^\circ$
(ii): $(\angle 2) + (\angle 3) = 180^\circ$.

Adding all four angles together,

$$(\angle 1) + (\angle 2) + (\angle 3) + (\angle 4) = 360^\circ.$$

Now we turn to Euclid's fifth postulate, or rather its contrapositive. The lines ℓ_1 and ℓ_2 are parallel, which means that they do not intersect on either side of t. Therefore Euclid's fifth says that on neither side of t may the sum of adjacent interior angles be less than 180°:

- $(\angle 1) + (\angle 2) \geq 180^\circ$
- $(\angle 3) + (\angle 4) \geq 180^\circ$.

If either sum was greater than 180°, though, the sum of all four angles would have to be more than 360°. We saw above that is not the case, so the inequalities are actually equalities:

(iii): $(\angle 1) + (\angle 2) = 180^\circ$
(iv): $(\angle 3) + (\angle 4) = 180^\circ$.

Now we have two systems of equations with four unknowns, and it is basic algebra from here. Subtract *(iv)* from *(i)* to get

$$(\angle 1) - (\angle 3) = 0 \implies (\angle 1) = (\angle 3).$$

Subtract *(i)* from *(iii)* to get

$$(\angle 2) - (\angle 4) = 0 \implies (\angle 2) = (\angle 4).$$

Therefore the alternate interior angles are congruent. □

One of the key theorems we proved in the neutral geometry section was the Saccheri-Legendre theorem: that the angle sum of a triangle is at most 180°. That is all you can say

with the axioms of neutral geometry, but in a world with Playfair's axiom and the converse of the alternate interior angle theorem, we can make a more bold statement about angle sums of triangles.

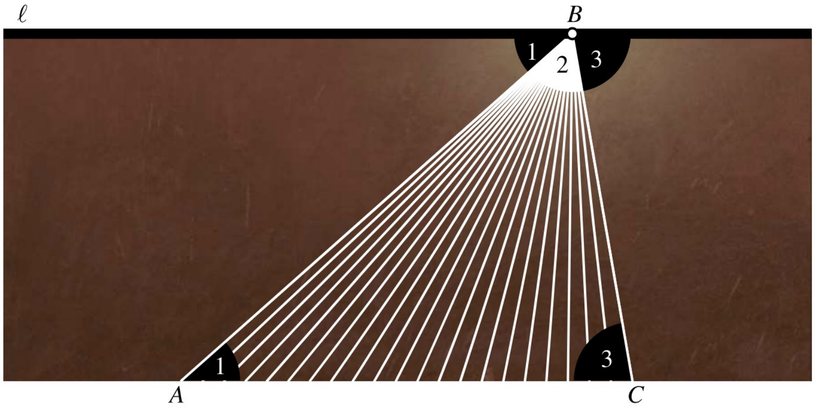

Figure 6. Use the converse of the alternate interior angle theorem to find the angle sum of a triangle.

Theorem 11.3 *The angle sum of a triangle is* 180°.

Proof Given $\triangle ABC$, by Playfair's axiom, there is a unique line ℓ through B that is parallel to $\overline{AC}$. That line and the rays $\overrightarrow{BA}$ and $\overrightarrow{BC}$ form three angles, $\angle 1$, $\angle 2$, and $\angle 3$ as shown in figure 6. By the converse of the alternate interior angle theorem, two pairs of alternate interior angles are congruent: $\angle 1 \simeq \angle A$ and $\angle 3 \simeq \angle C$. Therefore, the angle sum of $\triangle ABC$ is

$$s(\triangle ABC) = (\angle A) + (\angle B) + (\angle C) = (\angle 1) + (\angle 2) + (\angle 3) = 180^\circ. \qquad \square$$

So, the three angles in an equilateral triangle all measure 60° and the measures of the two acute angles in a right triangle must add up to 90°.

In the last chapter on quadrilaterals we talked a little bit about the uncertain status of rectangles in neutral geometry, saying that it is easy to make a convex quadrilateral with three right angles, but that once you have done that, there is no guarantee that the fourth angle will be a right angle. Here it is now in the Euclidean context:

Theorem 11.4 *Let* $\angle ABC$ *be a right angle. Let* r_A *and* r_C *be rays so that* r_A *has endpoint* A*, is on the same side of* $\overline{AB}$ *as* C*, and is perpendicular to* $\overline{AB}$*;* r_C *has endpoint* C*, is on the same side of* $\overline{BC}$ *as* A*, and is perpendicular to* $\overline{BC}$*. Then* r_A *and* r_C *intersect at a point* D*, and the angle formed at this intersection,* $\angle ADC$*, is a right angle. Therefore* $\square ABCD$ *is a rectangle.*

Proof First we need to make sure that r_A and r_C intersect. Let ℓ_A and ℓ_C be the lines containing r_A and r_C respectively. By the alternate interior angle theorem, the right angles at A and B imply that ℓ_A and $\overline{BC}$ are parallel. So $\overline{BC}$ is the one line parallel to ℓ_A through C, and that implies that ℓ_C cannot be parallel to ℓ_A: it has to intersect ℓ_A. Let's call that point of intersection D. This

theorem claims that it is the rays, not the lines, that intersect. Therefore we need to rule out the possibility that the intersection of ℓ_A and ℓ_C might happen on one (or both) of the opposite rays. Since ℓ_A is parallel to $\overline{BC}$, all the points of ℓ_A are on the same side of $\overline{BC}$ as A. None of the points of r_C^{op} is on that side of BC, so D cannot be on r_C^{op}. Likewise, all the points of ℓ_C are on the same side of $\overline{AB}$ as C. None of the points of r_A^{op} is on that side of AB, so D cannot be on r_A^{op}.

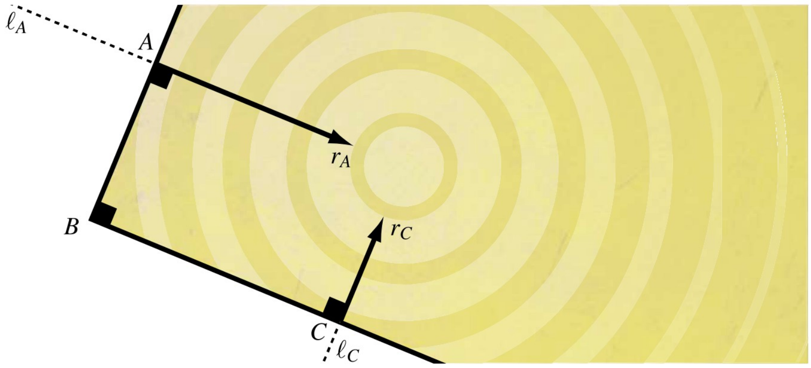

Figure 7. Constructing a rectangle.

So now $\square ABCD$ has three right angles, $\angle A$, $\angle B$, and $\angle C$. It is actually a convex quadrilateral too (verifying this is left as an exercise), so the diagonal AC divides $\square ABCD$ into two triangles $\triangle ABC$ and $\triangle ADC$ (see figure 8). Then, since the angle sum of a triangle is 180°,

$$\begin{gathered}
s(\triangle ABC) + s(\triangle ADC) = 180^\circ + 180^\circ \\
(\angle CAB) + (\angle B) + (\angle ACB) + (\angle CAD) + (\angle D) + (\angle ACD) = 360^\circ \\
(\angle A) + (\angle B) + (\angle C) + (\angle D) = 360^\circ \\
90^\circ + 90^\circ + 90^\circ + (\angle D) = 360^\circ \\
(\angle D) = 90^\circ.
\end{gathered}$$

Therefore $\angle D$ is a right angle. □

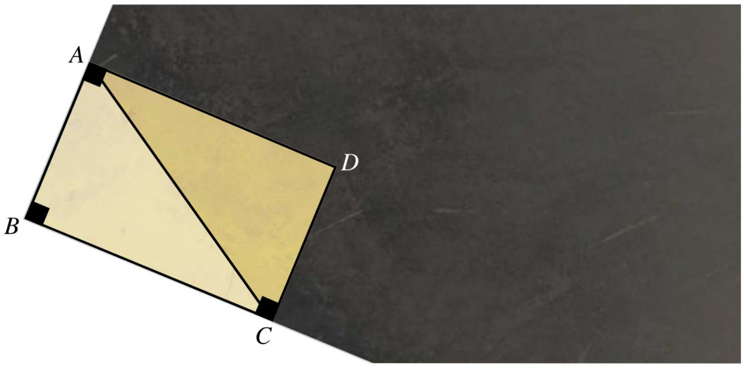

Figure 8. Verifying that the fourth angle is right.

Exercise 11.1 Fill in the gap in the proof by explaining why $\square ABCD$ must be convex.

We see then that, yes, rectangles exist in Euclidean geometry. Two essential properties of rectangles are provided in the following (easy) exercises.

Exercise 11.2 Let $\square ABCD$ be a rectangle. Prove that $\overline{AB}$ is parallel to $\overline{CD}$ and $\overline{AD}$ is parallel to $\overline{BC}$.

Exercise 11.3 Let $\square ABCD$ be a rectangle. Prove that $AB \simeq CD$ and $AD \simeq BC$ and $AC \simeq BD$.

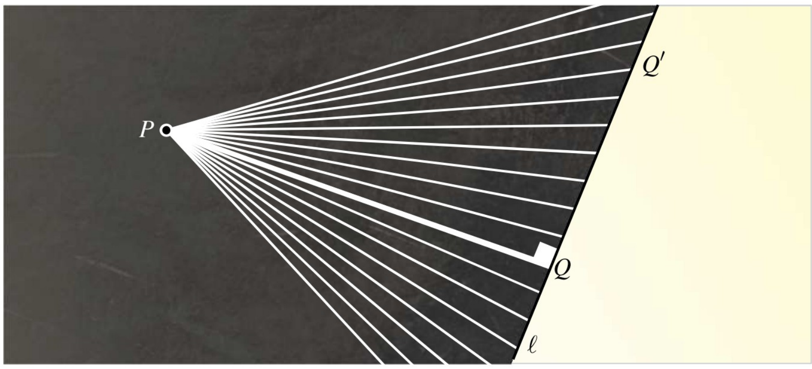

Figure 9. The distance from P to ℓ is measured along the segment from P to ℓ that is perpendicular to ℓ.

For the last result of this section, we return to parallel lines. One of the things that we will see when we study non-Euclidean geometry is that parallel lines tend to diverge from each other. That doesn't happen in Euclidean geometry. This is one of the key differences between the two geometries. Let's make this more precise. Suppose that P is a point that is not on a line ℓ. Define the distance from P to ℓ to be the minimum distance from P to a point on ℓ:

$$d(P,\ell) = \min \left\{ |PQ| \;\middle|\; Q \text{ is on } \ell \right\}.$$

Exercise 11.4 Prove that the minimum actually occurs when Q is the foot of the perpendicular to ℓ through P (this can be proved using solely the axioms of neutral geometry).

For a pair of parallel lines, that distance as measured along perpendiculars does not change.

Theorem 11.5 *If ℓ and ℓ' are parallel lines, then the distance from a point on ℓ to ℓ' is constant. In other words, if P and Q are points on ℓ, then*

$$d(P,\ell') = d(Q,\ell').$$

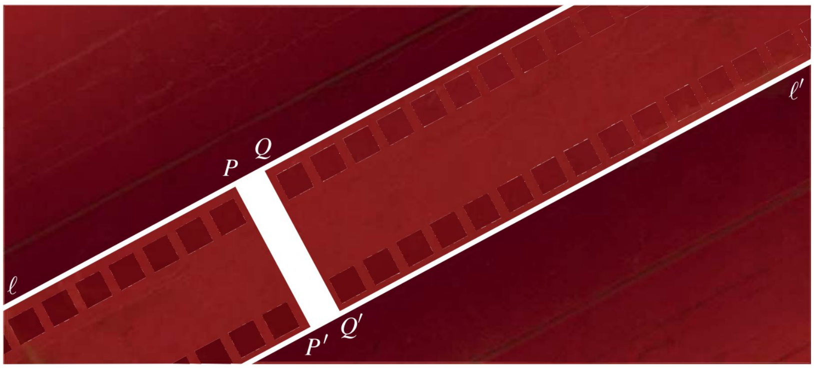

Figure 10. Perpendicular segments PP' and QQ' between parallel lines have the same length. That is, parallel lines are equidistant.

Proof Let P' and Q' be the feet of the perpendiculars on ℓ' from P and Q respectively. That way, by the previous exercise,

$$d(P,\ell') = |PP'| \text{ and } d(Q,\ell') = |QQ'|.$$

Then $\angle PP'Q'$ and $\angle QQ'P'$ are right angles. By the converse of the alternate interior angle theorem, $\angle P$ and $\angle Q$ are right angles too, so $\square PQQ'P'$ is a rectangle. According to exercise 11.2, PP' and QQ', which are opposite sides of a rectangle, are congruent. □

11.1 Exercises

11.5. Let ℓ be a line and P a point not on ℓ. Using only the results of neutral geometry, prove that there is at least one line through P that is parallel to ℓ.

11.6. Suppose that ℓ_1, ℓ_2, and ℓ_3 are three distinct lines such that ℓ_1 and ℓ_2 are parallel, and ℓ_2 and ℓ_3 are parallel. Prove that ℓ_1 and ℓ_3 are parallel.

11.7. Suppose that ℓ_1 and ℓ_2 are parallel lines, and that t is a line that intersects (but is distinct from) ℓ_1. Prove that t intersects ℓ_2.

11.8. Given three distinct parallel lines, prove that there is a labeling of them as ℓ_1, ℓ_2, and ℓ_3 so that

- no point of ℓ_1 lies between a point of ℓ_2 and a point of ℓ_3
- every point of ℓ_2 lies between a point of ℓ_1 and of ℓ_3
- no point of ℓ_3 lies between a point of ℓ_1 and a point of ℓ_2.

In this case, we can say that ℓ_2 is *between* ℓ_1 and ℓ_3.

11.9. This exercise is an extension of the previous one. Given n distinct parallel lines, prove that there is an ordering of them as $\ell_1, \ell_2, \ldots, \ell_n$ so that if $i < j < k$ then ℓ_j is between ℓ_i and ℓ_k.

11.10. Find the angle sum of a convex n-gon as a function of n.

11.11. What is the measure of an interior angle of a regular n-gon (as a function of n)?

11.12. Consider a convex quadrilateral $\square ABCD$. Prove that the two diagonals of $\square ABCD$ bisect each other if and only if $\square ABCD$ is a parallelogram.

11.13. Show that a parallelogram $\square ABCD$ is a rectangle if and only if $AC \simeq BD$.

11.14. Suppose that the diagonals of a convex quadrilateral $\square ABCD$ intersect one another at a point P and that

$$AP \simeq BP \simeq CP \simeq DP.$$

Prove that $\square ABCD$ is a rectangle.

11.15. Suppose that the diagonals of a convex quadrilateral bisect one another at right angles. Prove that the quadrilateral must be a rhombus.

11.16. Let $\triangle ABC$ be isosceles with $AB \simeq AC$, and let a be the midpoint of BC. Let b and c be points on the line through A that is parallel to BC so that $b * A * c$ and so that $bA \simeq cA \simeq Ba$. Prove that $\triangle ABC \simeq \triangle abc$.

11.17. Verify that the Cartesian model (as developed through the exercises in chapters 1–3) satisfies Playfair's axiom.

12

Parallel Projection

In the course of this chapter, we will need to use a few properties of parallelograms. It is rather common to confuse the properties of a parallelogram with its definition, so first, recall the definition of a parallelogram.

Definition 12.1 A *parallelogram* is a simple quadrilateral whose opposite sides are parallel.

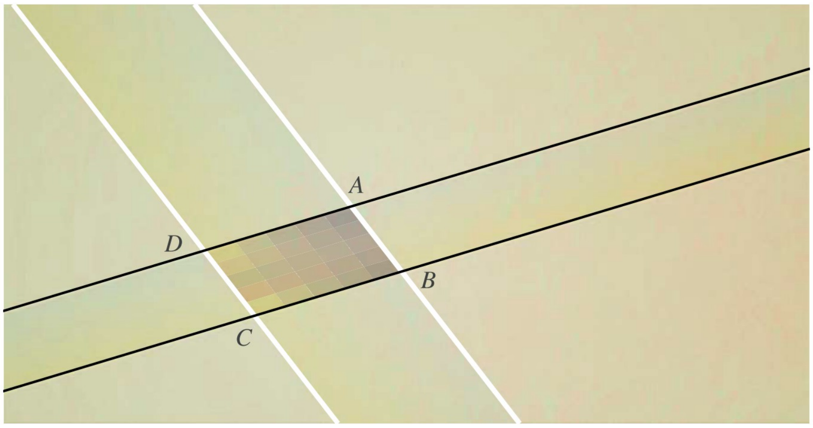

Figure 1. A parallelogram.

Now on to the properties of parallelograms that we will need for this chapter.

Exercise 12.1 Prove that in a parallelogram, the two pairs of opposite sides are congruent and the two pairs of opposite angles are congruent.

Exercise 12.2 Prove that if a convex quadrilateral has one pair of opposite sides that are both parallel and congruent, then it is a parallelogram.

Exercise 12.3 Let $\square ABB'A'$ be a simple quadrilateral. Verify that if AA' and BB' are parallel, but AB and $A'B'$ are not, then AA' and BB' cannot be congruent.

12.1 Parallel projection

The purpose of this chapter is to introduce a mechanism called *parallel projection*, a particular kind of mapping from the points on one line to the points on another. Parallel projection is the piece of machinery that you have to have in place to understand similarity, which is in turn essential for much of what we will be doing in the next chapters. The primary goal at this point is to understand how distances between points may be distorted by the parallel projection mapping. Once that is figured out, we will be able to turn our attention to the geometry of similarity.

Definition 12.2 A *parallel projection* from one line ℓ to another ℓ' is a map $\Phi : \ell \to \ell'$ that assigns to each point P on ℓ a point $\Phi(P)$ on ℓ' so that all the lines connecting a point and its image are parallel to one another.

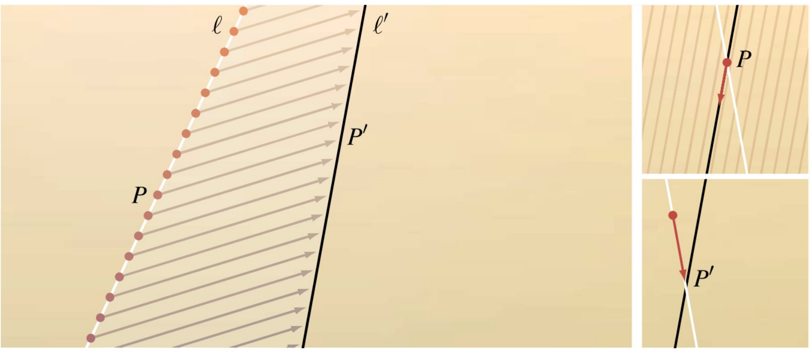

Figure 2. The path from a point P on ℓ to a point P' on ℓ' defines a parallel projection as long as neither P nor P' is the intersection of ℓ and ℓ' (as shown at right).

It is easy to construct parallel projections. Any point P on ℓ and its image $\Phi(P)$ on ℓ' completely determines the projection: for any other point Q on ℓ there is a unique line that passes through Q and is parallel to $\overline{P\,\Phi(P)}$. Wherever the line intersects ℓ' will have to be $\Phi(Q)$. There are only two cases where this construction will not work: if P is the intersection of ℓ and ℓ', then the lines of projection run parallel to ℓ' and so fail to provide a point of intersection; and if $\Phi(P)$ is the intersection of ℓ and ℓ', then the lines of projection actually coincide rather than being parallel.

Theorem 12.3 *A parallel projection is both one-to-one and onto.*

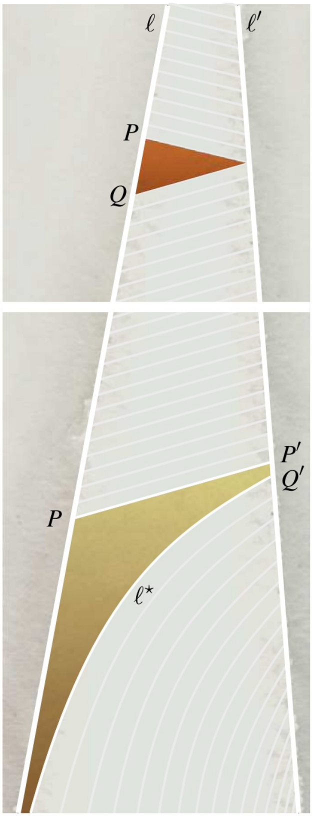

Figure 3. Using proofs by contradiction, we can show that parallel projection is both one-to-one (top) and onto (bottom).

Proof Let $\Phi : \ell \to \ell'$ be a parallel projection. First let's see why Φ is one-to-one. Suppose that it is not. That is, suppose that P and Q are two distinct points on ℓ but that $\Phi(P) = \Phi(Q)$. Then the two projecting lines $\overline{P\,\Phi(P)}$ and $\overline{Q\,\Phi(Q)}$, which ought to be parallel, actually share a point. This can't happen.

Now let's see why Φ is onto. Suppose that Q' is a point on ℓ' that is not in the image of Φ. To get a sense of how Φ is casting points from ℓ to ℓ', consider a point P on ℓ and its image $P' = \Phi(P)$ on ℓ'. By Playfair's axiom, there is a unique line $\ell^\star$ that passes through Q' and is parallel to $\overline{PP'}$. If $\ell^\star$ intersects ℓ at a point Q, then $\Phi(Q) = Q'$, contradicting the initial supposition that Q' is not in the image of Φ. If $\ell^\star$ does not intersect ℓ, then both ℓ and $\overline{PP'}$ are lines that pass through P and are parallel to $\ell^\star$, in violation of Playfair's axiom. In either case, we arrive at a contradiction. Therefore, an arbitrary point Q' of ℓ must be in the image of Φ, and so Φ is onto. □

Now that we have established that parallel projection is a bijection, it helps to use a naming convention to makes things more readable. I will use a prime mark $'$ to indicate the parallel projection of a point, so $\Phi(P) = P'$, $\Phi(Q) = Q'$, and so on.

12.2 Parallel projection, order, and congruence

So far we have seen that parallel projection establishes a correspondence between the points of one line and the points of another. What about the order of the points? Can points get shuffled up in the process of a parallel projection? No.

Theorem 12.4 *Let $\Phi : \ell \to \ell'$ be a parallel projection. If A, B, and C are points on ℓ and $A * B * C$, then $A' * B' * C'$.*

Proof Because B is between A and C, A and C must be on opposite sides of $\overline{BB'}$. But, $\overline{AA'}$ does not intersect $\overline{BB'}$, so A' has to be on the same side of $\overline{BB'}$ as A; and $\overline{CC'}$ does not

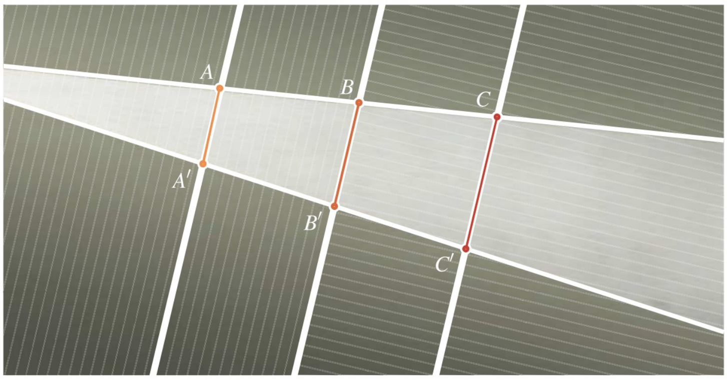

Figure 4. Parallel projection keeps points in order.

intersect $\overline{BB'}$, so C' has to be on the same side of $\overline{BB'}$ as C. Therefore A' and C' have to be on opposite sides of $\overline{BB'}$, and so the intersection of $\overline{BB'}$ and $A'C'$, which is B', must be between A' and C'. □

Now what about congruence?

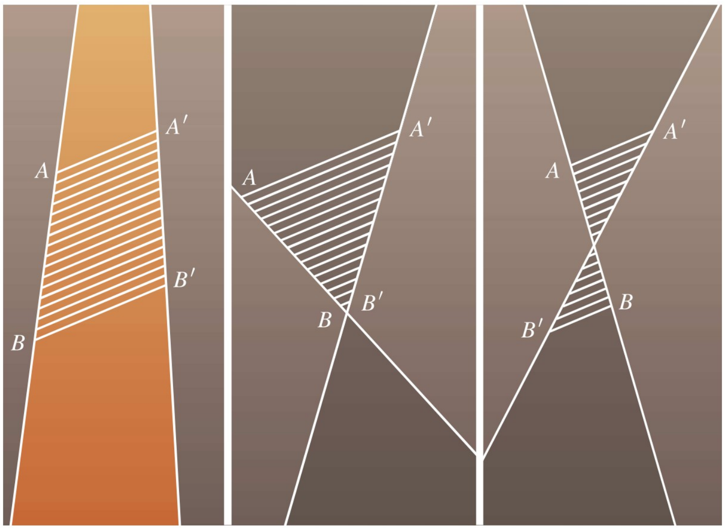

Figure 5. There are three positions for A and B relative to the image line: both on the same side, one on the image line, or one on each side. Likewise, there are three positions for a and b. There are nine cases in all.

Theorem 12.5 *Let $\Phi : \ell \to \ell'$ be a parallel projection. If a, b, A, and B are points on ℓ and if $ab \simeq AB$, then $a'b' \simeq A'B'$.*

Proof There are several cases, depending on the positions of ab and AB relative to ℓ'. They could lie on the same side of ℓ', they could lie on opposite sides of ℓ', one or both could straddle

ℓ', or one or both could have an endpoint on ℓ'. Each case must be handled differently. We will look at the case where both segments are on the same side of ℓ'. The others are left as exercises. There are still two cases to consider, depending on whether or not ℓ and ℓ' are parallel.

Case 1: when ℓ and ℓ' are parallel (see figure 6). This is the simpler case, but it helps illuminate the more general case. Because aa' is parallel to bb' and ab is parallel to $a'b'$, $\square aa'b'b$ is a parallelogram; AA' is parallel to BB' and AB is parallel to $A'B'$ so $\square AA'B'B$ is also a parallelogram. Because the opposite sides of a parallelogram are congruent (exercise 12.1), $a'b' \simeq ab$ and $AB \simeq A'B'$. Since $ab \simeq AB$, $a'b' \simeq A'B'$.

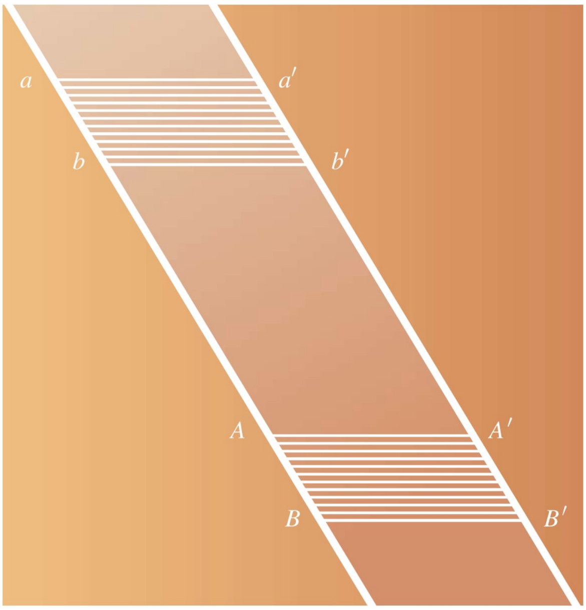

Figure 6. Case 1, when the two lines are parallel.

Case 2: when ℓ and ℓ' are not parallel (see figure 7). This is the more likely case, in which $\square aa'b'b$ and $\square AA'B'B$ will not be parallelograms. We can takes a similar approach to case 1, though, by building some parallelograms into the problem. Because ℓ and ℓ' are not parallel, the segments aa' and bb' cannot have the same length (exercise 12.3), and the segments AA' and BB' cannot have the same length. Let's assume that aa' is shorter than bb' and that AA' is shorter than BB'. If this is not the case, then it is just a matter of switching some labels to make it so. Then

- there is a point c between b and b' so that $bc \simeq aa'$, and
- there is a point C between B and B' so that $BC \simeq AA'$.

This creates four shapes of interest: the quadrilaterals $\square a'abc$ and $\square A'ABC$ that are parallelograms (exercise 12.2), and the triangles $\triangle a'b'c$ and $\triangle A'B'C$. The key here is to prove that $\triangle a'b'c \simeq \triangle A'B'C$.

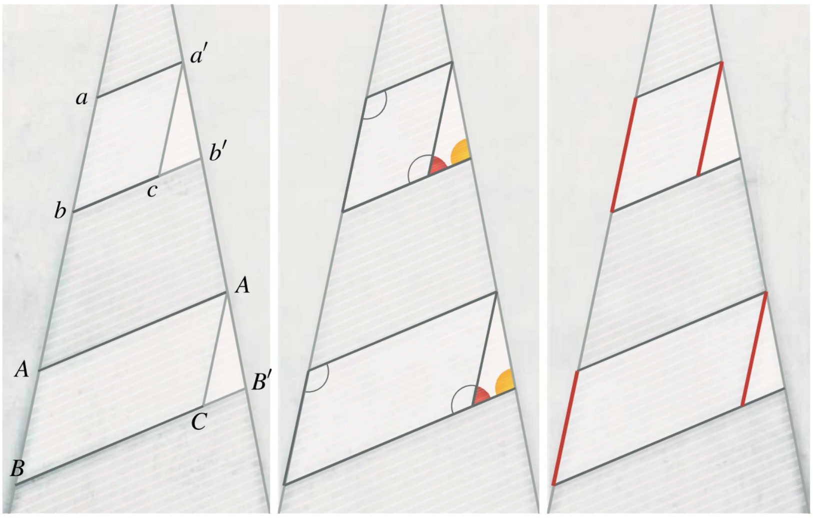

Figure 7. The non-parallel case. (l) First construct parallelograms. (c) The two angles and (r) the sides needed for AAS to show that $\triangle a'b'c' \simeq \triangle A'B'C'$.

- **A:** $\angle b' \simeq \angle B'$. The lines $\overline{cb'}$ and $\overline{CB'}$ are parallel (they are two of the projecting lines) and they are crossed by the transversal ℓ'. By the converse of the alternate interior angle theorem, $\angle a'b'c$ and $\angle A'B'C$ are congruent.
- **A:** $\angle c \simeq \angle C$. The opposite angles of the two parallelograms are congruent. Therefore $\angle a'cb \simeq \angle a'ab$ and $\angle A'AB \simeq \angle A'CB$. But $\overline{aa'}$ and $\overline{AA'}$ are parallel lines cut by the transversal ℓ, so $\angle a'ab \simeq \angle A'AB$, so $\angle a'cb \simeq \angle A'CB$, and so their supplements $\angle a'cb'$ and $\angle A'CB'$ are also congruent.
- **S:** $a'c \simeq A'C$. The opposite sides of the two parallelograms are congruent too. Therefore $a'c \simeq ab$ and $AB \simeq A'C$, and since $ab \simeq AB$, we get $a'c \simeq A'C$.

By AAS, then, $\triangle a'b'c \simeq \triangle A'B'C$. The corresponding sides $a'b'$ and $A'B'$ have to be congruent.

□

Exercise 12.4 Fill in some gaps:

(1) Prove the theorem in the case when both a and A lie on ℓ' (at the intersection of ℓ and ℓ').
(2) Prove the theorem in the case when a and A lie on opposite sides of ℓ' from b and B.

12.3 Parallel projection and distance

That brings us to the question at the very heart of parallel projection. If Φ is a parallel projection and A and B are two points on ℓ, how do the lengths $|AB|$ and $|A'B'|$ compare? In case 1 of the last proof, AB and $A'B'$ ended up being congruent, but that was because ℓ and ℓ' were parallel. In general, AB and $A'B'$ do not have to be congruent. But it turns out that in the process of parallel projecting from one line to another, all distances are scaled by a constant multiple.

Theorem 12.6 *If* $\Phi : \ell \to \ell'$ *is a parallel projection, then there is a constant* k *such that*

$$|A'B'| = k|AB|$$

for all points A *and* B *on* ℓ.

It is helpful to get a little perspective on this before the proof. First note that the previous theorem gives us a way to narrow the scope of the problem. Fix a point O on ℓ and let r be one of the two rays along ℓ with O as its endpoint. The segment construction axiom says that every segment AB on ℓ is congruent to a segment OP where P is some point on r. We have just seen that parallel projection maps congruent segments to congruent segments. So if Φ scales all segments of the form OP by a factor of k, then it must scale all the segments of ℓ by the same factor.

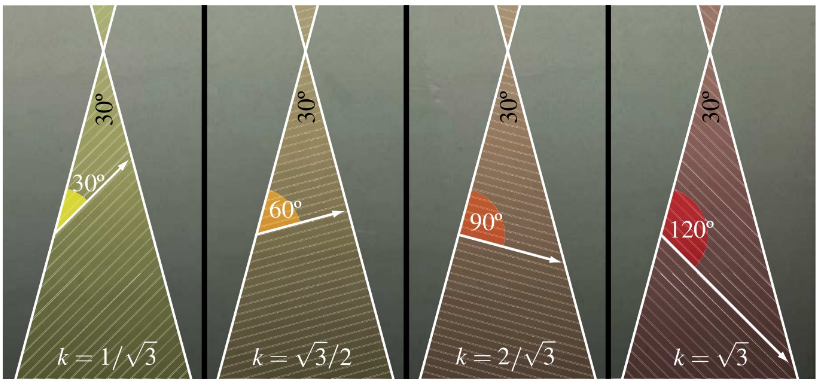

Figure 8. Some parallel projections and their scaling constants.

Second, we can extend that by considering what happens when we parallel project end-to-end congruent copies of a segment. For this, let me introduce another convenient notation convention: for the rest of this argument, let P_d denote the point on r that is a distance d from O. Now, pick a positive real value x, and let

$$k = |O'P'_x|/|OP_x|,$$

so that Φ scales the segment OP_x by a factor of k. Eventually we will have to show that Φ scales all segments by that factor, but for now let's restrict our attention to the segments OP_{nx}, where n is a positive integer. Between O and P_{nx} are P_x, P_{2x}, … $P_{(n-1)x}$ in order:

$$O * P_x * P_{2x} * \cdots * P_{(n-1)x} * P_{nx}.$$

We have seen that parallel projection preserves the order of points, so

$$O' * P'_x * P'_{2x} * \cdots * P'_{(n-1)x} * P'_{nx}.$$

Each segment $P_{ix}P_{(i+1)x}$ is congruent to OP_x and consequently each parallel projection $P'_{ix}P'_{(i+1)x}$ is congruent to $O'P'_x$. Add their lengths:

$$\begin{aligned}|O'P'_{nx}| &= |O'P'_x| + |P'_xP'_{2x}| + |P'_{2x}P'_{3x}| + \cdots + |P'_{(n-1)x}P'_{nx}|\\ &= kx + kx + kx + \cdots + kx \quad (n \text{ times})\\ &= k \cdot nx\end{aligned}$$

and so Φ scales OP_{nx} by a factor of k.

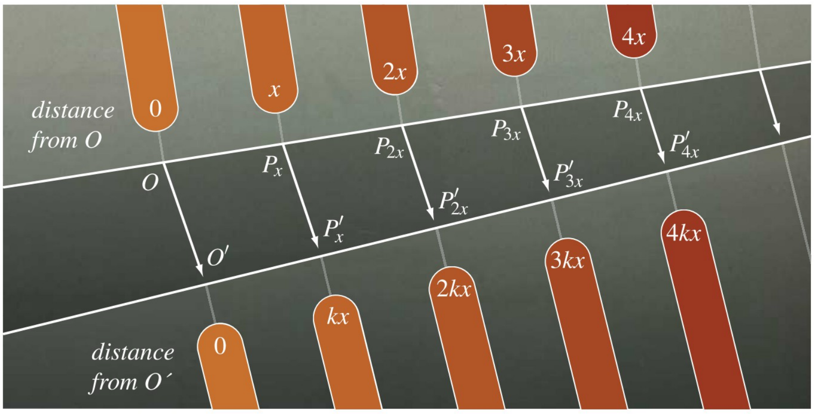

Figure 9. Scaling of segments of length kx, where k is an integer.

Sadly, no matter what x is, the points P_{nx} account for an inconsequential portion of the set of all points of r. However, if OP_x and OP_y were to have two different scaling factors we could use this end-to-end copying to magnify the difference between them. Third, then, consider an example that demonstrates how this works, and which shows how this ultimately prevents there being two different scaling factors. In this example, let's suppose that $|O'P'_1| = 2$, so all integer length segments on ℓ are scaled by a factor of 2. Let's take a look at what this means for $P_{3.45}$. Let k be the scaling factor for $OP_{3.45}$. Figure 10 shows how the first few end-to-end copies of $OP_{3.45}$ begin to limit the possible values of k.

Fourth, note that the floor function, $f(x) = \lfloor x \rfloor$, assigns to each real number x the largest integer that is less than or equal to it. The ceiling function, $f(x) = \lceil x \rceil$, assigns to each real number x the smallest integer that is greater than or equal to it.

It is finally time to prove that parallel projection scales distance.

Proof Let $k = |O'P'_1|$ so that k is the scaling factor for the segment of length 1 (and consequently for all integer length segments). Now take a point P_x on ℓ and let k' be the scaling factor for the segment OP_x. We want to show that $k' = k$ and we can do that by following the same strategy as in the example above, by capturing k' in an increasingly narrow band around k by looking at the parallel projection of P_{nx} as n increases. Start by working back and forth between

$1.93 < k < 2.03$

Figure 10. An example. Projecting end-to-end congruent copies of a segment of length 3.45 by a parallel projection that scales all integer length segments by a factor of two.

inequalities of real numbers and orders of points:

$$\lfloor nx \rfloor \le nx \le \lceil nx \rceil$$
$$O * P_{\lfloor nx \rfloor} * P_{nx} * P_{\lceil nx \rceil}$$
$$O' * P'_{\lfloor nx \rfloor} * P'_{nx} * P'_{\lceil nx \rceil}$$
$$k\lfloor nx \rfloor \le k'nx \le k\lceil nx \rceil.$$

(The notation here is a bit casual—if nx is an integer, then $\lfloor nx \rfloor = nx$, so $P_{\lfloor nx \rfloor}$ is not actually between O and P_{nx}. This does not cause any problems for the proof.) Because $(nx - 1) \le \lfloor nx \rfloor$

and $\lceil nx \rceil \leq (nx + 1)$ we can move to a less precise but more manageable set of inequalities:

$$k(nx - 1) \leq k'nx \leq k(nx + 1).$$

Divide by nx to get

$$k\left(\frac{nx - 1}{nx}\right) \leq k' \leq k\left(\frac{nx + 1}{nx}\right).$$

As n increases, the ratios $(nx - 1)/(nx)$ and $(nx + 1)/(nx)$ both approach 1. In the limit as n goes to infinity, they are 1. Since the inequalities have to be true for all n, the only possible value for k' , then, is k. □

12.4 Exercises

12.5. Suppose that Φ is a parallel projection from ℓ to ℓ'. If ℓ and ℓ' intersect at P, prove that $\Phi(P) = P$.

12.6. Prove that if ℓ and ℓ' are parallel, then the scaling factor of a parallel projection between them must be one, but that if ℓ and ℓ' are not parallel, then there is a parallel projection with every possible scaling factor k where $0 < k < \infty$.

12.7. Let $\Phi : \ell \to \ell'$ be a parallel projection. Show that the inverse map $\Phi^{-1} : \ell' \to \ell$ is also a parallel projection.

12.8. Let $\Phi_1 : \ell \to \ell'$ and $\Phi_2 : \ell' \to \ell''$ be parallel projections. Is the composition $\Phi_2 \circ \Phi_1 : \ell \to \ell''$ necessarily a parallel projection?

12.9. In chapter 6, we constructed a distance function, and one of the keys to the construction was locating the points on a ray that were a distance of $m/2^n$ from its endpoint. In Euclidean geometry, there is a construction that locates all the points on a ray that are any rational distance m/n from its endpoint. Take two non-opposite rays r and r' with a common endpoint O. Along r, lay out m congruent copies of a segment of length 1, ending at the point P_m. Along r', lay out n congruent copies of a segment of length 1, ending at the point Q_n. Mark the point Q_1 on r' that is a distance 1 from O. Verify that the line that passes through Q_1 and is parallel to $P_m Q_n$ intersects r a distance of m/n from O.

13

Similarity

In the chapters on neutral geometry, we spent a lot of effort to gain an understanding of polygon congruence, particularly congruence of triangles and quadrilaterals. Remember that polygon congruence is an equivalence relation (it is reflexive, symmetric, and transitive). It turns out that congruence is not the only important equivalence relation between polygons, though, and the purpose of this chapter is to investigate another: similarity. Similarity is a less demanding relation than congruence. Intuitively, we tend to think of congruent polygons as exactly the same, just positioned differently. Similar polygons are not just positioned differently, but are scaled versions of one another: the same shape, but possibly different sizes.

Definition 13.1 Two n-sided polygons $P_1P_2\dots P_n$ and $Q_1Q_2\dots Q_n$ are *similar* to one another if they meet two sets of conditions:

(1) corresponding interior angles are congruent:

$$\angle P_i \simeq \angle Q_i, \quad 1 \le i \le n.$$

(2) corresponding side lengths differ by the same constant multiple k:

$$|P_iP_{i+1}| = k \cdot |Q_iQ_{i+1}|, \quad 1 \le i \le n.$$

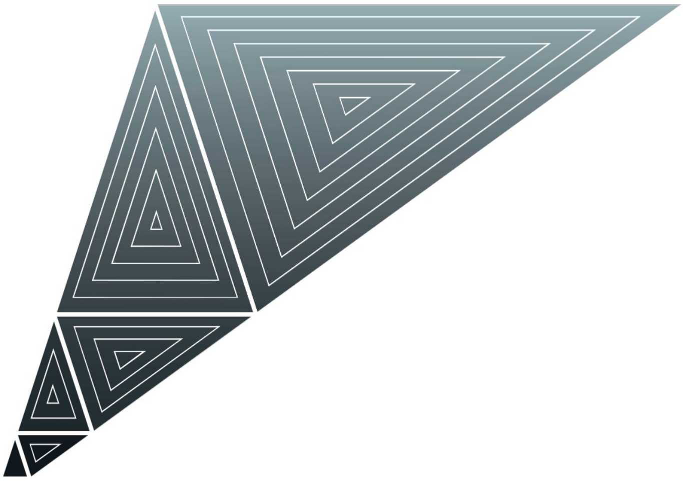

Figure 1. An arrangement of similar triangles.

To indicate that two polygons $P_1P_2\dots P_n$ and $Q_1Q_2\dots Q_n$ are similar, write $P_1P_2\dots P_n \sim Q_1Q_2\dots Q_n$. There are a few things worth noting here. First, if polygons are congruent, they will be similar as well with the scaling constant 1. Second, it is easy to see that similarity is reflexive, symmetric and transitive and so is an equivalence relation. Third, when you jump from one polygon to another similar polygon, the corresponding segment lengths are scaled by the same amount. That behavior echoes the work we did in the last chapter, and for good reason: parallel projection underlies everything that we are going to do in this chapter.

Much of the time, when working with either parallel projection or similarity, the scaling constant is not important. The only thing that matters is that there is one. Fortunately, the existence of a scaling constant can be indicated without ever mentioning what it is. The key to doing this is ratios. Consider a parallel projection from line ℓ to line ℓ'. Let A, B, a, and b be points on ℓ and let A', B', a', and b' be their respective images on ℓ'. The main result of the last chapter was that there is a scaling constant k so that

$$|A'B'| = k \cdot |AB| \quad\text{and}\quad |a'b'| = k \cdot |ab|.$$

The ratios are only a step away from this pair of equations.

Ratio 1: Solve for k in both equations and set them equal to each other:

$$\frac{|A'B'|}{|AB|} = \frac{|a'b'|}{|ab|}.$$

Ratio 2: Starting from the first ratio, multiply by $|AB|$ and divide by $|a'b'|$:

$$\frac{|A'B'|}{|a'b'|} = \frac{|AB|}{|ab|}.$$

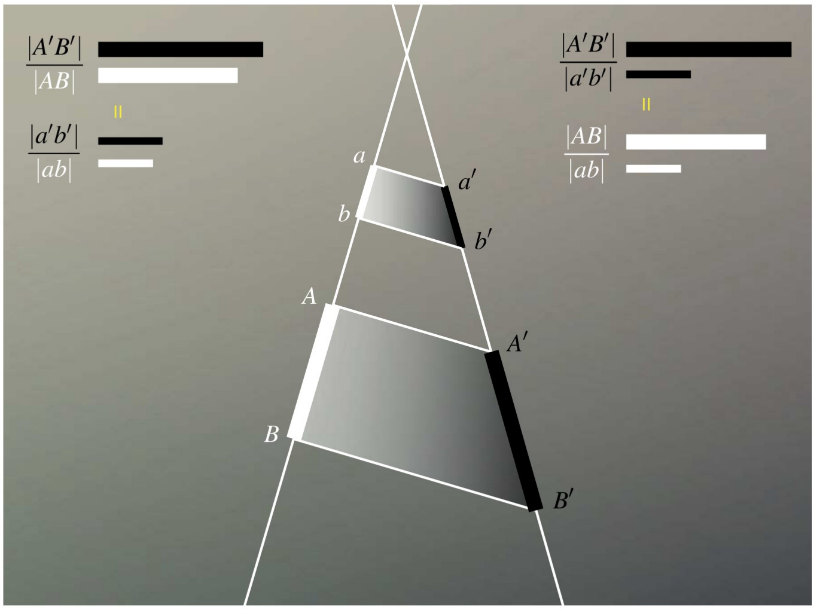

Figure 2. Two invariant ratios of a parallel projection.

13.1 Triangle similarity theorems

Let's begin with a few theorems that deal with similarity of triangles. I like to think of them as degenerations of the triangle congruence theorems, where the strict condition of side congruence, $A'B' \simeq AB$, is replaced with the more flexible condition of constant scaling, $|A'B'| = k|AB|$. The first is the SAS similarity theorem.

Theorem 13.2 *(SAS similarity) In $\triangle ABC$ and $\triangle A'B'C'$, if $\angle A \simeq \angle A'$ and if there is a constant k so that*

$$|A'B'| = k \cdot |AB| \text{ and } |A'C'| = k \cdot |AC|,$$

then $\triangle ABC \sim \triangle A'B'C'$.

Proof First note that as with parallel projection, the second condition in the SAS similarity theorem can be recast in terms of ratios:

$$\frac{|A'B'|}{|AB|} = \frac{|A'C'|}{|AC|} \text{ or } \frac{|A'B'|}{|A'C'|} = \frac{|AB|}{|AC|}.$$

With that said, what we need to do in the proof is to establish two more angle congruences, that $\angle B \simeq \angle B'$ and $\angle C \simeq \angle C'$, and one more ratio of sides, that $|B'C'| = k|BC|$. Two parallel projections form the backbone of this proof.

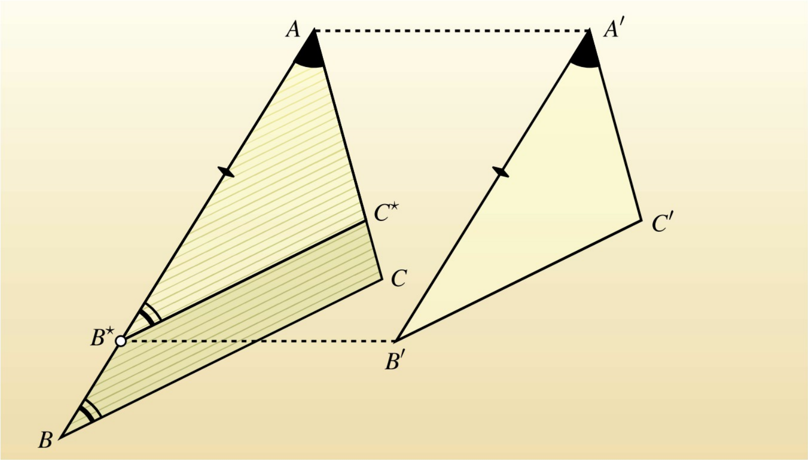

Figure 3. Proving SAS similarity. The first parallel projection.

The first parallel projection. The primary purpose of the first projection is to build a transitional triangle that is congruent to $\triangle A'B'C'$ but positioned on top of $\triangle ABC$. Begin by locating the point $B^\star$ on $\overrightarrow{AB}$ so that $AB^\star \simeq A'B'$. We cannot know the exact location of $B^\star$ relative to B on this ray. It depends on whether $A'B'$ is shorter or longer than AB. For this argument, assume that $A'B'$ is shorter than AB, which will place $B^\star$ between A and B (the other case is not substantially different). Consider the parallel projection

$$\Phi_1 : (\overline{AB}) \longrightarrow (\overline{AC})$$

that maps B to C. Because A is the intersection of these two lines, $\Phi_1(A) = A$. Label $C^\star = \Phi_1(B^\star)$. Let's see how the newly formed $\triangle AB^\star C^\star$ compares with $\triangle A'B'C'$. By parallel projection,

$$\frac{|AC^\star|}{|AC|} = \frac{|AB^\star|}{|AB|},$$

but we chose $B^\star$ so that $|AB^\star| = |A'B'|$. Therefore

$$\frac{|AC^\star|}{|AC|} = \frac{|A'B'|}{|AB|} = \frac{|A'C'|}{|AC|},$$

and so $|AC^\star| = |A'C'|$. Put that together with what we already know, that $AB^\star \simeq A'B'$ and $\angle A \simeq \angle A'$, and by SAS, $\triangle A'B'C'$ and $\triangle AB^\star C^\star$ are congruent. In particular, that means $\angle B' \simeq \angle B^\star$ and $\angle C' \simeq \angle C^\star$. Now let's turn back to see how $\triangle AB^\star C^\star$ relates to $\triangle ABC$. To locate $C^\star$, we used a projection that was parallel to $\overline{BC}$. Hence $\overline{B^\star C^\star}$ and $\overline{BC}$ are parallel, and so, by the converse of the alternate interior angle theorem, $\angle B^\star \simeq \angle B$ and $\angle C^\star \simeq \angle C$. Since angle congruence is transitive, we now have the required angle congruences, $\angle B \simeq \angle B'$ and $\angle C \simeq \angle C'$.

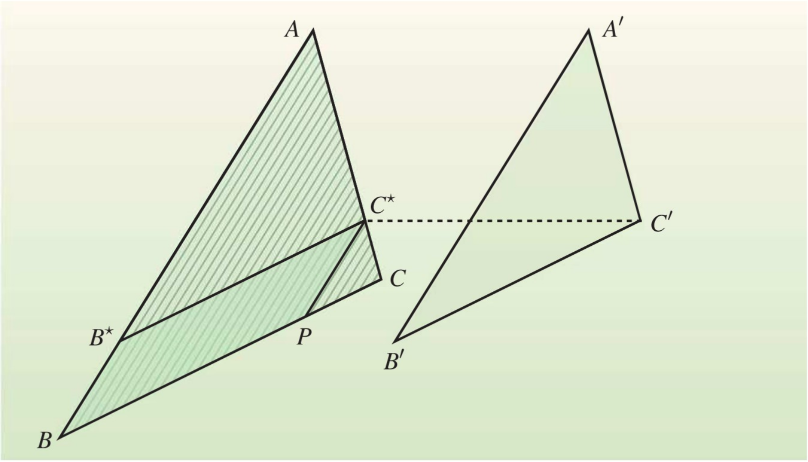

Figure 4. Proving SAS similarity. The second parallel projection.

The second parallel projection. Now consider the parallel projection

$$\Phi_2 : (\overline{AC}) \longrightarrow (\overline{BC})$$

that maps A to B. Since C is the intersection of $\overline{AC}$ and $\overline{BC}$, $\Phi_2(C) = C$. The other point of interest this time is $C^\star$. Let $P = \Phi_2(C^\star)$. In doing so, we have effectively carved out a parallelogram $\square BB^\star C^\star P$. Recall (from the last chapter) that the opposite sides of a parallelogram are congruent, so $B^\star C^\star \simeq BP$, and therefore $|B'C'| = |BP|$. The parallel projection Φ_2 establishes equal ratios $|BP|/|BC| = |AC^\star|/|AC|$, and so

$$\frac{|B'C'|}{|BC|} = \frac{|BP|}{|BC|} = \frac{|AC^\star|}{|AC|} = \frac{|A'C'|}{|AC|} = k.$$

Thus, $|B'C'| = k|BC|$, as needed. □

Back in the neutral geometry chapters, after SAS we next encountered ASA and AAS. Unlike SAS, both theorems reference only one pair of sides in the triangles. Let's look at what happens when we try to modify those congruence conditions into similarity conditions.

ASA congruence	ASA similarity (?)
$\angle A \simeq \angle A'$	$\angle A \simeq \angle A'$
$AB \simeq A'B'$	$\|A'B'\| = k \cdot \|AB\|$
$\angle B \simeq \angle B'$	$\angle B \simeq \angle B'$

AAS congruence	AAS similarity (?)
$\angle A \simeq \angle A'$	$\angle A \simeq \angle A'$
$\angle B \simeq \angle B'$	$\angle B \simeq \angle B'$
$BC \simeq B'C'$	$\|B'C'\| = k \cdot \|BC\|$

In each of these conversions, the condition on the one side is automatically satisfied: there will always be a real value of k that makes the equation true. That suggests that it may take only two angle congruences to guarantee similarity.

Theorem 13.3 *(AA similarity) In $\triangle ABC$ and $\triangle A'B'C'$, if $\angle A \simeq \angle A'$ and $\angle B \simeq \angle B'$, then $\triangle ABC \sim \triangle A'B'C'$.*

We have plenty of information about the angles, so what we need is some information about ratios of sides. If we can show that

$$\frac{|A'B'|}{|AB|} = \frac{|A'C'|}{|AC|},$$

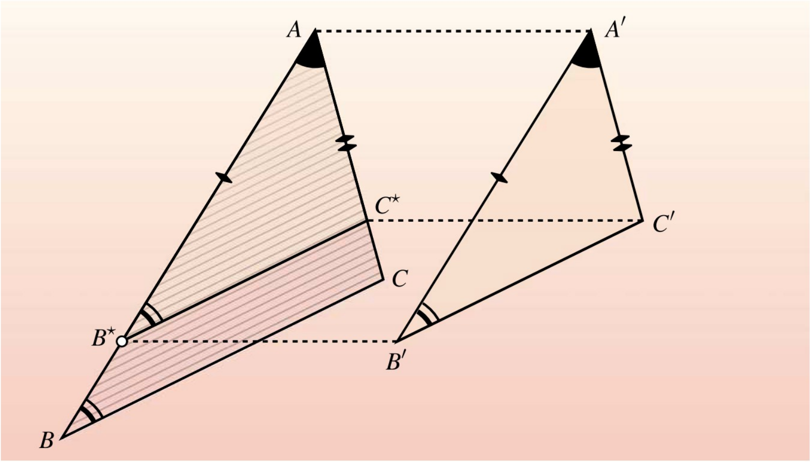

Figure 5. Proof of AA similarity, by parallel projection.

then that, along with the congruence $\angle A \simeq \angle A'$, will be enough to use the SAS similarity theorem.

Proof Start by constructing a transition triangle: one that is positioned on top of $\triangle ABC$ but that is congruent to $\triangle A'B'C'$. To do that, locate $B^\star$ on $\overrightarrow{AB}$ so that $AB^\star \simeq A'B'$, and $C^\star$ on $\overrightarrow{AC}$ so that $AC^\star \simeq A'C'$. By SAS, $\triangle AB^\star C^\star$ and $\triangle A'B'C'$ are congruent. Consider the congruent angles

$$\angle B^\star \simeq \angle B' \simeq \angle B.$$

According to the alternate interior angle theorem, $\overline{B^\star C^\star}$ and $\overline{BC}$ must be parallel. Therefore the parallel projection from $\overline{AB}$ to $\overline{AC}$ that maps B to C and A to itself will also map $B^\star$ to $C^\star$ and so

$$\frac{|A'B'|}{|AB|} = \frac{|AB^\star|}{|AB|} = \frac{|AC^\star|}{|AC|} = \frac{|A'C'|}{|AC|}.$$

The first and last terms give the ratio we need. That, together with the known congruence $\angle A \simeq \angle A'$, is enough for SAS similarity, so $\triangle ABC \sim \triangle A'B'C'$. □

While AAA was not enough to guarantee congruence, thanks to the result above, we now know that it is (more than) enough to guarantee similarity. The last of the triangle similarity theorems is SSS similarity (SSA, which just misses as a congruence theorem, is done in again by the same counterexample).

Theorem 13.4 *(SSS similarity) In $\triangle ABC$ and $\triangle A'B'C'$, if there is a constant k so that*

$$|A'B'| = k \cdot |AB|, \quad |B'C'| = k \cdot |BC|, \quad \textit{and} \quad |C'A'| = k \cdot |CA|,$$

then $\triangle ABC \sim \triangle A'B'C'$.

Exercise 13.1 Prove the SSS triangle similarity theorem.

13.2 The Pythagorean theorem

Before we close this chapter, let's meet one of the real celebrities of the subject, the Pythagorean theorem. There are many, many proofs of this theorem. This one involves dividing the triangle into two smaller triangles, each similar to the initial triangle, and then working with ratios.

Theorem 13.5 *(The Pythagorean theorem) Let $\triangle ABC$ be a right triangle whose right angle is at the vertex C. Let*

$$a = |BC|, \quad b = |AC|, \quad \textit{and} \quad c = |AB|.$$

Then $c^2 = a^2 + b^2$.

Proof Let D be the foot of the perpendicular to AB through C. The segment CD divides $\triangle ABC$ into two smaller triangles: $\triangle ACD$ and $\triangle BCD$. Label the lengths of their sides as $c_1 = |AD|$, $c_2 = |BD|$, and $d = |CD|$, and note that $c = c_1 + c_2$. Now $\triangle ADC$ shares $\angle A$ with $\triangle ACB$, and they both have a right angle, so by the AA similarity theorem, $\triangle ADC \sim \triangle ACB$. Similarly, $\triangle BDC$ shares $\angle B$ with $\triangle ACB$, and they both have a right angle as well, so again by AA similarity, $\triangle BDC \sim \triangle BCA$. From these similarities, there are many ratios, but the two that we need are

$$\frac{a}{c} = \frac{c_2}{a} \implies a^2 = c \cdot c_2 \text{ and } \frac{b}{c} = \frac{c_1}{b} \implies b^2 = c \cdot c_1.$$

All that is left is to add the equations and simplify to get the Pythagorean theorem:

$$a^2 + b^2 = c \cdot c_2 + c \cdot c_1 = c(c_2 + c_1) = c^2. \qquad \square$$

Here is a first application of the Pythagorean theorem. The triangle inequality says that if a, b, and c are the lengths of the sides of a triangle, then

$$|a - b| < c < a + b.$$

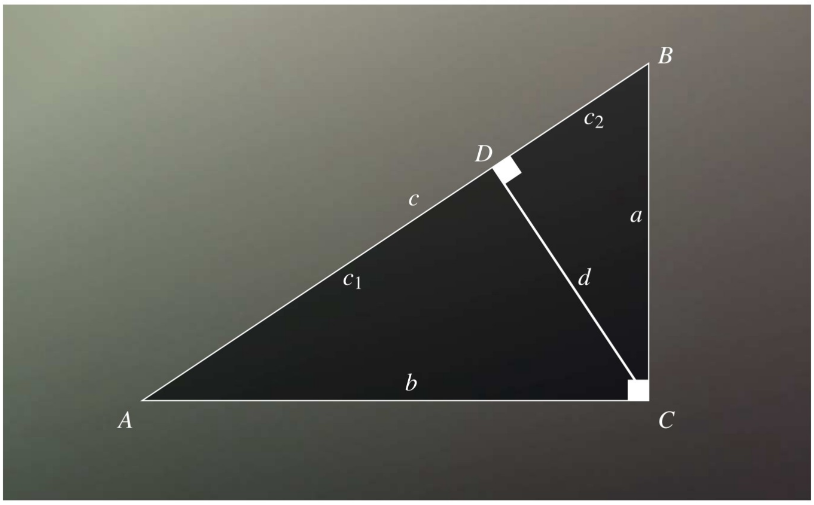

Figure 6. A proof of the Pythagorean theorem via similarity.

What about the converse? If a, b, and c are positive reals satisfying the triangle inequality conditions, can we put together a triangle with sides of those lengths?

Theorem 13.6 *Let a, b, and c be positive real numbers. Suppose that c is the largest of them and that $c < a + b$. Then there is a triangle with sides of length a, b, and c.*

Proof Start with a segment AB whose length is c. We need to place a third point C so that it is a distance a from B and b from A (according to SSS, there is only one such triangle up to congruence, so this may not be too easy). The strategy is to build the triangle out of two right triangles. Mark D on $\overrightarrow{AB}$ and label $d = |AD|$. Mark C on one of the rays with endpoint D

that is perpendicular to AB and label $e = |CD|$. Then $\triangle ACD$ and $\triangle BCD$ are right triangles. Furthermore, by sliding D and C along their respective rays, we can make d and e any positive numbers.

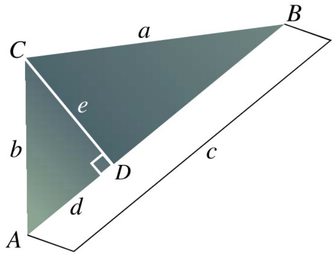

Figure 7. Building a triangle out of two right triangles.

We need to see if it is possible to position the two so that $|AC| = b$ and $|BC| = a$. To get $|AC| = b$, we will need

$$d^2 + e^2 = b^2.$$

To get $|BC| = a$, we will need

$$(c - d)^2 + e^2 = a^2.$$

With a little algebra, we can find d and e. Solve for e^2 in the equations and set them equal:

$$\begin{gathered} b^2 - d^2 = e^2 = a^2 - (c-d)^2 \\ b^2 - d^2 = a^2 - c^2 + 2cd - d^2 \\ b^2 = a^2 - c^2 + 2cd \\ (b^2 - a^2 + c^2)/2c = d. \end{gathered}$$

Since we required $c > a$, d will be positive. Substitute to find e:

$$e^2 = b^2 - d^2 = b^2 - \left(\frac{b^2 - a^2 + c^2}{2c}\right)^2.$$

Here is the essential part. Because we will have to take a square root to find e, the right hand side of this equation has to be positive; if not the equation has no solution and the triangle cannot be built. Let's go back to see if the triangle inequality condition on the three sides will help:

$$\begin{gathered} c < a + b \\ c - b < a \\ (c-b)^2 < a^2 \\ c^2 - 2bc + b^2 < a^2 \\ c^2 - a^2 + b^2 < 2bc \\ (c^2 - a^2 + b^2)/2c < b \\ ((c^2 - a^2 + b^2)/2c)^2 < b^2 \\ 0 < b^2 - ((c^2 - a^2 + b^2)/2c)^2 \end{gathered}$$

which is exactly what we want. As long as $c < a + b$, then, a value for e can be found, and the triangle can be built. $\square$

13.3 Exercises

13.2. Prove that similarity of polygons is an equivalence relation.

13.3. State and prove the SASAS similarity theorem for convex quadrilaterals.

13.4. State and prove the ASASA similarity theorem for convex quadrilaterals.

13.5. State and prove the SSSSA similarity theorem for convex quadrilaterals.

13.6. Is AAAA a valid similarity theorem for quadrilaterals?

13.7. Suppose that $P_1P_2\cdots P_n$ and $Q_1Q_2\cdots Q_n$ are similar polygons, and P_1P_j is a diagonal that lies entirely in the interior of $P_1P_2\cdots P_n$ (other than its endpoints). Prove that Q_1Q_j lies entirely in the interior of $Q_1Q_2\cdots Q_n$ (other than its endpoints).

13.8. Suppose that $P_1P_2\cdots P_n$ and $Q_1Q_2\cdots Q_n$ are similar polygons, and P_1P_j is a diagonal that lies entirely in the interior of $P_1P_2\cdots P_n$ as in the last exercise. Prove that $P_1P_2\cdots P_j \sim Q_1Q_2\cdots Q_j$.

13.9. For $\triangle ABC$, the lines

- through A, parallel to BC;
- through B, parallel to AC; and
- through C, parallel to AB

intersect to form a triangle. Prove that the triangle is similar to $\triangle ABC$.

13.10. Let $\square ABCD$ be a trapezoid, with $AB \parallel CD$. Let M_1 be the midpoint of AB, M_2 the midpoint of CD, N_1 the midpoint of BC, and N_2 the midpoint of AD. Then the segments M_1M_2 and N_1N_2 cut $\square ABCD$ into four pieces. Under what conditions (on the original $\square ABCD$) are the four pieces each similar to the original $\square ABCD$?

13.11. Let $\triangle ABC$ be an isosceles triangle with $AB \simeq AC$. Label D so that $B * C * D$ and so that $AC \simeq CD$ (so that $\triangle ACD$ is isosceles). What angle measure or measures must $\angle B$ have in order for the large triangle $\triangle DAB$ to be similar to $\triangle ABC$?

13.12. Consider a rectangle $\square ABCD$ with $|AB| < |BC|$, and suppose that it has the property that if a square $\square ABEF$ is constructed inside $\square ABCD$, then the remaining rectangle $\square ECDF$ is similar to the original $\square ABCD$. A rectangle with this property is called a golden rectangle. Find the value of $|BC|/|AB|$, a value known as the golden ratio.

13.13. Let $\triangle ABC$ be a right triangle with right angle at C, and suppose that $|AB| = a$ and $|BC| = a/2$. Let M be the midpoint of AB. The line through M that is perpendicular to AB intersects AC at a point N. What is $|MN|$ in terms of a?

13.14. Let $\triangle ABC$ be an equilateral triangle with sides of length a. Prove that the three segments that connect each vertex to the midpoint of the opposite side intersect at a point P. What is the distance from a vertex to P in terms of a?

The six trigonometric functions can be defined, for values of θ between 0 and 90°, as ratios of pairs of sides of a right triangle with an interior angle θ. If the length of the hypotenuse is h, the length of the leg adjacent to θ is a, and the length of the leg opposite θ is o, then these functions are defined as

$$\begin{aligned}
&\text{sine: } \sin(\theta) = o/h\\
&\text{cosine: } \cos(\theta) = a/h\\
&\text{tangent: } \tan(\theta) = o/a\\
&\text{cotangent: } \cot(\theta) = a/o\\
&\text{secant: } \sec(\theta) = h/a\\
&\text{cosecant: } \csc(\theta) = h/o.
\end{aligned}$$

In chapter 21, we will extend these functions to accept all real values. In the meantime, we will have need of these functions, and some of the basic identities relating them as listed in the exercises below.

13.15. Verify that the six trigonometric functions are well-defined. That is, show that it does not matter which right triangle with interior angle θ you choose—these six ratios will not change.

13.16. Verify the Pythagorean identities (for values of θ between 0 and 90°).

$$\begin{aligned}
\sin^2\theta + \cos^2\theta &= 1\\
1 + \tan^2\theta &= \sec^2\theta\\
1 + \cot^2\theta &= \csc^2\theta
\end{aligned}$$

13.17. Verify the cofunction identities (for values of θ between 0 and 90°).

$$\begin{aligned}
\sin(90^\circ - \theta) &= \cos\theta\\
\cos(90^\circ - \theta) &= \sin\theta\\
\tan(90^\circ - \theta) &= \cot\theta\\
\cot(90^\circ - \theta) &= \tan\theta\\
\sec(90^\circ - \theta) &= \csc\theta\\
\csc(90^\circ - \theta) &= \sec\theta
\end{aligned}$$

Circles

This is the first of two chapters that deal with circles. This chapter gives some basic definitions and some elementary theorems, the most important of which is the inscribed angle theorem. In the next, we will tackle the important issue of circumference and see how that leads to the radian angle measurement system.

14.1 Definitions

Circles are basic geometric objects, but are making a late entrance in this book. In fact, circles can be defined very early in neutral geometry, the only prerequisites being points, segments, and congruence. However, most of the interesting theorems involving circles are specific to Euclidean geometry (or, in the case of the circumference formula, are different in Euclidean and non-Euclidean geometry). In any case, now is the time for a proper definition.

Definition 14.1 For a point O and positive real number r, the *circle* with *center* O and *radius* r is the set of points that are a distance r from O.

A few observations.

(1) A circle is a set, but we say that a point in the set is *on* the circle, rather than *in* the circle. The term *in* is reserved for points in the interior of the circle.
(2) In the definition, the radius is a number. We often talk about the radius as a geometric entity though, as one of the segments from the center to a point on the circle.
(3) We tend to think of the center of a circle as a fundamental part of it, but it is not a point on the circle.
(4) It is not common to talk about circles as congruent or not congruent. If you did, you would say that two circles are congruent if and only if they have the same radius.

Before we get into anything complicated, let's make some related definitions.

Definition 14.2 A line segment with both endpoints on a circle is called a *chord* of the circle. A chord that passes through the center of the circle is called a *diameter* of the circle.

Just like the term radius, the term diameter plays two roles, a numerical one and a geometric one. The diameter in the numerical sense is just the length of the diameter in the geometric sense (and is twice the radius).

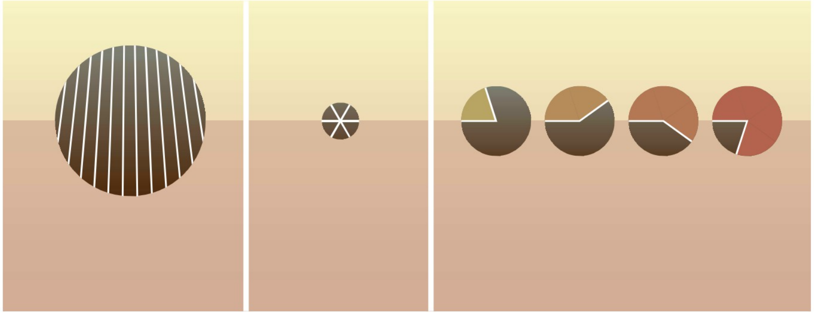

Figure 1. Twelve chords, three diameters, and four central angles.

Definition 14.3 An angle with its vertex at the center of a circle is called a *central angle* of the circle.

We will see in the next section that a line intersects a circle at most twice. Therefore, if AB is a chord of a circle, then all the points of the circle other than A and B are on one side or the other of $\overline{AB}$. Thus $\overline{AB}$ separates the points into two sets, called *arcs* of the circle. There are three types of arcs—semicircles, major arcs, and minor arcs—depending on where the chord crosses the circle.

Definition 14.4 Let AB be a diameter of a circle $\mathcal{C}$. All the points of $\mathcal{C}$ that are on one side of $\overline{AB}$, together with the endpoints A and B, form a *semicircle*.

Each diameter divides the circle into two semicircles, overlapping at the endpoints A and B.

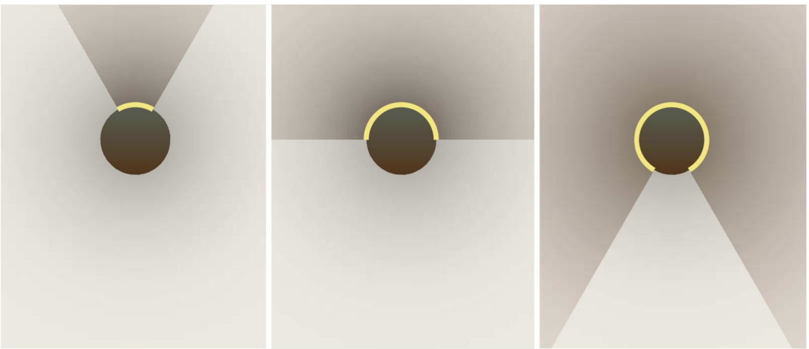

Figure 2. (l) A minor arc, (c) a semicircle, and (r) a major arc.

Definition 14.5 Let AB be a chord of a circle $\mathcal{C}$ that is not a diameter, and let O be the center of the circle. The points of $\mathcal{C}$ that are on the same side of $\overline{AB}$ as O, together with the endpoints A and B, form a *major arc*. The points of $\mathcal{C}$ that are on the opposite side of $\overline{AB}$ from O, together with the endpoints A and B, form a *minor arc*.

Like the two semicircles defined by a diameter, the major arc and minor arc defined by a chord overlap only at the endpoints A and B. We will use the notation $\overset{\frown}{AB}$ for arcs, including diameters. The notation is ambiguous, as it does not specify whether we are referring to the minor arc or to the major arc. In practice, this ambiguity rarely causes problems. Furthermore, we are usually interested in the minor arc.

There is a simple, direct, and important correspondence between arcs and central angles. Recall from chapter 9, that two rays with a common endpoint define not one, but two angles, a proper angle and a reflex angle, that are related to the minor and major arcs as described in the next exercise.

Exercise 14.1 Let AB be a chord of a circle $\mathcal{C}$ with center O that is not a diameter. Prove that the points of the minor arc $\widehat{AB}$ are A, B, and the points of $\mathcal{C}$ in the interior of the proper angle $\angle AOB$. Prove that the points of the major arc $\widehat{AB}$ are A, B, and the points of $\mathcal{C}$ in the interior of the reflex angle $\angle AOB$ (that is, the points exterior to the proper angle).

14.2 Intersections

Circles are different from the shapes we have studied up this point because they are not built out of lines or line segments. Circles share at least one characteristic with simple polygons though: they have an interior and an exterior.

Definition 14.6 For a circle $\mathcal{C}$ with center O and radius r, and for a point P that is not on $\mathcal{C}$,

- if $|OP| < r$, then P is inside $\mathcal{C}$,
- if $|OP| > r$, then P is outside $\mathcal{C}$.

The set of points inside the circle is the *interior* of the circle. The set of points outside the circle is its *exterior*.

Just like simple polygons, circles separate their interior and exterior. To get a better sense of that, we need to look at how circles intersect other geometric objects.

Theorem 14.7 *A line will intersect a circle in 0, 1, or 2 points.*

Proof Let O be the center of a circle $\mathcal{C}$ of radius r, and let ℓ be a line. It is easy to find points on ℓ that are far from $\mathcal{C}$, but are there points on ℓ that are close to $\mathcal{C}$? The easiest way to figure out how close ℓ gets to $\mathcal{C}$ is to look at the closest point on ℓ to the center O. We have seen

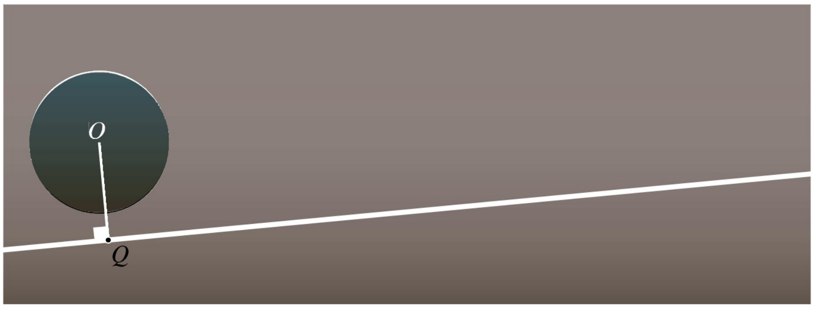

Figure 3. A circle and line that do not intersect.

(lemma 10.3) that the closest point to O on ℓ is the foot of the perpendicular, call it Q. There are three possibilities.

Zero intersections: If $|OQ| > r$, then the other points of ℓ are even farther from O, so none of the points on ℓ can be on $\mathcal{C}$.

One intersection: If $|OQ| = r$, then Q is an intersection, but it is the only intersection because the other points on ℓ are farther away from O.

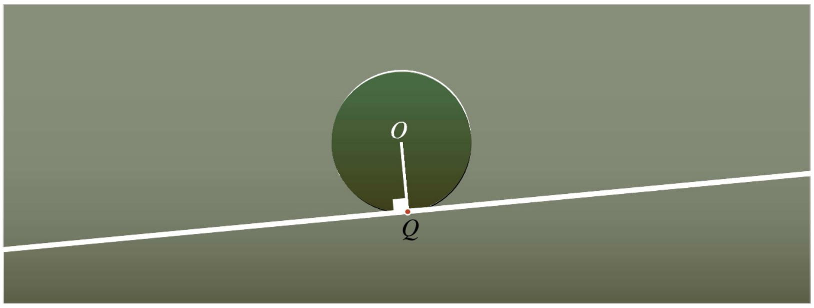

Figure 4. A circle and line that intersect at a single point.

Two intersections: If $|OQ| < r$, then the line lies both inside and outside the circle. We just need to find where the line crosses into, and then back out of, the circle. The idea is to relate a point's distance from O to its distance from Q, and we can do that with the Pythagorean theorem. If P is a point on ℓ other than Q, then $\triangle OQP$ will be a right triangle with side lengths that are related by the Pythagorean theorem:

$$|OQ|^2 + |QP|^2 = |OP|^2.$$

If P is on the circle, $|OP| = r$. Therefore $|PQ| = \sqrt{r^2 - |OQ|^2}$. Since $|OQ| < r$, this expression is a positive real number. There are then exactly two points on ℓ, one on each side of Q, that are this distance from Q.

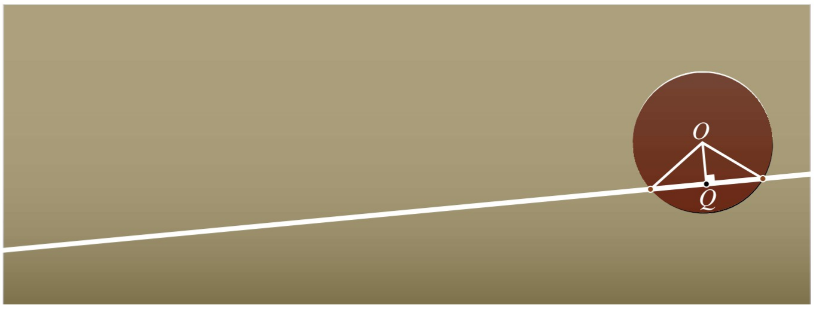

Figure 5. A circle and line that intersect at two points. □

A line that intersects a circle once (at the foot of the perpendicular) is called a *tangent* line to the circle. A line that intersects a circle twice is called a *secant* line of the circle.

There is a important corollary that turns this last theorem about lines into a statement about segments.

Corollary 14.8 *If a point P is inside a circle, and a point Q is outside it, then the segment PQ intersects the circle (exactly once).*

Proof Label the center of the circle O. From the last theorem, we know that $\overline{PQ}$ intersects the circle twice, and that the two intersections are separated by F, the foot of the perpendicular to PQ through O. The important intersection here is the one that is on the same side of the foot of the perpendicular as Q, call it R. According to the Pythagorean theorem (with $\triangle OFQ$ and $\triangle OFR$),

$$|FQ| = \sqrt{|OQ|^2 - |OF|^2} \text{ and } |FR| = \sqrt{|OR|^2 - |OF|^2}.$$

Since $|OQ| > |OR|$, $|FQ| > |FR|$, which places R between F and Q. We cannot say whether P and Q are on the same side of F, though. If they are on opposite sides of F, then $P * F * R * Q$, so R is between P and Q as needed. If P and Q are on the same side of F, then we need to look at the right triangles $\triangle OFP$ and $\triangle OFR$. They tell us that

$$|FP| = \sqrt{|OP|^2 - |OF|^2} \text{ and } |FR| = \sqrt{|OR|^2 - |OF|^2}.$$

Since $|OP| < |OR|$, $|FP| < |FR|$, which places P between F and R. Finally, if $F * P * R$ and $F * R * Q$, then R has to be between P and Q. □

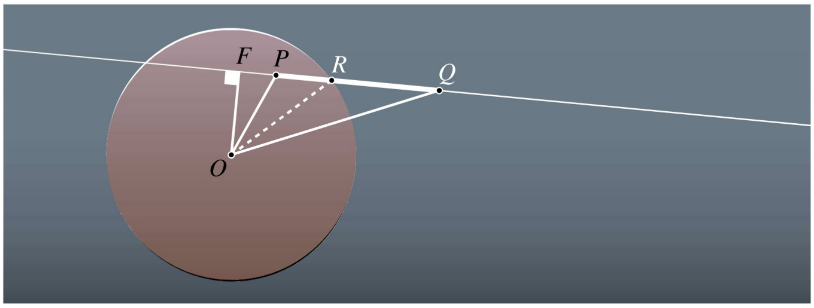

Figure 6. Intersection of a circle and a segment.

There is another important question of intersections: how can two circles intersect?

Theorem 14.9 *Two circles intersect at 0, 1, or 2 points.*

Proof Three factors come in to play here: the radii of the circles and the distance between their centers. Label

O_1, O_2 : the centers of the two circles,
r_1, r_2 : the radii of the two circles, and
c : the distance between the centers.

An intersection point X will have to be a distance r_1 from O_1 and r_2 from O_2. We know that $|O_1O_2| = c$, so the question is: can we build a triangle with sides of lengths r_1, r_2, and c? We studied this question at the end of the last chapter. There are three possibilities.

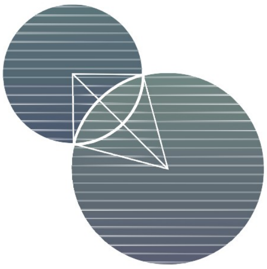

Figure 7. Two intersections.

Two intersections: when $|r_1 - r_2| < c < r_1 + r_2$.
In this case, the proposed side lengths satisfy the triangle inequality conditions. Therefore, there are exactly two triangles, $\triangle O_1XO_2$ and $\triangle O_1YO_2$, one on each side of O_1O_2, with sides of the required lengths. There are then exactly two intersections of the circles.

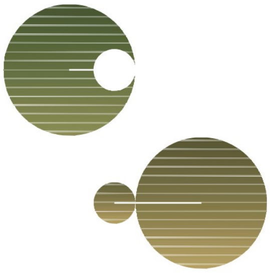

Figure 8. One intersection.

One intersection: when $c = |r_1 - r_2|$ *or* $c = r_1 + r_2$.
In these limiting cases, the triangle devolves into a line segment and the two intersections merge. In the first, either $O_1 * O_2 * X$ or $X * O_1 * O_2$, depending on which radius is larger. In the second, $O_1 * X * O_2$.

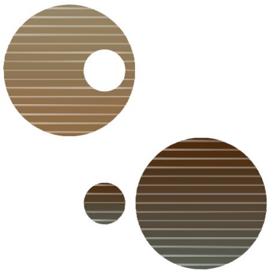

Figure 9. No intersections.

Zero intersections: when $c < |r_1 - r_2|$ *or* $c > r_1 + r_2$.
In this case, the proposed side lengths do not satisfy the triangle inequality conditions. No triangle can be formed with sides of these lengths, so the two circles cannot intersect. In the first case, one circles lies entirely inside the other. In the second, they are separated from one another.

□

As you established in exercise 14.1, there is a correspondence between central angles and arcs. In the next chapter we will establish a metrical connection between the measure of the central angle and the length of the corresponding arc (which is the basis for radian measure). In the meantime, the correspondence is a helpful way to simplify illustrations. Using an arc

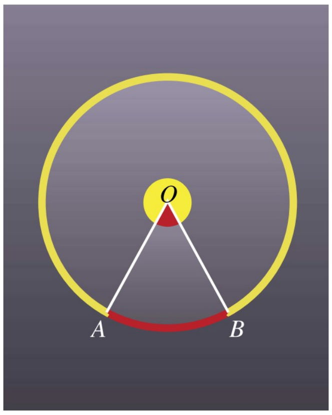

Figure 10. The major arc corresponds to the reflex angle $\angle AOB$. The minor arc corresponds to the proper angle $\angle AOB$.

to indicate a central angle keeps a picture from getting too crowded around the center of the circle.

14.3 The inscribed angle theorem

In this section we will prove the inscribed angle theorem, a result that is indispensable when working with circles. I suspect that this theorem is the most elementary result of Euclidean geometry that is generally not known to the average calculus student. Before stating the theorem, we must define an inscribed angle, the subject of the theorem.

Definition 14.10 If A, B, and C are points on a circle, then $\angle ABC$ is an *inscribed angle* on the circle.

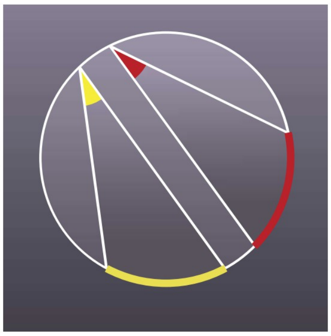

Figure 11. Two angles inscribed in a circle.

Given an inscribed angle $\angle ABC$, either proper or reflex, the points A and C are the endpoints of two arcs, either a minor and a major arc or two semicircles. Excluding the endpoints, one of the arcs will be contained in the interior of $\angle ABC$. We say, then, that $\angle ABC$ is inscribed on the arc $\overset{\frown}{AC}$. The inscribed angle theorem describes the relationship between an inscribed angle and the central angle on the same arc.

Theorem 14.11 *(The inscribed angle theorem) If $\angle ABC$ is an inscribed angle on a circle with center O, then*

$$(\angle ABC) = \frac{1}{2}(\angle AOC).$$

The proof of the inscribed angle theorem is a good demonstration of the benefits of starting with an easy case. There are three cases in the proof, depending on the location of the vertex B relative to the lines $\overline{OA}$ and $\overline{OC}$. The first case establishes the theorem for two particular locations of B, where things work out easily. But the special cases are the key that unlocks everything else.

Proof *Case 1. Where B is the intersection of $\overrightarrow{OC}^{op}$ with the circle, or where B is the intersection of $\overrightarrow{OA}^{op}$ with the circle.* We will prove the result where B is on $\overrightarrow{OC}^{op}$. To deal with the other possibility, where B is on $\overrightarrow{OA}^{op}$, just switch the letters A and C. Label $\angle AOB$ as $\angle 1$ and $\angle AOC$ as $\angle 2$. These angles are supplementary, so

$$(i) \quad (\angle 1) + (\angle 2) = 180^\circ.$$

The angle sum of $\triangle AOB$ is 180°, but in that triangle $\angle A$ and $\angle B$ are opposite congruent segments (radii), so by the isosceles triangle theorem they are congruent. Therefore

$$(ii) \quad 2(\angle B) + (\angle 1) = 180^\circ,$$

and if we subtract (ii) from (i), we get $(\angle 2) - 2(\angle B) = 0$, so $(\angle AOC) = 2(\angle ABC)$.

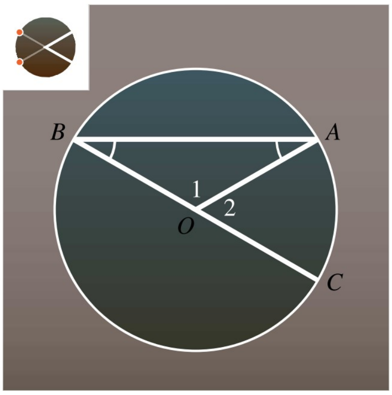

Figure 12. The inscribed angle theorem, case 1: an inscribed angle with one ray along a diameter.

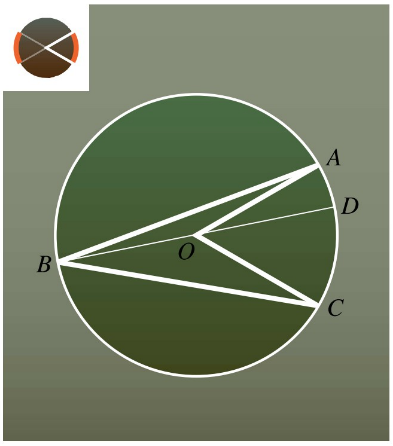

Figure 13. The inscribed angle theorem, case 2.

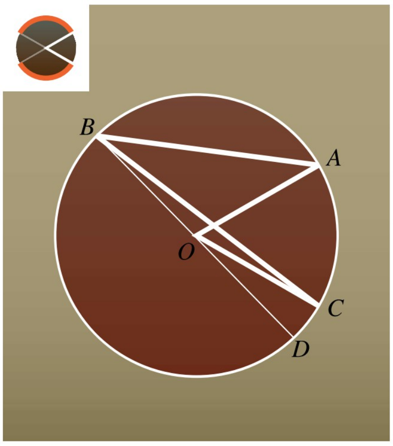

Figure 14. The inscribed angle theorem, case 3.

Case 2. Where B is in the interior of $\angle AOC$*, or where B is in the interior of the angle formed by* $\overrightarrow{OA}^{op}$ *and* $\overrightarrow{OC}^{op}$*, or when* $A * O * C$. There are three cases here—in the first the central angle is reflex, in the second it is proper, and in the third it is a straight angle—but the proof is the same for all of them. In each case, $\overline{OB}$ splits both the inscribed and the central angles. To identify the four angles, label one more point: D is the second intersection of $\overline{OB}$ with the circle (so BD is a diameter of the circle). Using angle addition in conjunction with the previous results,

$$\begin{aligned}(\angle AOC) &= (\angle AOD) + (\angle DOC)\\ &= 2(\angle ABD) + 2(\angle DBC)\\ &= 2((\angle ABD) + (\angle DBC))\\ &= 2(\angle ABC).\end{aligned}$$

Case 3. Where B is in the interior of the angle formed by $\overrightarrow{OA}$ *and* $\overrightarrow{OC}^{op}$*, or where B is in the interior of the angle formed by* $\overrightarrow{OC}$ *and* $\overrightarrow{OA}^{op}$. As in the last case, label D so that BD is a diameter. The difference this time is that we need to use angle subtraction instead of angle addition. Since subtraction is less symmetric than addition, the two cases will differ slightly (in terms of lettering). In the first,

$$\begin{aligned}(\angle AOC) &= (\angle AOD) - (\angle DOC)\\ &= 2(\angle ABD) - 2(\angle DBC)\\ &= 2((\angle ABD) - (\angle DBC))\\ &= 2(\angle ABC).\end{aligned}$$

To get the second, just switch A and C. □

There are two important and immediate corollaries to this theorem. First, because all inscribed angles on a given arc share the same central angle,

Corollary 14.12 *All inscribed angles on a given arc are congruent.*

Second, the special case where the central angle $\angle AOC$ is a straight angle, so that the inscribed angle $\angle ABC$ is a right angle, is important enough to earn its own name.

Corollary 14.13 *(Thales' theorem) If C is a point on a circle with diameter AB (and C is neither A nor B), then $\triangle ABC$ is a right triangle.*

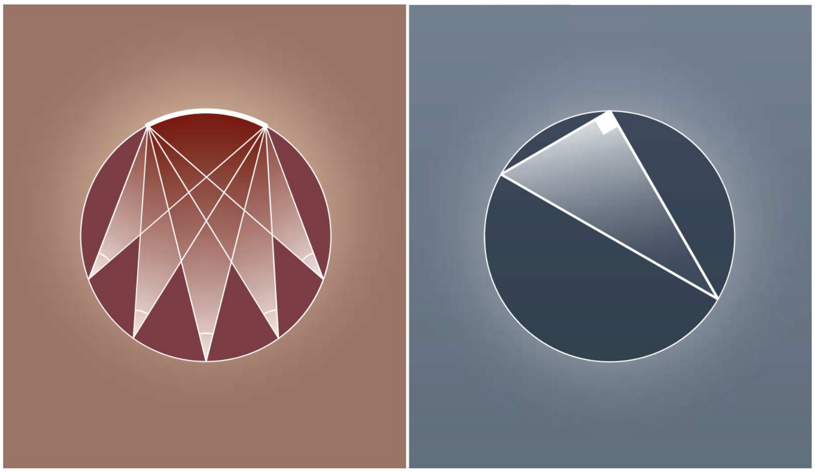

Figure 15. (l) Five congruent angles inscribed on the same arc. (r) A right angle inscribed on a semicircle.

Thales' theorem is often presented as an if-and-only-if statement, and both directions are quite useful.

Exercise 14.2 Prove that if $\triangle ABC$ is a right triangle with right angle at C, then C is a point on the circle with diameter AB.

14.4 Applications of the inscribed angle theorem

Using the inscribed angle theorem, we can establish several nice relationships between chords, secants, and tangents associated with a circle. We will look at two of these results to end this chapter.

Theorem 14.14 *(The chord-chord formula) Let $\mathscr{C}$ be a circle with center O. Suppose that AC and BD are chords of $\mathscr{C}$, and suppose that they intersect at a point P. Label the angle of intersection, $\theta = \angle APD \simeq \angle BPC$. Then*

$$(\theta) = \frac{(\angle AOD) + (\angle BOC)}{2}.$$

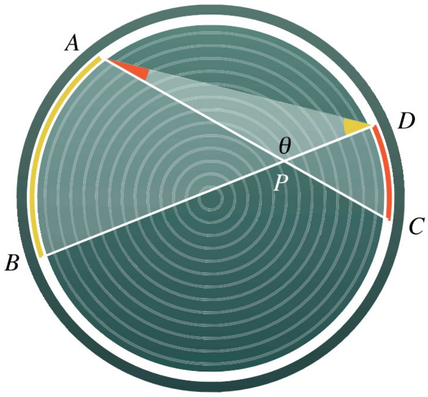

Figure 16. Two intersecting chords in a circle.

Proof The angle θ is an interior angle of $\triangle APD$, so

$$(\theta) = 180^\circ - (\angle A) - (\angle D).$$

$\angle A$ and $\angle D$ are inscribed angles: $\angle A$ is inscribed on the arc $\overset{\frown}{CD}$ and $\angle D$ is inscribed on the arc $\overset{\frown}{AB}$. According to the inscribed angle theorem, they are half the size of the corresponding central angles, so

$$\begin{aligned}(\theta) &= 180^\circ - \tfrac{1}{2}(\angle COD) - \tfrac{1}{2}(\angle AOB)\\ &= \tfrac{1}{2}(360^\circ - (\angle COD) - (\angle AOB)).\end{aligned}$$

This relates θ to central angles, but alas, not to the central angles in the formula. If we add all four central angles around O, though,

$$(\angle AOB) + (\angle BOC) + (\angle COD) + (\angle DOA) = 360^\circ$$

and so

$$(\angle BOC) + (\angle DOA) = 360^\circ - (\angle COD) - (\angle AOB).$$

Now substitute to get the desired formula:

$$(\theta) = \tfrac{1}{2}((\angle BOC) + (\angle DOA)). \qquad \square$$

According to the chord-chord formula, as long as the intersection point P is inside the circle, θ can be computed as the average of two central angles. What would happen if P moved outside the circle? Then we would not be talking about chords, since chords stop at the circle boundary, but about the secant lines containing them.

Theorem 14.15 *(The secant-secant formula) Suppose that A, B, C, and D are points on a circle arranged so that $\square ABCD$ is a simple quadrilateral, and that the secant lines AB and CD intersect at a point P that is outside the circle. Label the angle of intersection, $\angle APD$, as θ. Let $\angle AOD$ and $\angle BOC$ be taken so that P is in their interiors (that is, the angles may be reflex). If P occurs on the same side of AD as B and C, then*

$$(\theta) = \frac{(\angle AOD) - (\angle BOC)}{2}.$$

If P occurs on the same side of BC as A and D, then

$$(\theta) = \frac{(\angle BOC) - (\angle AOD)}{2}.$$

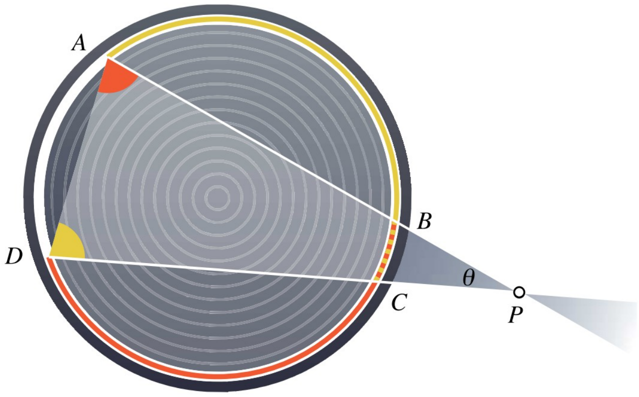

Figure 17. Two lines that intersect outside of the circle.

Proof There is obviously a great deal of symmetry between the two cases, so let me just address the first. The same principles apply here as in the last proof. Angle θ is an interior angle of $\triangle APD$, so

$$(\theta) = 180^\circ - (\angle A) - (\angle D).$$

$\angle A$ and $\angle D$ are inscribed angles— $\angle A$ is inscribed on arc $\widehat{BD}$ and $\angle D$ is inscribed on arc $\widehat{AC}$. We need to use the inscribed angle theorem to relate the angles to central angles, and in this case, the central angles overlap, so we will need to break them down further, but the rest is straightforward.

$$\begin{aligned}(\theta) &= 180^\circ - \tfrac{1}{2}(\angle BOD) - \tfrac{1}{2}(\angle AOC)\\ &= \tfrac{1}{2}[360^\circ - (\angle BOD) - (\angle AOC)]\\ &= \tfrac{1}{2}[360^\circ - (\angle BOC) - (\angle COD) - (\angle AOB) - (\angle BOC)]\\ &= \tfrac{1}{2}[[360^\circ - (\angle AOB) - (\angle BOC) - (\angle COD)] - (\angle BOC)]\\ &= \tfrac{1}{2}[(\angle AOD) - (\angle BOC)].\end{aligned}$$

□

14.5 Exercises

14.3. Prove that no line is entirely contained in any circle.

14.4. Prove that a circle is convex. That is, prove that if points P and Q are inside a circle, then all the points on the segment PQ are inside the circle.

14.5. Prove that for any circle there is a triangle entirely contained in it, so all the points of the triangle are inside the circle.

14.6. Prove that for any circle there is a triangle which entirely contains it, so all the points of the circle are in the interior of the triangle.

14.7. Let P be a point on a line ℓ, and let Q be a point that is not on ℓ. Prove that there is a unique circle $\mathcal{C}$ that passes through Q and is tangent to ℓ at P.

14.8. Suppose that $\square ABCD$ is cyclic, so there is a circle through all four of its vertices. Prove that $(\angle A) + (\angle C) = 180^\circ$ and $(\angle B) + (\angle D) = 180^\circ$.

14.9. Given a circle $\mathcal{C}$ with center O and points A and C on $\mathcal{C}$, prove that:

- if a point B is inside $\mathcal{C}$, then $(\angle ABC) > \frac{1}{2}(\angle AOC)$, and
- if a point B is outside $\mathcal{C}$, then $(\angle ABC) < \frac{1}{2}(\angle AOC)$.

Note that you will have to think about when $\angle ABC$ and $\angle AOC$ should be taken as the reflex angle.

14.10. Let $\angle ABC$ be an inscribed angle on a circle. Prove that, excluding the endpoints, exactly one of the two arcs $\overset{\frown}{AC}$ lies in the interior of $\angle ABC$.

14.11. Let $\mathcal{C}$ be a circle and P be a point outside of it. Prove that there are exactly two lines that pass through P and are tangent to $\mathcal{C}$. Let Q and R be the points of tangency for the two lines. Prove that PQ and PR are congruent.

14.12. Let A be a point outside of a circle $\mathcal{C}$ with center O. Let B be the point on $\mathcal{C}$ so that $A * O * B$. There are two lines through A that are tangent to $\mathcal{C}$. Label their intersections with $\mathcal{C}$ as P and Q. What is the relationship between the angle measures $(\angle PAQ)$ and $(\angle PBQ)$?

14.13. Let $\mathcal{P}$ be a regular polygon. Prove that there is a unique circle $\mathcal{C}$ contained in $\mathcal{P}$ so that $\mathcal{C}$ is tangent to each of the sides of $\mathcal{P}$. This is called the circle *inscribed* in $\mathcal{P}$.

14.14. Suppose that a parallelogram is inscribed in a circle. Prove that the parallelogram must be a rectangle.

14.15. Let $\square ABCD$ be a trapezoid with exactly one set of parallel sides that is inscribed in a circle. Prove that the non-parallel sides of $\square ABCD$ must be congruent.

14.16. Suppose that circles $\mathcal{C}_1$ with center O_1 and $\mathcal{C}_2$ with center O_2 intersect at two points P and Q. Prove that $\angle O_1PO_2 \simeq \angle O_1QO_2$.

14.17. Let $\triangle ABC$ be equilateral, with sides of length a. Let $\mathcal{C}_A$, $\mathcal{C}_B$, and $\mathcal{C}_C$ be three circles, each with radius $a/2$, centered at A, B, and C. The three circles are tangent to one another and determine a curved but approximately triangular region in the center of $\triangle ABC$. Show that a circle can be inscribed in the region, tangent to $\mathcal{C}_A$, $\mathcal{C}_B$, and $\mathcal{C}_C$. What is the radius of this circle? Hint: see exercise 13.14.

14.18. The "tangent-tangent" formula. Let P be a point that is outside of a circle $\mathscr{C}$. Consider the two tangent lines to $\mathscr{C}$ that pass through P and let A and B be the points of tangency between those lines and the circle. Prove that

$$(\angle APB) = \frac{(\angle 1) - (\angle 2)}{2}$$

where $\angle 1$ is the reflex central angle corresponding to the major arc $\widehat{AB}$ and $\angle 2$ is the proper central angle corresponding to the minor arc $\widehat{AB}$.

14.19. Let AC and BD be two chords of a circle that intersect at a point P inside the circle. Prove that

$$|AP| \cdot |CP| = |BP| \cdot |DP|.$$

14.6 References

I learned of the chord-chord, secant-secant, and tangent-tangent formulas in the Wallace and West book *Roads to Geometry* [WW04]. They use the names two-chord angle theorem, two-secant angle theorem, and two-tangent angle theorem.

15

Circumference

15.1 A theorem on perimeters

In chapter 9 on polygons, we defined the perimeter of a polygon $\mathcal{P} = P_1 \cdots P_n$ as

$$|\mathcal{P}| = \sum_{i=1}^{n} |P_i P_{i+1}|,$$

but then left it at that. In this lesson we are going to use perimeters of cyclic polygons to find the circumference of the circle. Along the way, we will need to use the following result that compares the perimeters of two convex polygons when one is contained in the other. We will prove the theorem by a process of "shaving down" the sides of the larger polygon until we reach the smaller one.

Theorem 15.1 *If $\mathcal{P}$ and $\mathcal{Q}$ are convex polygons and all the points of $\mathcal{P}$ are on or inside $\mathcal{Q}$, then $|\mathcal{P}| \leq |\mathcal{Q}|$.*

Proof Some of the edges of $\mathcal{P}$ may run along the edges of $\mathcal{Q}$, but unless $\mathcal{P} = \mathcal{Q}$, at least one edge of $\mathcal{P}$ must pass through the interior of $\mathcal{Q}$. Let s be one of those interior edges. The line containing s intersects $\mathcal{Q}$ twice—call the intersections a and b—dividing $\mathcal{Q}$ into two smaller polygons that share the side ab, one on the same side of s as $\mathcal{P}$, the other on the opposite side. Define a new polygon $\mathcal{Q}_1$ that consists of

- points of $\mathcal{Q}$ on the same side of s as $\mathcal{P}$, and
- points on the segment ab.

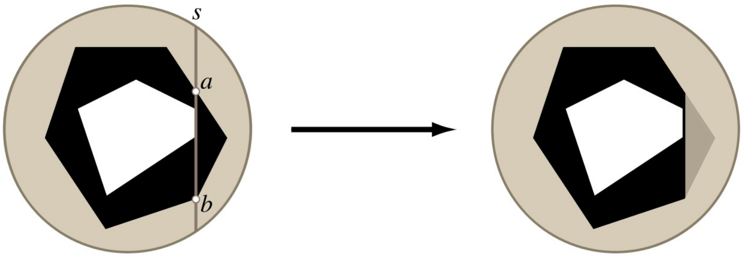

Figure 1. Shaving a corner off of a polygon.

There are two things to notice about $\mathcal{Q}_1$. First, $\mathcal{Q}_1$ and $\mathcal{P}$ have one more coincident side (the side s) than $\mathcal{Q}$ and $\mathcal{P}$ had. Second, the portions of $\mathcal{Q}$ and $\mathcal{Q}_1$ on the side of s with $\mathcal{P}$ are identical, so the segments making up that part contribute the same amount to their perimeters. On the other side, though, the path that $\mathcal{Q}$ takes from a to b is longer than the direct route along the segment ab of $\mathcal{Q}_1$ (because of the triangle inequality). Combining the two parts, we get $|\mathcal{Q}_1| \leq |\mathcal{Q}|$.

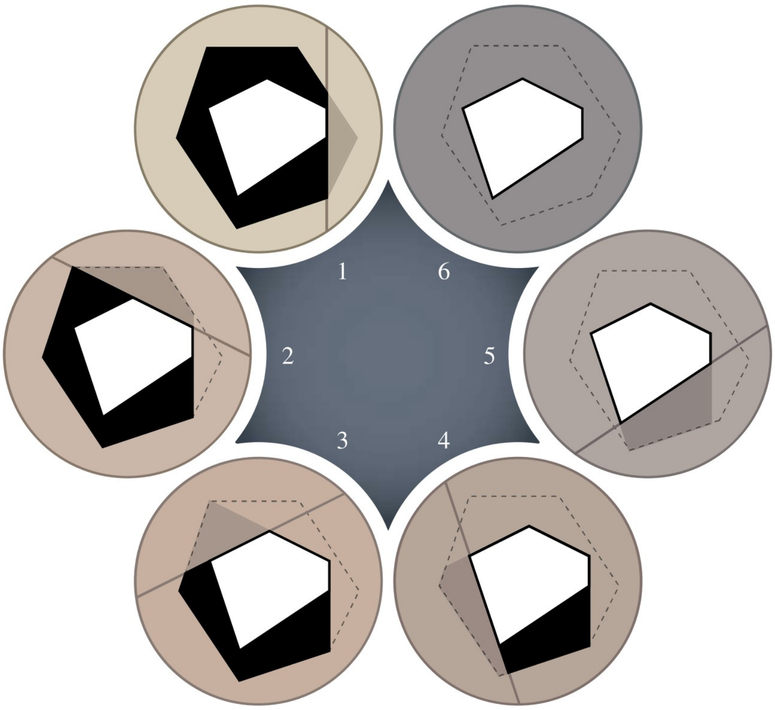

Figure 2. One at a time, shave the edges of the outer polygon down to the inner one.

Now we can repeat this process with $\mathcal{P}$ and $\mathcal{Q}_1$, generating $\mathcal{Q}_2$ with even smaller perimeter than $\mathcal{Q}_1$ and another coincident side with $\mathcal{P}$. And again, to get $\mathcal{Q}_3$. Eventually, though, after say m steps, we run out of sides that pass through the interior, at which point $\mathcal{P} = \mathcal{Q}_m$. Then

$$|\mathcal{P}| = |\mathcal{Q}_m| \leq |\mathcal{Q}_{m-1}| \leq \cdots \leq |\mathcal{Q}_2| \leq |\mathcal{Q}_1| \leq |\mathcal{Q}|. \qquad \square$$

15.2 Circumference

The purpose of this chapter is to understand the connection between the radius of a circle, and the distance around it, its circumference. The final result, the formula $C = 2\pi r$, ranks with the Pythagorean theorem in celebrity, although I think it is an often misunderstood celebrity. Let's be clear about what this equation is not. It is not an equation comparing two known quantities C and $2\pi r$. Instead, it is saying that the ratio $C/(2r)$ is a constant. The constant is what we have come to call π.

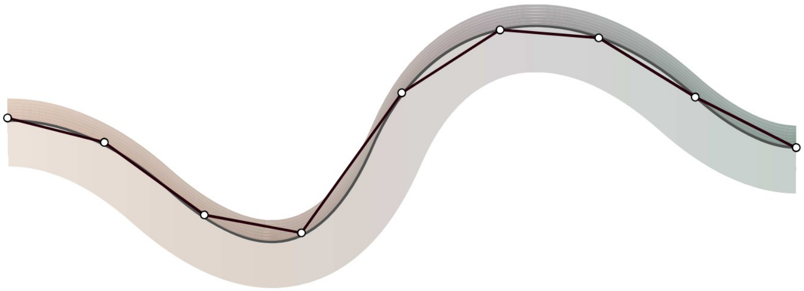

Figure 3. An approximation of an arc by segments.

To define the circumference of a circle, let's borrow an idea from calculus, the idea of approximating a curve by straight line segments, and then refining the approximation by increasing the number of segments. For a circle $\mathcal{C}$, the approximating line segments will be the edges of a simple cyclic polygon $\mathcal{P}$ inscribed in the circle. We will want the circumference of $\mathcal{C}$ to be bigger than the perimeter of $\mathcal{P}$. We should also expect that by adding in additional vertices to $\mathcal{P}$, we should be able to get the perimeter of $\mathcal{P}$ as close as we want to the circumference of $\mathcal{C}$. All this suggests that to get the circumference of $\mathcal{C}$, we need to find out how large the perimeters of inscribed polygons can be.

Definition 15.2 The circumference of a circle $\mathcal{C}$, written $|\mathcal{C}|$, is

$$|\mathcal{C}| = \sup \left\{ |\mathcal{P}| \middle| \mathcal{P} \text{ is a simple cyclic polygon inscribed in } \mathcal{C} \right\}.$$

There is nothing in the definition to guarantee that the supremum exists. It is conceivable that the lengths of the approximating perimeters might grow with bound. An example is the *Koch snowflake*. It is constructed as follows. Take an equilateral triangle with sides of length 1. The perimeter of this triangle is 3. Divide each side into thirds. On each middle third, build an equilateral triangle by adding two more sides then remove the original side. You have made a shape with $3 \cdot 4$ sides, each with length 1/3, for a perimeter of 4. Now iterate: divide the sides into thirds; build equilateral triangles on each middle third, and remove the base. That will make $3 \cdot 16$ sides of length 1/9, for a perimeter of 16/3. After the next step, there are $3 \cdot 64$ sides of length 1/27 for a perimeter of 64/9. Generally, after n iterations, there are $3 \cdot 4^n$ sides of length $1/3^n$ for a total perimeter of $4^n/3^{n-1}$, and

$$\lim_{n\to\infty} \frac{4^n}{3^{n-1}} = \lim_{n\to\infty} 3 \left(\frac{4}{3}\right)^n = \infty.$$

The Koch snowflake, which is the limiting shape in this process, has infinite perimeter! The first thing we need to do, then, is to make sure that circles are better behaved than this.

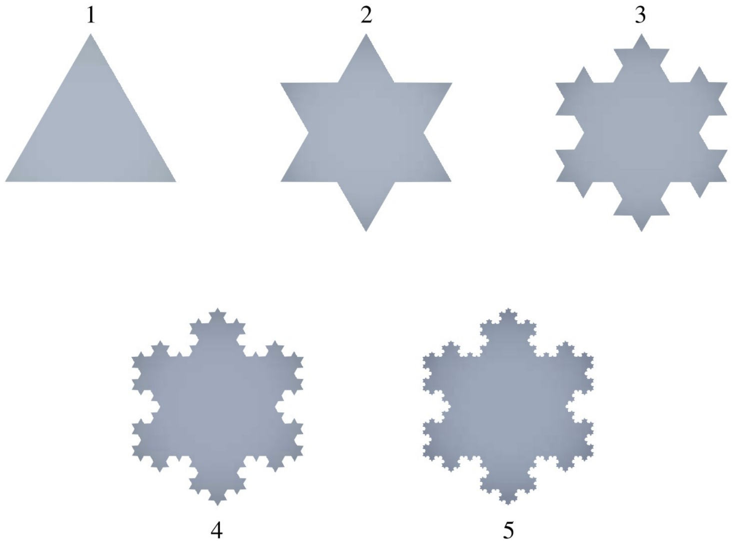

Figure 4. The first few steps in the construction of the Koch snowflake.

Theorem 15.3 *If* $\mathcal{C}$ *is a circle of radius* r*, then* $|\mathcal{C}| \leq 8r$.

Proof The first step is to build a circumscribing square around $\mathcal{C}$, the smallest square that still contains $\mathcal{C}$. Begin by choosing two perpendicular diameters d_1 and d_2. Each will intersect $\mathcal{C}$ twice, for a total of four intersections, P_1, P_2, P_3, and P_4. For each i between 1 and 4, let t_i be the tangent line to $\mathcal{C}$ at P_i. The tangents intersect to form the circumscribing square. The length of each side of the square is equal to the diameter of $\mathcal{C}$, so the perimeter of the square is $4 \cdot 2r = 8r$.

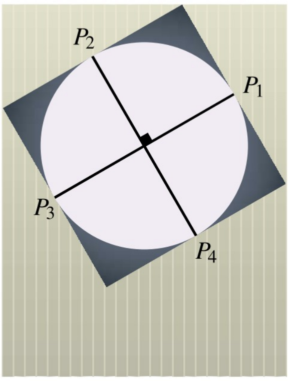

Figure 5. The circumscribing square.

Now we turn to the theorem we proved to start this chapter. Each simple cyclic polygon inscribed in $\mathcal{C}$ is a convex polygon contained in the circumscribing square. Therefore the perimeter of any such approximating polygon is bounded above by $8r$. Remember that we have defined $|\mathcal{C}|$ to be the supremum of all the approximating perimeters, so it cannot exceed $8r$ either. □

Now that we know that a circle has a circumference, the next step is to find a way to calculate it. The key to that is the next theorem.

Theorem 15.4 *The ratio of the circumference of a circle to its radius is a constant.*

Proof Let's suppose that the ratio is not a constant, so that there are two circles $\mathcal{C}_1$ and $\mathcal{C}_2$ with centers O_1 and O_2 and radii r_1 and r_2, but with unequal ratios

$$|\mathcal{C}_1|/r_1 > |\mathcal{C}_2|/r_2.$$

As we have defined circumference, there are approximating cyclic polygons to $\mathcal{C}_1$ whose perimeters are arbitrarily close to its circumference. In particular, there is an approximating cyclic polygon $\mathcal{P} = P_1P_2\ldots P_n$ for $\mathcal{C}_1$ so that

$$|\mathcal{P}|/r_1 > |\mathcal{C}_2|/r_2.$$

We can construct a cyclic polygon $\mathcal{Q}$ on $\mathcal{C}_2$ that is similar to $\mathcal{P}$. Intuitively, we just need to scale $\mathcal{P}$ so that it fits in the circle $\mathcal{C}_2$. The formal construction is:

- Begin by placing a point Q_1 on circle $\mathcal{C}_2$.
- Locate Q_2 on $\mathcal{C}_2$ so that $\angle P_1O_1P_2$ is congruent to $\angle Q_1O_2Q_2$ (there are two choices for Q_2).
- Locate Q_3 on $\mathcal{C}_2$ and on the opposite side of O_2Q_2 from Q_1 so that $\angle P_2O_1P_3$ is congruent to $\angle Q_2O_2Q_3$.
- Continue placing points on $\mathcal{C}_2$ in this fashion until Q_n has been placed to form the polygon $\mathcal{Q} = Q_1Q_2\ldots Q_n$. At the end of the process $\angle P_nO_1P_1$ is congruent to $\angle Q_nO_2Q_1$ by angle subtraction.

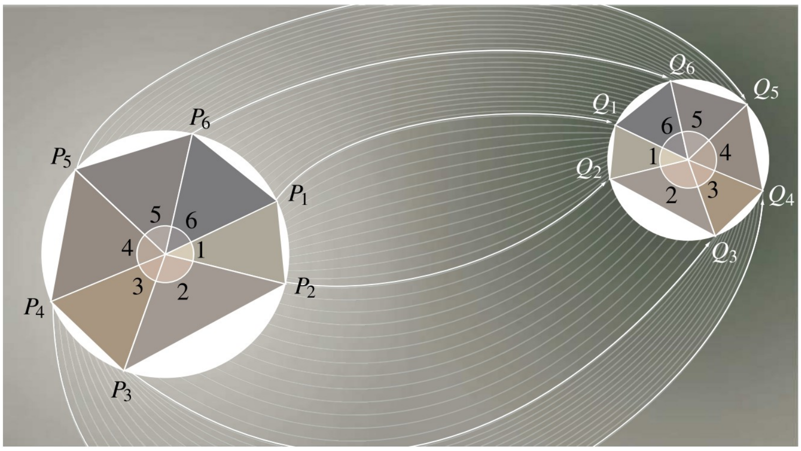

Figure 6. The ratio $|Q_iQ_{i+1}|/|P_iP_{i+1}|$ is a constant.

Then

$$\frac{|O_2Q_i|}{|O_1P_i|} = \frac{r_2}{r_1} = \frac{|O_2Q_{i+1}|}{|O_1P_{i+1}|} \text{ and } \angle Q_iO_2Q_{i+1} \simeq \angle P_iO_1P_{i+1},$$

so by SAS similarity, $\triangle Q_iO_2Q_{i+1}$ is similar to $\triangle P_iO_1P_{i+1}$. That gives us the ratio of the third sides of the triangle as

$$\frac{|Q_iQ_{i+1}|}{|P_iP_{i+1}|} = \frac{r_2}{r_1}.$$

Thus we can describe the perimeter of $\mathcal{Q}$ as

$$|\mathcal{Q}| = \sum_{i=1}^{n} |Q_iQ_{i+1}| = \sum_{i=1}^{n} \frac{r_2}{r_1}|P_iP_{i+1}| = \frac{r_2}{r_1}\sum_{i=1}^{n} |P_iP_{i+1}| = \frac{r_2}{r_1}|\mathcal{P}|.$$

That would mean that

$$\frac{|\mathcal{Q}|}{r_2} = \frac{|\mathcal{P}|}{r_1} > \frac{|\mathcal{C}_2|}{r_2}.$$

That is, $|\mathcal{Q}| > |\mathcal{C}_2|$, when in fact the circumference of $\mathcal{C}_2$ is supposed to be greater than the perimeter of any of its approximating cyclic polygons. □

Definition 15.5 The constant π is the ratio of the circumference of a circle to its diameter: $\pi = |\mathcal{C}|/(2r)$.

It is more convenient to express this definition in terms of a limit rather than a supremum. Fortunately, the supremum can be reached as a limit of perimeters of a sequence of regular polygons as follows. Arrange n angles each measuring $360^\circ/n$ around the center of a circle $\mathcal{C}$. The rays of the angles intersect $\mathcal{C}$ n times, and the points P_i are the vertices of a regular n-gon, $\mathcal{P}_n = P_1P_2 \ldots P_n$. The tangent lines to $\mathcal{C}$ at the neighboring points P_i and P_{i+1} intersect at a point Q_i. Taken together, the n points are the vertices of another regular n-gon $\mathcal{Q}_n = Q_1Q_2 \ldots Q_n$. The polygon $\mathcal{P}_n$ is just one of the many cyclic polygons inscribed in $\mathcal{C}$ so $|\mathcal{P}_n| \leq |\mathcal{C}|$. The polygon $\mathcal{Q}_n$ circumscribes $\mathcal{C}$, and every cyclic polygon inscribed on $\mathcal{C}$ lies inside $\mathcal{Q}_n$, so $|\mathcal{Q}_n| \geq |\mathcal{C}|$.

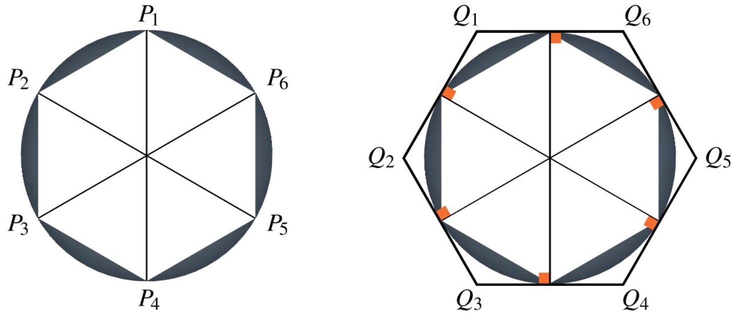

Figure 7. Regular inscribed (l) and circumscribed (r) hexagons.

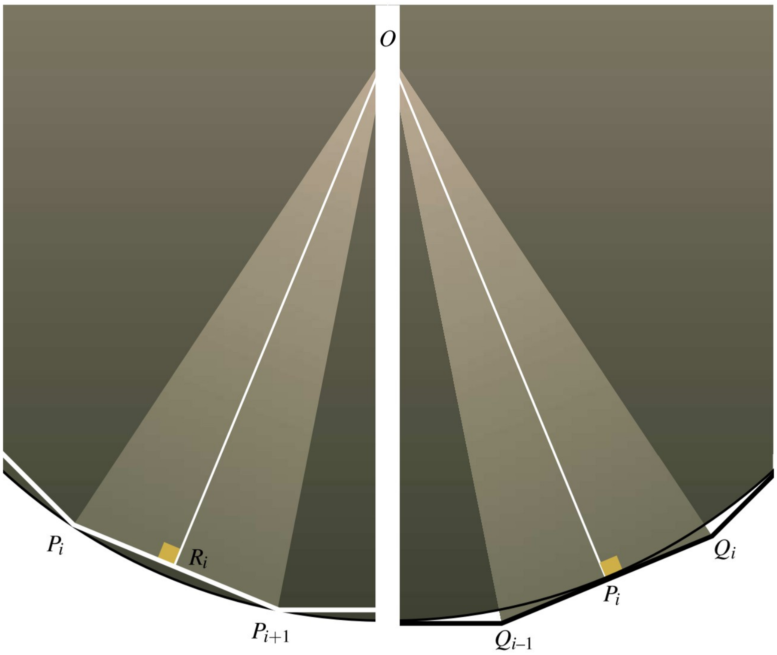

Figure 8. Approximation by inscribed and circumscribed polgons.

The lower bound prescribed by $\mathcal{P}_n$. $\overrightarrow{OQ_i}$ is a perpendicular bisector of P_iP_{i+1}, intersecting it at a point R_i and dividing $\triangle OP_iP_{i+1}$ in two. By the HL congruence theorem for right triangles, the two parts, $\triangle OR_iP_i$ and $\triangle OR_iP_{i+1}$, are congruent. Then $\mathcal{P}_n$ is built from $2n$ segments of length $|P_iR_i|$. Now for a little trigonometry:

$$\sin(360^\circ/2n) = \frac{|P_iR_i|}{r} \implies |P_iR_i| = r\sin(360^\circ/2n)$$

so $|\mathcal{P}_n| = 2nr\sin(360^\circ/2n)$.

The upper bound prescribed by $\mathcal{Q}_n$. $\overrightarrow{OP_i}$ is a perpendicular bisector of $Q_{i-1}Q_i$, intersecting it at P_i and dividing $\triangle OQ_{i-1}Q_i$ in two. By SAS, the two parts, $\triangle OP_iQ_{i-1}$ and $\triangle OP_iQ_i$, are congruent. Then $\mathcal{Q}_n$ is built from $2n$ segments of length $|P_iQ_i|$. Because

$$\tan(360^\circ/2n) = |P_iQ_i|/r \implies |P_iQ_i| = r\tan(360^\circ/2n),$$

$|\mathcal{Q}_n| = 2nr\tan(360^\circ/2n)$.

Let's compare $|\mathcal{P}_n|$ and $|\mathcal{Q}_n|$ as n increases (the key to the calculation is that as x approaches 0, $\cos(x)$ approaches 1):

$$\begin{aligned}
\lim_{n\to\infty}\frac{|\mathcal{P}_n|}{|\mathcal{Q}_n|} &= \lim_{n\to\infty}\frac{2nr\tan(360^\circ/2n)}{2nr\sin(360^\circ/2n)}\\
&= \lim_{n\to\infty}\frac{\sin(360^\circ/2n)}{\cos(360^\circ/2n)}\cdot\frac{1}{\sin(360^\circ/2n)}\\
&= \lim_{n\to\infty}\frac{1}{\cos(360^\circ/2n)}\\
&= 1.
\end{aligned}$$

Therefore $\lim_{n\to\infty} |\mathcal{P}_n| = \lim_{n\to\infty} |\mathcal{Q}_n|$. Since $|\mathcal{C}|$ is trapped between $|\mathcal{P}_n|$ and $|\mathcal{Q}_n|$ for all n, and since they approach the same number as n goes to infinity, $|\mathcal{C}|$ also approaches this number. That gives a more comfortable equation for circumference as

$$|\mathcal{C}| = \lim_{n\to\infty} 2nr \sin(360^\circ/2n),$$

and since $|\mathcal{C}| = 2\pi r$, we can make a definition of π as

$$\pi = \lim_{n\to\infty} n \sin(360^\circ/2n).$$

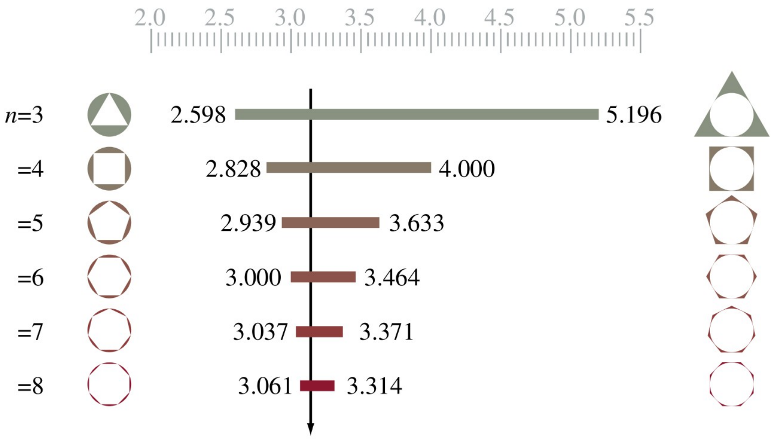

Figure 9. Using perimeters of regular inscribed and circumscribed polygons to determine upper and lower bounds for π.

15.3 Lengths of arcs and radians

It doesn't take much modification to get a formula for the length of an arc. The 360° in the formula for $|\mathcal{C}|$ is the measure of the central angle corresponding to an arc that goes completely around the circle. To get the measure of any other arc, we can replace the 360° with the measure of the corresponding central angle.

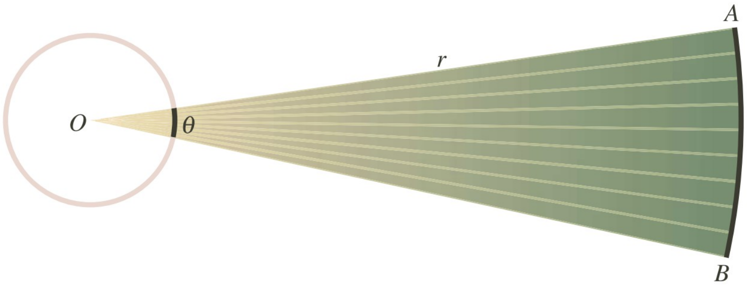

Figure 10. An arc.

Theorem 15.6 *If $\widehat{AB}$ is the arc of a circle with radius r, and if θ is the measure of the central angle $\angle AOB$, then*

$$|\widehat{AB}| = \frac{\pi}{180^\circ}\theta \cdot r.$$

Proof To start, replace the 360° in the circumference formula with θ:

$$|\widehat{AB}| = \lim_{n\to\infty} 2nr \sin(\theta/2n) = 2r \cdot \lim_{n\to\infty} n \sin(\theta/2n).$$

This limit is clearly related to the one that defines π. We can absorb the difference between the two into the variable with the substitution $n = m \cdot \theta/360^\circ$. As n approaches infinity, m will as well, so

$$\begin{aligned} |\widehat{AB}| &= 2r \cdot \lim_{m\to\infty} \frac{m\cdot\theta}{360^\circ} \sin\left(\frac{\theta}{2m\cdot\theta/360^\circ}\right) \\ &= \frac{2r\theta}{360^\circ} \cdot \lim_{m\to\infty} m \sin(360^\circ/2m) \\ &= \frac{\theta}{180^\circ} r\pi. \end{aligned}$$

□

There is one more thing to notice before the end of this chapter. The arc length formula provides a direct connection between angle measure (of the central angle) and distance (along the arc). And yet, the $\frac{\pi}{180^\circ}$ factor in that formula suggests that distance and the degree measurement system are a little out of sync with one another. This can be fixed by modernizing our method of angle measurement. The preferred angle measurement system, and the one that we will use, is *radian* measurement.

Definition 15.7 One radian is $180^\circ/\pi$.

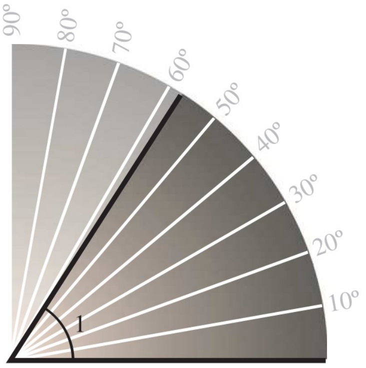

Figure 11. One radian is approximately 57.296°.

Then the measure of a straight angle is π radians. The measure of a right angle is $\pi/2$ radians. One complete turn of the circle is 2π radians. If $\theta = (\angle AOB)$ is measured in radians, then $|\widehat{AB}| = r \cdot \theta$.

15.4 Exercises

15.1. Let A and B be points on a circle $\mathcal{C}$ with radius r. Let θ be the measure of the central angle corresponding to the minor arc (or semicircle) $\widehat{AB}$. What is the relationship (in the form of an equation) between θ, r, and $|AB|$?

15.2. Let A and B be points on a circle $\mathcal{C}$ with center O and radius r. If $(\angle BAO) = \theta$, what is $|\widehat{AB}|$ (in terms of r and θ)?

15.3. Let AB be a diameter of a circle $\mathcal{C}$, and let P be a point on AB. Let $\mathcal{C}_1$ be the circle with diameter AP and let $\mathcal{C}_2$ be the circle with diameter BP. Show that the sum of the circumferences of $\mathcal{C}_1$ and $\mathcal{C}_2$ is equal to the circumference of $\mathcal{C}$ (the shape formed by the three semicircles on one side of AB is called an *arbelos*).

15.4. What is the radius of the circle that passes through the three vertices of a equilateral triangle with sides of length 1?

15.5. Let $\mathcal{C}_1$ be the circle inscribed in an equilateral triangle $\triangle ABC$ with sides of length 1. There is a line that is parallel to AB and tangent to $\mathcal{C}_1$ that divides $\triangle ABC$ into a trapezoid and a smaller equilateral triangle. Let $\mathcal{C}_2$ be the circle inscribed in the smaller equilateral triangle. Continuing in this way, we can form a stack of smaller and smaller circles. Is the sum of their circumferences finite, and if so, what is it?

15.6. In the construction of the Koch snowflake, the middle third of each segment is replaced with two-thirds of an equilateral triangle. Suppose, instead, that middle third was replaced with three of the four sides of a square. What is the perimeter of the n-th stage of this operation? Would the limiting perimeter still be infinite?

15.7. This problem deals with the possibility of angle measurement systems other than degrees or radians. Let $\mathscr{A}$ be the set of angles in the plane. Consider a function

$$\star : \mathscr{A} \to (0, \infty) : \angle A \to (\angle A)^\star$$

that satisfies

- if $\angle A \simeq \angle B$, then $(\angle A)^\star = (\angle B)^\star$
- if D is in the interior of $\angle ABC$, then

$$(\angle ABC)^\star = (\angle ABD)^\star + (\angle DBC)^\star.$$

Prove that the $\star$ measurement system is a constant multiple of the degree measurement system (or, for that matter, the radian measurement system). That is, prove that there is a $k > 0$ such that for all $\angle A \in \mathscr{A}$,

$$(\angle A)^\star = k \cdot (\angle A).$$

15.5 References

The Koch snowflake is an example of a fractal. Gerald Edgar's book *Measure, Topology, and Fractal Geometry* [Edg90], deals with these objects and their measures.

;.   :A5 886   )

23

Reflections

This chapter introduces the first type of isometry, reflection across a line. As it turns out, reflections are the building blocks for all isometries. In this chapter we will see why, in the three reflections theorem. This theorem provides the strategy that we will use over the next few chapters to classify all isometries. First, we must define a reflection.

Definition 23.1 Given a line ℓ, the *reflection* across ℓ is the mapping $s : \mathbb{E} \to \mathbb{E}$ so that

- if P is on ℓ, then $s(P) = P$, and
- if P is not on ℓ, then $s(P)$ is the unique point on the line through P perpendicular to ℓ that is the same distance from ℓ as P, but that is on the opposite side of ℓ from P.

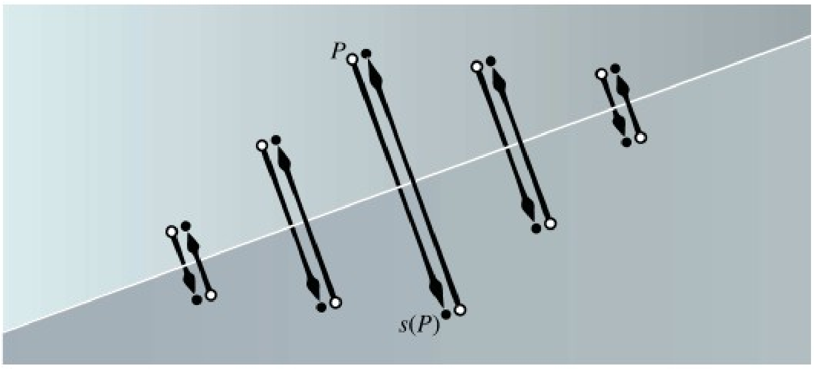

Figure 1. Reflecting points across a line.

We first verify that a reflection is an isometry.

Theorem 23.2 *A reflection is an isometry.*

Proof It is easy to see that a reflection s is a bijection. Look at the composition $s \circ s$: the swap of points done by the first application of s is immediately undone by the second application of s, so that $s^2 = id$. Therefore s is its own inverse, and for a mapping to have an inverse, it must be a bijection.

-7 X* H*3 & Y 4 *1 JZ[51 J & . ,6 X* *7\

The other step is to show that s preserves distances, that $|s(PQ)| = |PQ|$ for any points P and Q. The only thing that makes this part difficult is that there are many possible positions of P and Q relative to each other and to ℓ, the line of reflection:

- **I:** P and Q are both on ℓ.
- **II:** One of P and Q is on ℓ, while the other is not.
  - [1] $\overline{PQ}$ is perpendicular to ℓ
  - [2] $\overline{PQ}$ is not perpendicular to ℓ
- **III:** Neither P nor Q is on ℓ.
  - [1] $\overline{PQ}$ is perpendicular to ℓ
    - [i] P and Q are on the same side of ℓ
    - [ii] P and Q are on opposite sides of ℓ
  - [2] $\overline{PQ}$ is not perpendicular to ℓ
    - [i] P and Q are on the same side of ℓ
    - [ii] P and Q are on opposite sides of ℓ

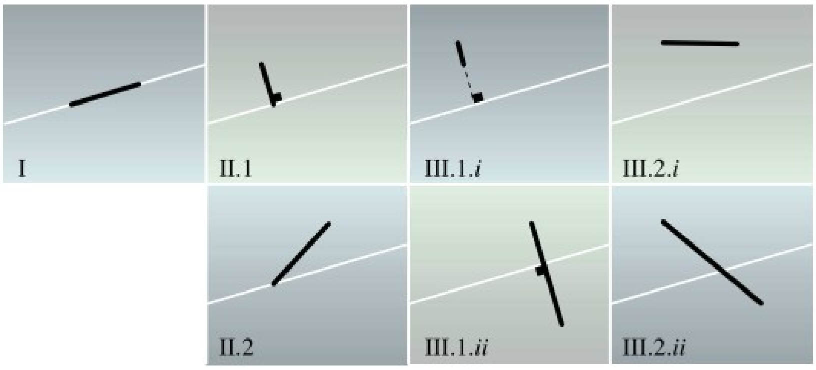

Figure 2. Verifying that a reflection is an isometry. There are many cases, depending on the position of the segment PQ relative to the reflecting line ℓ.

At this point, none of these cases should cause any trouble. Consider case III.2.*i*, which is the archetypal case in this proof. To verify the claim in this case, first label two more points (both of which are fixed by s):

F_P**:** the foot of the perpendicular to ℓ through P, and
F_Q**:** the foot of the perpendicular to ℓ through Q.

From the definition of a reflection,

$$PF_P \simeq s(PF_P) \quad \text{and} \quad QF_Q \simeq s(QF_Q)$$

and the angles at F_P and F_Q are right angles. Because $F_P F_Q$ is congruent to itself, by SASAS, $\square PF_PF_QQ$ and $s(\square PF_PF_QQ)$ are congruent, and therefore PQ and $s(PQ)$ are the same length. □

We saw in the last chapter that if an isometry fixes two points, it must fix all the points on the line through them. Of course, every reflection fixes all the points of a line. A good question

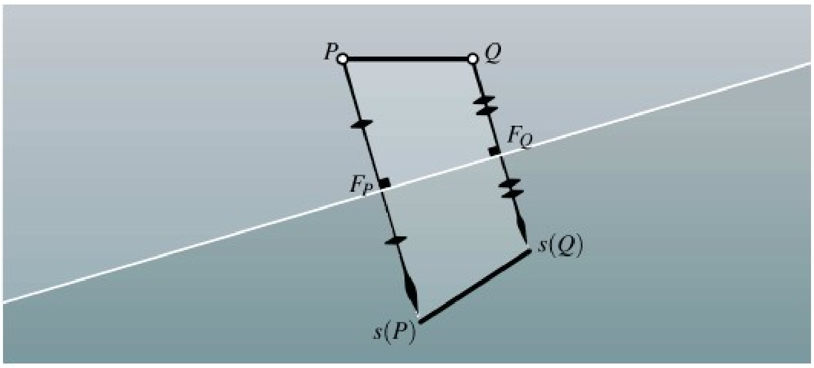

Figure 3. Use SASAS to verify that reflections preserve isometries in case III.2.*i*.

to ask, then, is how common is this "line-fixing" behavior? Not that common, as it turns out, and so this is a useful characterization of a reflection.

Theorem 23.3 *If an isometry fixes all the points of a line but is not the identity, then it must be a reflection.*

Proof Let f be an isometry that fixes all the points on a line ℓ but is not the identity. Let s be the reflection across ℓ. We already know that f and s agree on ℓ, so we just need to show that they agree on one point that isn't on ℓ. Take two points A and B on ℓ and a third point C that is not on ℓ. Since an isometry preserves distance, and since A and B are fixed,

$$AC \simeq f(AC) \simeq Af(C) \implies f(C) \text{ is on the circle with center } A \text{ and radius } |AC|\text{, and}$$
$$BC \simeq f(BC) \simeq Bf(C) \implies f(C) \text{ is on the circle with center } B \text{ and radius } |BC|.$$

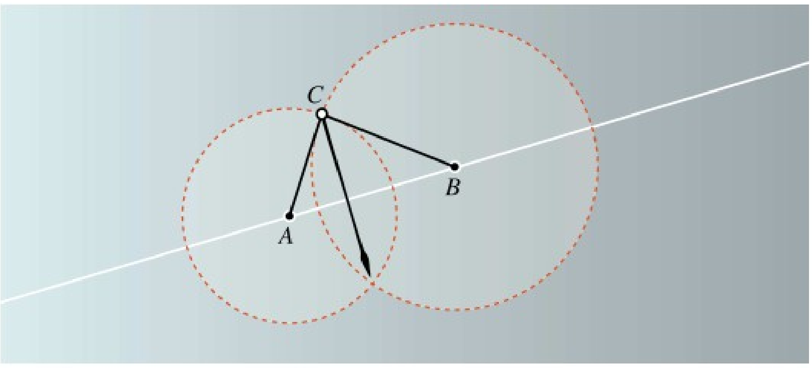

Figure 4. If a non-identity isometry fixes a line, then it is a reflection.

Therefore $f(C)$ is at an intersection of these two circles, and there are only two (distinct circles intersect at most twice). Furthermore, one of them is C, and if $f(C) = C$, then f would fix three non-collinear points and would be the identity. We excluded that possibility, so $f(C)$ has to be the other point of intersection. For the same reasons, $s(C)$ must be the second intersection. Therefore $f(C) = s(C)$; the two isometries agree on three non-collinear points, A, B, and C and so they must be equal. ☐

Theorem 23.4 *(Three reflections theorem) Any isometry can be written as a reflection, a composition of two reflections, or a composition of three reflections.*

We saw in the last chapter that when isometries agree on three non-collinear points they have to be the same. That is how we will proceed. We just need to find a composition of up to three reflections $s_3 \circ s_2 \circ s_1$ that agrees with T on three non-collinear points. There are three steps to this, as we build up each of the three reflections. At each step we will make the composition of reflections match T on another point without moving any of the previously set points.

Proof Let A, B, and C be three non-collinear points and let T be an isometry.

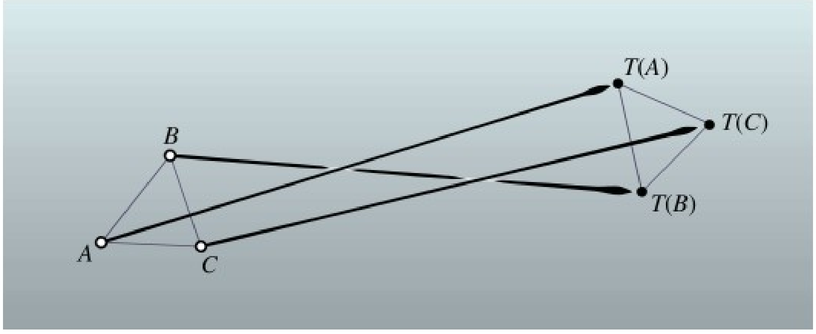

Figure 5. The image of a triangle under an isometry T.

Step One. With the first isometry, s_1, we put A into position. If $A = T(A)$, let s_1 be the identity isometry. If $A \neq T(A)$, let s_1 be the reflection across the perpendicular bisector of $AT(A)$. Either way, $s_1(A) = T(A)$.

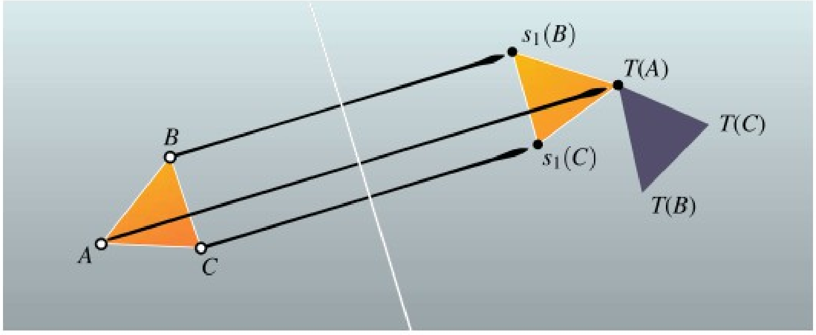

Figure 6. The first reflection.

Step Two. With the second isometry, s_2, we put B into position. To do this, we look at where $s_1(B)$ ended up after step one. It is possible (but unlikely) that $s_1(B)$ ended up on the line $T(\overline{AB})$. If that is the case, then because

$$|s_1(AB)| = |AB| = |T(AB)|,$$

there are only two possible spots for $s_1(B)$, one on either side of $T(A)$. If $s_1(B)$ is on the same side of $T(A)$ as $T(B)$, then $s_1(B) = T(B)$ already, so we can let s_2 be the identity isometry. If $s_1(B)$ is on the opposite side of $T(A)$ from $T(B)$, then let s_2 be the reflection across the line that passes through $T(A)$ and is perpendicular to $s_1(B)T(B)$. That reflection fixes $T(A)$ and maps $s_1(B)$ to $T(B)$.

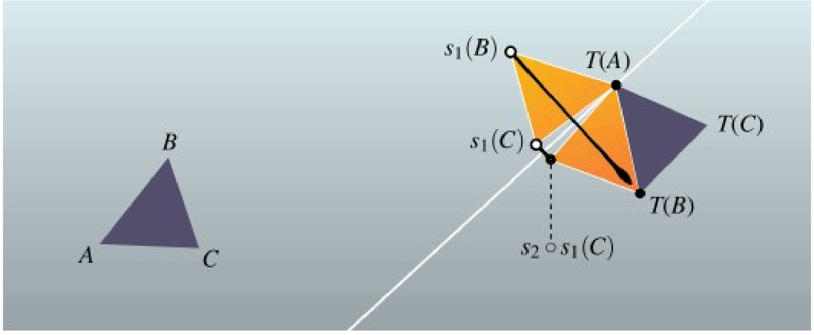

Figure 7. The second reflection.

The more likely possibility is that $s_1(B)$ is not on $T(\overline{AB})$. In that case, let s_2 be the reflection across the bisector of $\angle s_1(B)T(A)T(B)$. Then $T(A)$ is on the line of reflection, so it will be fixed by s_2. Furthermore, the reflecting line cuts $\triangle s_1(B)T(A)T(B)$ in two pieces, that, by SAS, are congruent. Therefore the reflecting line is the perpendicular bisector to $s_1(B)T(B)$, and that means s_2 will map $s_1(B)$ to $T(B)$. Here is where we stand after step two:

$$s_2 \circ s_1(A) = s_2 \circ T(A) = T(A),$$
$$s_2 \circ s_1(B) = T(B).$$

Step Three. That leaves point C. As in the previous step, what we do next depends upon where $s_2 \circ s_1(C)$ is. There aren't many possibilities. We know that $s_2 \circ s_1(AB) = T(AB)$, and we know that $s_2 \circ s_1(\triangle ABC)$ is congruent to $\triangle ABC$, which is congruent to $T(\triangle ABC)$. There are only two ways to build that triangle on a given side of $T(AB)$, one on either side of it. If $s_2 \circ s_1(C)$ is on the same side of $T(AB)$ as $T(C)$, then $s_2 \circ s_1(C) = T(C)$ already, so let s_3 be the identity map. If $s_2 \circ s_1(C)$ is on the opposite side of $T(AB)$ from $T(C)$, then let s_3 be the reflection across the line $T(AB)$. That fixes $T(A)$ and $T(B)$, but maps $s_2 \circ s_1(C)$ to $T(C)$. Putting it all together,

$$s_3 \circ s_2 \circ s_1(A) = T(A)$$
$$s_3 \circ s_2 \circ s_1(B) = T(B)$$
$$s_3 \circ s_2 \circ s_1(C) = T(C).$$

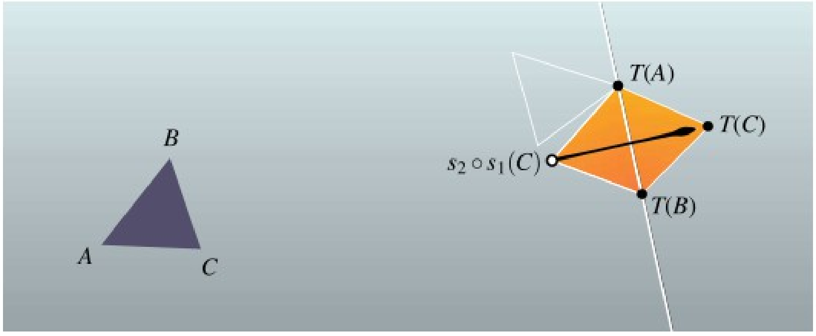

Figure 8. The third reflection.

Since the two isometries agree on three non-collinear points, they must be the same. As long as at least one of s_1, s_2, and s_3 is a reflection, we have met the requirements of the theorem. What if all of them are the identity map? In that case, T is the identity map, and the identity can be written as the composition of any reflection s with itself: $T = s \circ s$. □

Over the next few chapters, we will use this result to classify all isometries. In the next chapter, we will look at what happens when we compose two reflections. Then, after a brief discussion of orientation, we will look at what happens when we tack on a third reflection.

23.1 The analytic viewpoint

It is a little messy to try to work out an equation for an arbitrary reflection at this point. We can, however, find an equation for a reflection across a line that passes through the origin. Let's close out this chapter by doing so.

Theorem 23.5 *Let ℓ be a line through the origin, and let (a, b) be the coordinates of an intersection of ℓ with the unit circle. Then the reflection s across ℓ is given by*

$$s\begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} a^2 - b^2 & 2ab \\ 2ab & b^2 - a^2 \end{pmatrix}\begin{pmatrix} x \\ y \end{pmatrix}.$$

Proof Since (a, b) is on the unit circle, it can be written as $(\cos\theta, \sin\theta)$ for some real number θ. Let D be the distance from the point (x, y) to the origin and let ϕ be its angle measure as measured from the x-axis, in the counterclockwise direction, so that

$$\begin{matrix} \cos\phi = x/D \\ \sin\phi = y/D \end{matrix} \implies \begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} D\cos\phi \\ D\sin\phi \end{pmatrix}.$$

If α is the angle between ϕ and θ, $\alpha = \phi - \theta$, then $s(x, y)$ will still be at a distance D from the origin, but at an angle

$$\phi - 2\alpha = \phi - 2(\phi - \theta) = 2\theta - \phi.$$

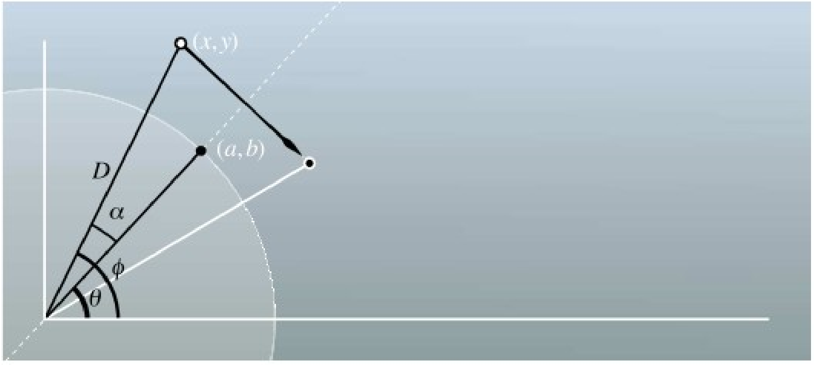

Figure 9. A reflection across a line that passes through the origin. In this case $\phi > \theta$ so that $\alpha > 0$, but the calculations are the same if $\alpha < 0$.

Therefore

$$s\begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} D\cos(2\theta - \phi) \\ D\sin(2\theta - \phi) \end{pmatrix}$$

and we can use the addition rules for sine and cosine:

$$\begin{aligned} s\begin{pmatrix} x \\ y \end{pmatrix} &= \begin{pmatrix} D\cos(2\theta)\cos(-\phi) - D\sin(2\theta)\sin(-\phi) \\ D\sin(2\theta)\cos(-\phi) + D\cos(2\theta)\sin(-\phi) \end{pmatrix} \\ &= \begin{pmatrix} D\cos(2\theta)\cos\phi + D\sin(2\theta)\sin\phi \\ D\sin(2\theta)\cos\phi - D\cos(2\theta)\sin\phi \end{pmatrix}. \end{aligned}$$

This can factored into a matrix form, and from there, the double angle formulas will take us the rest of the way.

$$\begin{aligned} s\begin{pmatrix} x \\ y \end{pmatrix} &= \begin{pmatrix} \cos(2\theta) & \sin(2\theta) \\ \sin(2\theta) & -\cos(\theta) \end{pmatrix} \begin{pmatrix} D\cos\phi \\ D\sin\phi \end{pmatrix} \\ &= \begin{pmatrix} \cos^2\theta - \sin^2\theta & 2\sin\theta\cos\theta \\ 2\sin\theta\cos\theta & \sin^2\theta - \cos^2\theta \end{pmatrix} \begin{pmatrix} D\cos\phi \\ D\sin\phi \end{pmatrix} \\ &= \begin{pmatrix} a^2 - b^2 & 2ab \\ 2ab & b^2 - a^2 \end{pmatrix} \begin{pmatrix} x \\ y \end{pmatrix}. \end{aligned}$$

□

There are two special cases worth noting. The equation for reflecting across the x-axis is

$$s\begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} \begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} x \\ -y \end{pmatrix},$$

and the equation for reflecting across the y-axis is

$$s\begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} -1 & 0 \\ 0 & 1 \end{pmatrix} \begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} -x \\ y \end{pmatrix}.$$

23.2 Exercises

23.1. Given $\triangle ABC$, let s be the reflection across the perpendicular bisector of BC. Prove that if $\triangle ABC$ is invariant under s (that is, $s(\triangle ABC) = \triangle ABC$), then $\triangle ABC$ is isosceles.

23.2. Given $\square ABCD$, let E and F be midpoints of AB and CD respectively. Let s be the reflection across the line EF. Prove that if $s(A) = B$ and $s(C) = D$, then $\square AEFD \simeq \square BEFC$.

23.3. Given a convex quadrilateral $\square ABCD$, let s_1 be the reflection across the diagonal AC, and let s_2 be the reflection across the diagonal BD. If $s_1(B) = D$ and $s_2(A) = C$, what can you say about $\square ABCD$?

23.4. What is the matrix equation for a reflection across the line $y = x$?

23.5. What is the matrix equation for a reflection across the horizontal line $y = k$?

23.6. Suppose that s_1 and s_2 are reflections, and that for some point P, $s_1(P) = s_2(P) \neq P$. Is it necessarily true that $s_1 = s_2$?

23.7. Suppose that s_1 and s_2 are reflections, and that for two distinct points P and Q, $s_1(P) = s_2(P)$ and $s_1(Q) = s_2(Q)$. Is it necessarily true that $s_1 = s_2$?

23.8. Given lines ℓ_1 and ℓ_2 is there necessarily a reflection s so that $s(\ell_1) = \ell_2$? If so, is it unique?

23.9. Let s_1 and s_2 be reflections across perpendicular lines ℓ_1 and ℓ_2 that intersect at a point P. Show that if Q is any other point, then P is the midpoint of the segment connecting Q to $s_2 \circ s_1(Q)$.

23.10. Let s_1 and s_2 be reflections across perpendicular lines ℓ_1 and ℓ_2. For any point P, prove that

$$P = s_2 \circ s_1 \circ s_2 \circ s_1(P),$$

and that there is a circle which passes through the points P, $s_1(P)$, $s_2 \circ s_1(P)$, and $s_1 \circ s_2 \circ s_1(P)$.

24

Translations and Rotations

The big result of the last chapter was that every isometry can be written as a reflection or as a composition of two or three reflections. In this chapter we will look at the types of isometries that we can get by composing two reflections. Any reflection composed with itself results in the identity, so we are interested in compositions of two distinct reflections. Then there are two cases: either the reflecting lines are parallel or the reflecting lines are intersecting.

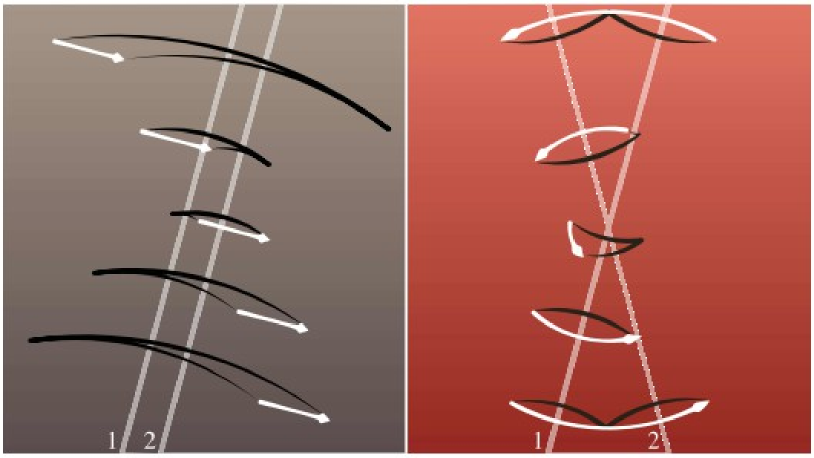

Figure 1. Pairs of reflections: (l) across parallel lines and (r) across intersecting lines.

The two cases describe fundamentally different types of isometries. In the second, the intersection point of the two lines is fixed by the composition of isometries. This doesn't happen in the first, since there is no intersection point, and in fact, this composition does not have any fixed points.

Definition 24.1 A *translation* is a composition of reflections across parallel lines. A *rotation* is a composition of reflections across intersecting lines.

By defining translations and rotations as compositions of isometries, it is automatically true that they will be isometries as well. But the definitions do not do a good job of revealing what a translation or rotation actually looks like. Doing that is the purpose of this chapter.

24.1 Translation

First, let's tackle the case of the translation. To do that, it is helpful to take a more measured look at the behavior of a single reflection. Consider a reflection s across a line ℓ. Let P be a point that is not on ℓ and let $\ell_\perp$ be the line through P that is perpendicular to ℓ. Now let's set up $\ell_\perp$ as a number line. That is, choose an arbitrary point O to be the origin, and a ray from O that points in the positive direction; then every point on $\ell_\perp$ has a coordinate, its signed distance from O. Suppose that P is at coordinate x and that ℓ and $\ell_\perp$ intersect at the point Q with coordinate y. Given the definition of a reflection, $s(P)$ has to be somewhere on $\ell_\perp$, and so it too must correspond to some coordinate. What coordinate? The distance from P to Q is $|y-x|$. Since s is an isometry and Q is a fixed point, the distance from $s(P)$ to Q is $|y-x|$ too. That limits the coordinate for $s(P)$ to one of two possibilities:

$$y+|y-x| = \begin{cases} y+(y-x) = 2y-x & \text{if } y-x \geq 0 \\ y-(y-x) = x & \text{if } y-x < 0 \end{cases}$$

or

$$y-|y-x| = \begin{cases} y-(y-x) = x & \text{if } y-x \geq 0 \\ y-(-(y-x)) = 2y-x & \text{if } y-x < 0. \end{cases}$$

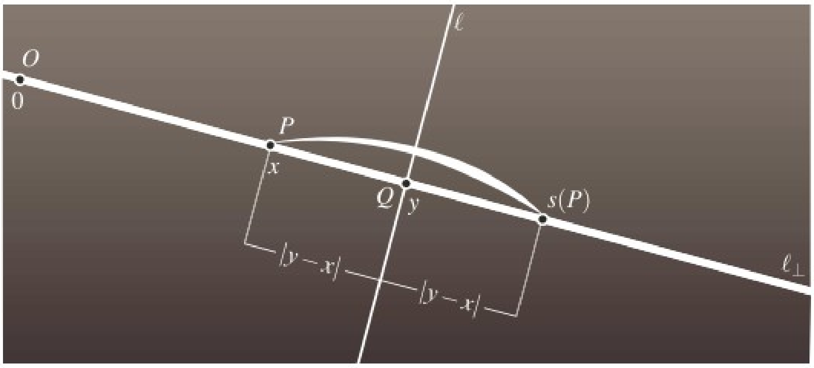

Figure 2. Measuring reflections along a line.

Since P is not on ℓ it is not a fixed point, so $s(P)$ is not at the coordinate x. The only other possibility, then, is that $s(P)$ is at the coordinate $2y-x$. The formula still works even if P is on ℓ. For in that case P is fixed, so $s(P)$ is also at coordinate x. That is what the formula reveals: if P is on ℓ, $y=x$, and so $2y-x=x$. Having this formula in hand will make it a little easier to compose parallel reflections.

Theorem 24.2 *Suppose that t is the translation $s_2 \circ s_1$ where s_1 and s_2 are reflections across parallel lines ℓ_1 and ℓ_2 that are separated by a distance d. Then for any point P, $t(P)$ is located*

- *on the line through P that is perpendicular to both ℓ_1 and ℓ_2,*
- *in the direction of the ray that points from ℓ_1 to ℓ_2,*
- *at a distance $2d$ from P.*

Proof Take a point P, and let $\ell_\perp$ be the line through P that is perpendicular to ℓ_1 and ℓ_2. By definition, $s_1(P)$ will still be on $\ell_\perp$, and then so will $s_2(s_1(P))$. Let's just look along this line, and, as in the preceding discussion, lay out a number line along it. It does not matter where we put the origin on the line, but it does help the discussion to choose the positive direction so that going from ℓ_1 to ℓ_2 moves in the positive direction. Then mark the coordinates

x : coordinate of P,
y_1 : coordinate for the intersection of $\ell_\perp$ and ℓ_1,
y_2 : coordinate for the intersection of $\ell_\perp$ and ℓ_2.

According to our previous calculations, $s_1(x)$ will be at the coordinate $2y_1 - x$ and $s_2 \circ s_1(x)$ will be at the coordinate

$$2y_2 - (2y_1 - x) = x + 2(y_2 - y_1) = x + 2d.$$

Therefore $s_2 \circ s_1(P)$ will be $2d$ farther along the line $\ell_\perp$ than P in the direction pointing from ℓ_1 to ℓ_2.

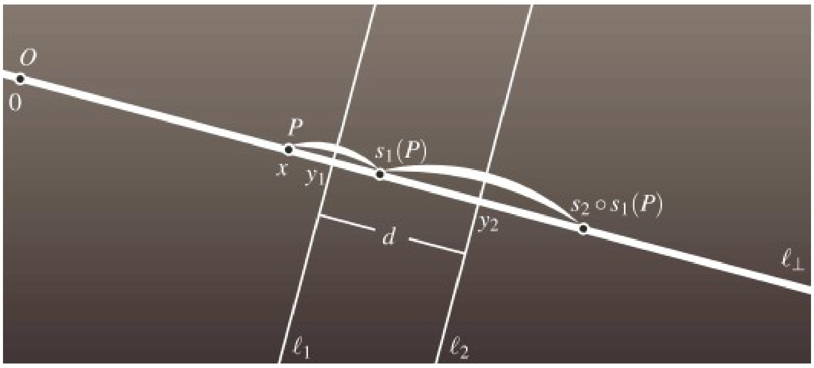

Figure 3. Measuring a composition of parallel reflections along a line. ☐

To recap, a translation moves all points along lines that are perpendicular to ℓ_1 and ℓ_2. They move in parallel, in the same direction, over the same distance. All of that—the parallel lines, the direction, and the distance—can be determined by looking at the effect of the translation on a single point. Therefore a translation is completely determined by its behavior on a single point. Because of that, we can get a precise idea of how many translations there are.

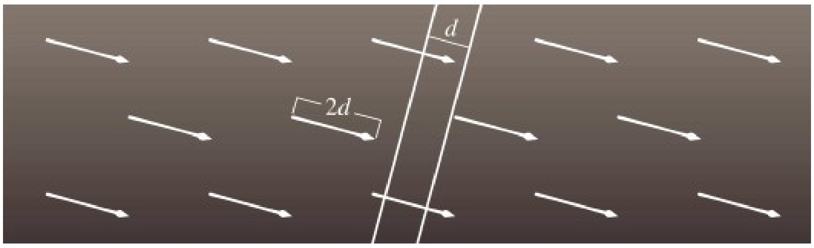

Figure 4. Transations shift all points the same amount in the same direction.

Theorem 24.3 *Given two distinct points P and Q, there is exactly one translation t so that $t(P) = Q$.*

Proof To prove existence, we will describe (as a composition of reflections) a translation that maps P to Q. The two reflections, s_1 and s_2, will be across lines that are perpendicular to PQ (and hence are parallel to one another). Let s_1 be the reflection across the line through P. Let s_2 be the reflection across the line through the midpoint of PQ. Then $s_2 \circ s_1$ is a translation and

$$s_2 \circ s_1(P) = s_2(P) = Q.$$

Proving uniqueness is easy: since a translation is completely determined by its behavior on one point, there can be only one translation taking P to Q. ☐

It is cumbersome to try to think of a translation as a composition of reflections. The properties we derived give a much better sense of the effects of a translation, and they can be formalized as follows. A *directed segment* is a line segment that distinguishes between its ends: one is called the initial endpoint, the other the terminal endpoint. We can define an equivalence relation $\sim$ on the set of all directed segments as follows: two directed segments σ_1 and σ_2 are equivalent if there is a translation t mapping σ_1 to σ_2 so that initial point is mapped to initial point and terminal point is mapped to terminal point.

Exercise 24.1 Verify that the relation $\sim$ is an equivalence relation on the set of all directed segments.

Definition 24.4 A *vector* is an equivalence class of directed segments under the $\sim$ equivalence relation.

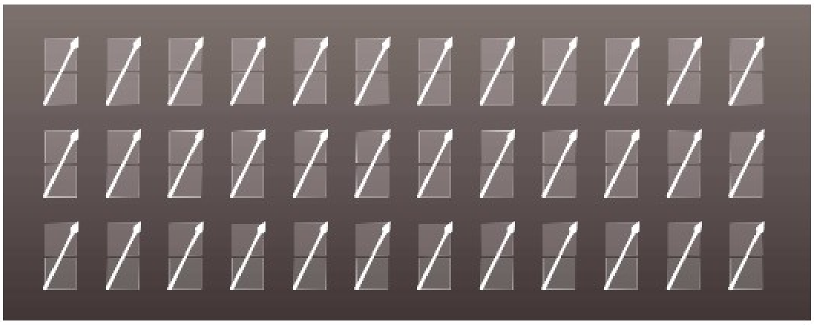

Figure 5. Some equivalence class representatives of a vector (one over, two up).

Associated to any transformation t is the vector that is represented by directed segments of the form $Pt(P)$ with initial point P and terminal point $t(P)$. The vector defines and is defined by t. It is called the *translation vector* of t. It is almost always more convenient and natural to think about a translation in terms of its translation vector than as a composition of reflections. For instance, if you think of a translation t as a composition of reflections, it might not be that clear that t has no fixed points. If you think of that translation in terms of its translation vector, it is clear that no point P can be fixed by t, since $Pt(P)$ is always a directed segment with two distinct endpoints.

24.2 Rotations

The illustrations at the start of this chapter suggest that when ℓ_1 and ℓ_2 intersect, the rotation $r = s_2 \circ s_1$ acts by turning points around the intersection point O. To measure the effect of the turning, we establish an angular coordinate system around O (just as we established a linear coordinate system on $\ell_\perp$ when ℓ_1 and ℓ_2 were parallel). Choose a ray $\overrightarrow{OR}$ with endpoint O. This marks the zero angle and a direction around that point (this amounts to a choice of clockwise or counterclockwise, which is discussed in the next chapter). After choosing, every ray from O will form an angle with $\overrightarrow{OR}$ and we can then associate each point on the ray with the angle measure. Before attempting two reflections, let's try to understand how the angular coordinate of a point behaves when we apply one reflection s across a line ℓ to it. Pick a point O on ℓ and set up an angular coordinate system as described. Let P be an arbitrary point that is not on ℓ. Then label

θ : the angular coordinate at P
ϕ : the angular coordinate of one of the rays from O that make up ℓ.

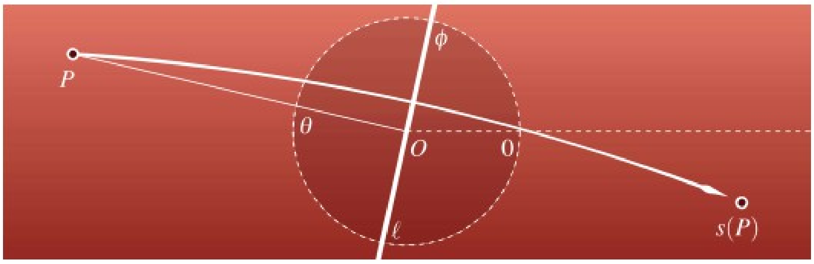

Figure 6. Measuring reflections around a fixed point.

There are two choices for ϕ that differ by π, but for the calculation, it makes no difference which one we pick. The angle between ℓ and OP has a measure of $|\phi - \theta|$. Since isometries preserve angle measure and ℓ is fixed by s, the angle between ℓ and $Os(P)$ also has a measure of $|\phi - \theta|$. That limits the possibilities for the angular coordinates of $s(P)$ to

$$\phi + |\phi - \theta| = \begin{cases} 2\phi - \theta & \text{if } \phi - \theta \geq 0 \\ \theta & \text{if } \phi - \theta < 0 \end{cases}$$

or

$$\phi - |\phi - \theta| = \begin{cases} \theta & \text{if } \phi - \theta \geq 0 \\ 2\phi - \theta & \text{if } \phi - \theta < 0. \end{cases}$$

Since P is not on ℓ, it is not fixed, and therefore $s(P)$ will not be at angle θ. The only other possibility is that $s(P)$ is at angle $2\phi - \theta$. Furthermore, the formula still holds when P is on ℓ. In that case, P is fixed, so $s(P)$ is also at angle θ. That is what the formula indicates: if P is on ℓ, then $\phi = \theta$ and so $2\phi - \theta = \theta$. Now let's take the formula and use it to see what happens when we compose two intersecting reflections.

Theorem 24.5 *Suppose that r is the rotation $s_2 \circ s_1$ where s_1 and s_2 are reflections across lines ℓ_1 and ℓ_2 intersecting at a point O and at an angle of θ to one another. For any point P, $r(P)$ is located*

- *on the circle centered at O that passes through P*
- *so that OP and $Os(P)$ form an angle with measure 2θ,*
- *in the direction indicated by the arc from ℓ_1 to ℓ_2.*

Proof Since $s_2 \circ s_1$ preserves distances and O is a fixed point, the distance from O to $s(P)$ is the same as the distance from O to P. That places $s(P)$ on the circle centered at O passing through P. Where precisely? As in the discussion above, set up an angular coordinate system centered at O. Mark the coordinates

α **:** the angular coordinate for P,
ϕ_1 **:** the angular coordinate for ℓ_1,
ϕ_2 **:** the angular coordinate for ℓ_2.

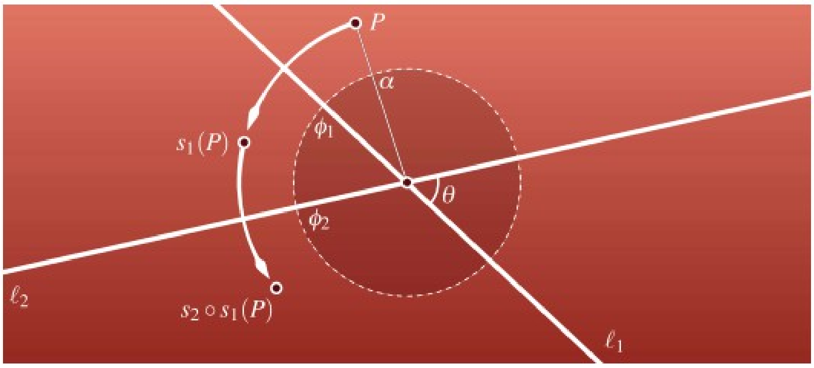

Figure 7. Measuring a composition of reflections around the fixed point.

The intersection of ℓ_1 and ℓ_2 forms two vertical angle pairs. It is helpful to measure angles in the direction so that the directed angle from ℓ_1 to ℓ_2 is the smaller of them (if ℓ_1 and ℓ_2 intersect at right angles, it doesn't matter which orientation you choose). According to the previous discussion, $s_1(P)$ will have the coordinate $2\phi_1 - \alpha$. Then $s_2(s_1(P))$ will have the angular coordinate

$$2\phi_2 - (2\phi_1 - \alpha) = \alpha + 2(\phi_2 - \phi_1) = \alpha + 2\theta.$$

Therefore OP and $Os(P)$ form an angle of 2θ, measured in the direction from ℓ_1 to ℓ_2. ☐

It is generally more convenient to think of a rotation in terms of the angle 2θ, the *rotation angle*, and the fixed point, the *center of rotation*, rather than as a composition of reflections. For instance, by thinking of a rotation in terms of its rotation angle and center, it is clear that a rotation only has one fixed point, the center of rotation. This viewpoint also gives a good perspective on just how common rotations are. The proof of the following result is left to the reader.

Theorem 24.6 *For a point O and angle measure $0 < \theta < 2\pi$, there is exactly one rotation in each of the two directions around O that has rotation center O and rotation angle θ. When $\theta = \pi$, the rotations in those two directions coincide (a half-turn).*

Exercise 24.2 Prove theorem 24.6.

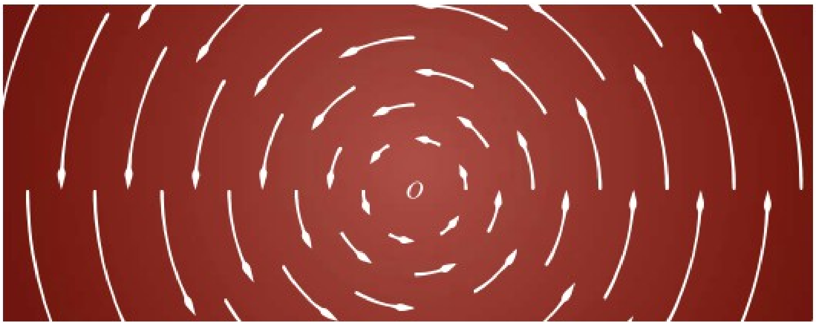

Figure 8. A counterclockwise rotation by $\pi/6$ centered at O.

24.3 The analytic viewpoint

Analytically, translations are the simplest of the isometries. If we break the translation vector of a translation T down into a horizontal component h and a vertical component k, then

$$T\begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} x+h \\ y+k \end{pmatrix}.$$

The equations for rotations are more challenging. For now, let's restrict our attention to rotations that are centered at the origin.

Theorem 24.7 *The analytic equation for a rotation r around the origin by an angle θ in the counterclockwise direction is*

$$r\begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} \cos\theta & -\sin\theta \\ \sin\theta & \cos\theta \end{pmatrix}\begin{pmatrix} x \\ y \end{pmatrix}.$$

Proof We can realize this rotation as a composition of two reflections across lines through the origin. For convenience, let's choose the reflections s_1 across ℓ_1 and s_2 across ℓ_2, where ℓ_1 is the x-axis and ℓ_2 forms an angle of $\theta/2$ (counterclockwise) with the x-axis.

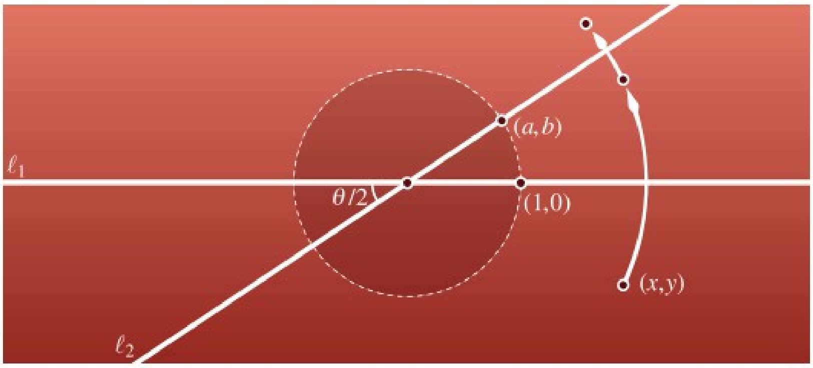

Figure 9. A rotation by θ around the origin can be written as a composition of reflections across two lines which form a $\theta/2$ angle at the origin.

Then $s_2 \circ s_1$ will be a rotation by an angle of $2 \cdot \theta/2 = \theta$. In the last chapter, we found out that equations for these reflections take the form

$$s\begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} a^2 - b^2 & 2ab \\ 2ab & b^2 - a^2 \end{pmatrix}$$

where (a, b) marks the intersection of the line and the unit circle. We can use that equation now. The first line intersects the unit circle at $(1, 0)$, so

$$s_1\begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}\begin{pmatrix} x \\ y \end{pmatrix}.$$

The second line intersects the unit circle at $(\cos\theta/2, \sin\theta/2)$, so

$$s_2\begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} \cos^2(\theta/2) - \sin^2(\theta/2) & 2\cos(\theta/2)\sin(\theta/2) \\ 2\cos(\theta/2)\sin(\theta/2) & \sin^2(\theta/2) - \cos^2(\theta/2) \end{pmatrix}\begin{pmatrix} x \\ y \end{pmatrix}.$$

We can use the double angle formulas to write

$$\begin{aligned} \cos^2(\theta/2) - \sin^2(\theta/2) &= \cos(\theta), \\ 2\cos(\theta/2)\sin(\theta/2) &= \sin(\theta), \end{aligned}$$

which simplifies the matrix considerably to

$$s_2\begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} \cos\theta & \sin\theta \\ \sin\theta & -\cos\theta \end{pmatrix}\begin{pmatrix} x \\ y \end{pmatrix}.$$

To compute the composition of the transformations, multiply the matrices:

$$r\begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} \cos\theta & \sin\theta \\ \sin\theta & -\cos\theta \end{pmatrix}\begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}\begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} \cos\theta & -\sin\theta \\ \sin\theta & \cos\theta \end{pmatrix}\begin{pmatrix} x \\ y \end{pmatrix}. \qquad \square$$

24.4 Exercises

24.3. Prove that every isometry T can be written as a composition $t_1 \circ t_2$ where t_1 is a translation (or the identity) and t_2 is an isometry that fixes the origin.

24.4. Find the analytic equations for reflections across the lines $x = a$ and $x = b$. Then verify that their composition is a translation.

24.5. Suppose that r_1 and r_2 are counterclockwise rotations about the origin by angles of θ_1 and θ_2 respectively. From the matrix equations for r_2 and r_1, show that the matrix equations for $r_2 \circ r_1$ have the form of a rotation or the identity.

24.6. Suppose that ℓ is an invariant line of a rotation r. That is, if P is a point on ℓ, then $r(P)$ is also on ℓ. Show that ℓ passes through the center of rotation and the angle of rotation is π.

24.7. Let r be a rotation that maps the point $(0, 0)$ to the point $(1, 0)$ and the point $(1, 0)$ to the point (a, b). What conditions are required of a and b for this to be possible?

24.8. In exercise 21.17 of chapter 21, we found the equation of a parabola with focus $(0, a)$ and directrix line $y = -a$, where $a \neq 0$. Find the equation of a parabola with focus $(a, 0)$ and directrix line $x = -a$ in two ways. First, do a direct calculation, as in chapter 21. Second, write a point on the parabola from exercise 21.17 in the parametrized form $(t, t^2/(4a))$ and apply a rotation.

24.9. Working from the previous exercise, find the equation for a parabola with focus $(3, 5)$ and directrix line $x = -1$.

24.10. Show that the parabola with focus at $(1, 1)$ and directrix line $y = -2 - x$ has the equation

$$(x - y)^2 - 8(x + y) = 0.$$

24.11. Find the equation of the ellipse with foci $(2, 0)$ and $(6, 0)$ that passes through the point $(0, 0)$.

24.12. Find the equation of the ellipse with foci $Q_1 = (1, \sqrt{3})$ and $Q_2 = (-1, -\sqrt{3})$ so that for a point $P = (x, y)$ on it

$$d(P, Q_1) + d(P, Q_2) = 8.$$

25

Orientation

The remaining step in the classification of isometries is to tackle compositions of three reflections. We would like to know whether compositions of three reflections can devolve into any of the previously identified isometries (reflection, translation, rotation). It turns out that composing three reflections can yield another reflection, but it will never result in a translation or rotation. This is helpful. It comes down to the issue of orientation, which we will investigate in this chapter.

An *orthonormal frame* is an ordered pair of perpendicular unit length segments that share a common endpoint. One such frame, $\mathscr{F}_+ = \{OP_x, OP_y\}$, centered at the origin with

$$O = (0, 0), \quad P_x = (1, 0), \quad \text{and} \quad P_y = (0, 1),$$

is at the heart of the coordinate system. There is another such frame, $\mathscr{F}_- = \{OP_x, OP'_y\}$, that shares the same first segment as $\mathscr{F}_+$, but that has $P'_y = (0, -1)$. In general, a frame can be viewed as a way to represent information about orientation, whether it is clockwise or counterclockwise. Until now, we have only made that choice at the origin: in $\mathscr{F}_+$, the directed minor arc from P_x to P_y points in the counterclockwise direction; in $\mathscr{F}_-$, the directed minor arc from P_x to P_y points in the clockwise direction. By using translations and rotations, we can now propagate that choice across the rest of the plane. Consider a frame $\mathscr{F} = \{QQ_x, QQ_y\}$. Let r be the rotation centered at O so that the vectors $r(OP_x)$ and QQ_x are parallel and pointed in the same direction. Let t be the translation which maps the point O to Q. Then

$$t \circ r(O) = Q \quad \text{and} \quad t \circ r(P_x) = Q_x.$$

What about P_y and P'_y? Both $t \circ r(OP_y)$ and $t \circ r(OP'_y)$ are perpendicular to QQ_x, and both $t \circ r(P_y)$ and $t \circ r(P'_y)$ are located a distance of 1 from Q along their segments. Because of the segment and angle construction axioms, there are only two points that meet both requirements. One of them is Q_y. Therefore, exactly one of two things may happen: either $t \circ r(P_y) = Q_y$ or $t \circ r(P'_y) = Q_y$. In the first case, $t \circ r$ maps $\mathscr{F}_+$ to $\mathscr{F}$; then we call $\mathscr{F}$ a counterclockwise frame, and the directed minor arc from Q_x to Q_y is in the counterclockwise direction. In the second case, $t \circ r$ maps $\mathscr{F}_-$ to $\mathscr{F}$; then we call $\mathscr{F}$ a clockwise frame, and the directed minor arc from Q_x to Q_y is in the clockwise direction.

This is a two-step process, in the order $t \circ r$, where r is a rotation around the origin, followed by a translation t. As long as we stick to that way of doing it, there is one and only one way to map one of the two original frames to any other. Hence there is no issue about making a consistent choice because there is no choice to make. This is not a trivial issue because not all

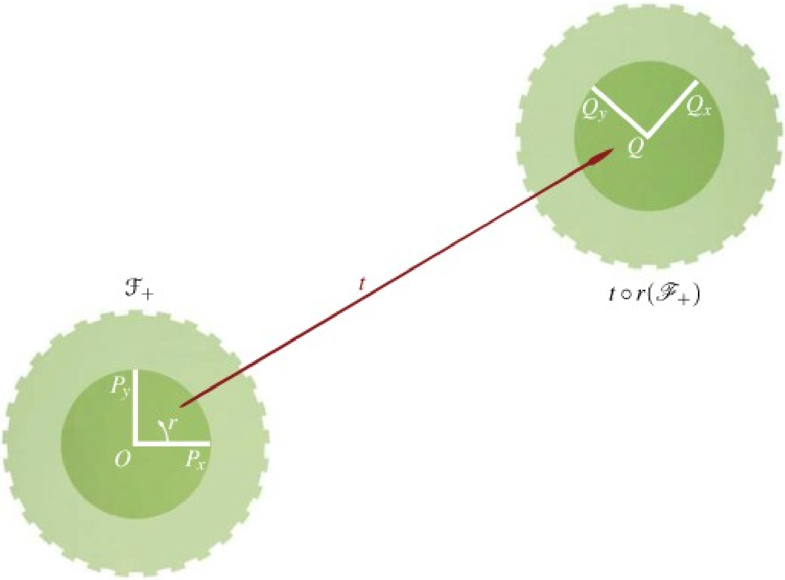

Figure 1. A rotation followed by a translation maps the frame $\mathcal{F}_+$ to the frame $\mathcal{F} = \{QQ_x, QQ_y\}$. Therefore $\mathcal{F}$ is a counterclockwise frame.

surfaces can be oriented consistently like this. The most famous non-orientable surface is the Möbius strip. It is formed by taking a strip, giving it a half-twist, and joining the ends. A frame $\mathcal{F}$ on the Möbius strip can be translated from one point to another in two different ways, t_1 and t_2, and the resulting frames $t_1(\mathcal{F})$ and $t_2(\mathcal{F})$ are not oriented the same way. The unfortunate side effect of the two-step process is that it doesn't determine whether other combinations of rotations and translations might actually reverse orientation, even though we instinctively know that to not be true. We will show that soon as an easy consequence of the fact that a reflection reverses the orientation of a frame, which we will tackle next. That argument will require the following lemma.

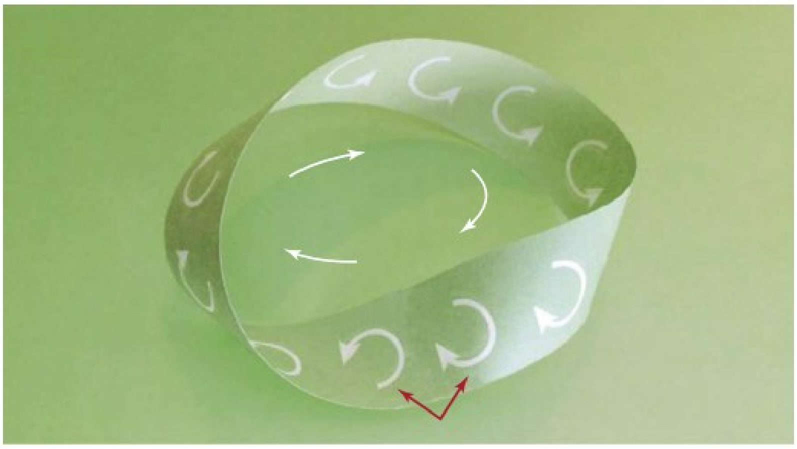

Figure 2. One lap around the Möbius strip flips orientation.

Lemma 25.1 *Let r be a rotation by an angle θ (not a half-turn), and let ℓ be a line. Then the angle between ℓ and $r(\ell)$ is θ.*

Exercise 25.1 Prove the previous lemma.

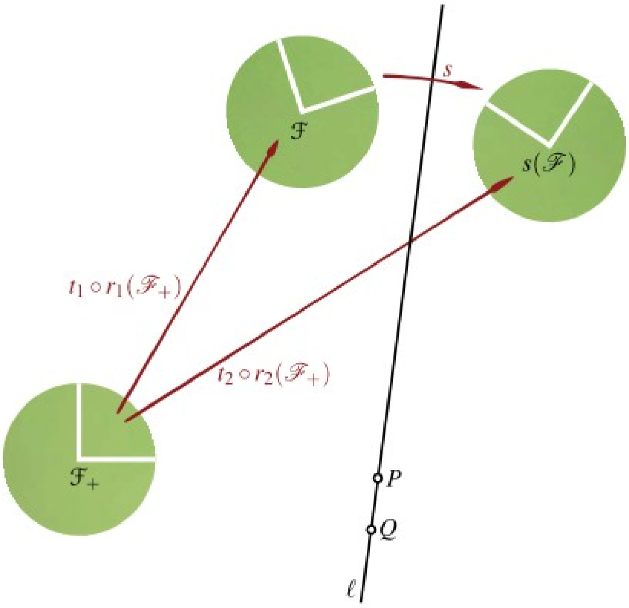
Theorem 25.2 *Let s be a reflection and $\mathscr{F}$ be a frame. Then $\mathscr{F}$ and $s(\mathscr{F})$ have the opposite orientation.*

Proof Let $\mathscr{F}$ be a counterclockwise frame (the clockwise case is essentially the same). Now let's suppose that $s(\mathscr{F})$ is also counterclockwise and try to arrive at a contradiction. Because both are counterclockwise, there are rotations r_1 and r_2 around the origin and translations t_1 and t_2 so that

$$t_1 \circ r_1(\mathscr{F}_+) = \mathscr{F} \quad \text{and} \quad t_2 \circ r_2(\mathscr{F}_+) = s(\mathscr{F})$$

so

$$s \circ t_1 \circ r_1(\mathscr{F}_+) = s(\mathscr{F}) = t_2 \circ r_2(\mathscr{F}_+).$$



s
$\mathscr{F}$
$s(\mathscr{F})$
$t_1 \circ r_1(\mathscr{F}_+)$
$t_2 \circ r_2(\mathscr{F}_+)$
$\mathscr{F}_+$
P
Q
ℓ

Figure 3. A reflection will always reverse the orientation of a frame because the composition of a rotation, translation, and reflection cannot have the same effect as the composition of just a rotation and a translation.

We have seen that if isometries agree on three non-collinear points, then they must be the same. The frame $\mathscr{F}_+$ contains three non-collinear points, and thus, $s \circ t_1 \circ r_1$ and $t_2 \circ r_2$ are the same. Therefore

$$\begin{aligned} s \circ t_1 \circ r_1 &= t_2 \circ r_2 \\ s \circ t_1 &= t_2 \circ r_2 \circ r_1^{-1} \\ s &= t_2 \circ r_2 \circ r_1^{-1} \circ t_1^{-1}. \end{aligned}$$

On the right hand side, $r_2 \circ r_1^{-1}$ is a composition of two rotations around the origin. Either the two rotations cancel, leaving the identity map, or they compose to form another rotation around the origin. Let ρ denote this composition. On the left, the map s is a reflection, so it fixes a line of points. Choose two distinct points on it, P and Q. Then

$$\begin{aligned} t_2 \circ \rho \circ t_1^{-1}(P) = s(P) = P &\implies \rho \circ t_1^{-1}(P) = t_2^{-1}(P) \\ t_2 \circ \rho \circ t_1^{-1}(Q) = s(Q) = Q &\implies \rho \circ t_1^{-1}(Q) = t_2^{-1}(Q). \end{aligned}$$

According to the last lemma, the angle between $\rho \circ t_1^{-1}(PQ)$ and $t_1^{-1}(PQ)$ is the angle of rotation of ρ, say θ. Both t_1^{-1} and t_2^{-1} are translations, however, so both $t_1^{-1}(PQ)$ and $t_2^{-1}(PQ)$ are parallel to PQ, and hence to each other. Therefore $\rho \circ t_1^{-1}(PQ)$ also forms an angle of θ with $t_2^{-1}(PQ)$. The only way the two segments can coincide, then, is if ρ is either a half-turn or the identity. We may rule out the half-turn since a half-turn would reverse the direction of the vector PQ. Hence ρ must be the identity. That means that $s = t_2 \circ t_1^{-1}$ and we arrive at a contradiction: the composition $t_2 \circ t_1^{-1}$ of two translations is another translation, not a reflection. □

This shows that a reflection is a wholesale swap of orientations. All the clockwise frames reflect to counterclockwise ones and all the counterclockwise frames reflect to clockwise ones.

Definition 25.3 An isometry is *orientation-preserving* if it maps clockwise frames to clockwise frames and counterclockwise frames to counterclockwise frames. A isometry is *orientation-reversing* if it swaps clockwise and counterclockwise frames.

We have just proved that reflections are orientation-reversing. Because every isometry can be written as a composition of reflections, determining whether an isometry is orientation preserving or reversing is a matter of counting flips.

Corollary 25.4 *A composition of two orientation-preserving maps is orientation-preserving; a composition of two orientation-reversing maps is orientation-preserving; a composition of one orientation-preserving map and one orientation-reversing map is orientation-reversing.*

Exercise 25.2 Prove the corollary.

Corollary 25.5 *Translations, rotations, and the identity map are orientation-preserving. They are the only orientation-preserving isometries.*

Exercise 25.3 Prove the corollary.

Let's now recap our progress in the classification of isometries.

# of reflections	isometry	orientation	fixed points
1	reflection	reversing	line
2	identity	preserving	all
	translation	"	none
	rotation	"	point
3	?	reversing	?

In the next chapter we find what goes in place of the question mark.

25.1 Exercises

25.4. Show that if τ is an orientation-preserving isometry that fixes two points, then it is the identity. Show that if τ is an orientation-preserving isometry that has at least one fixed point and at least one non-fixed point, then it is a rotation.

25.5. Let τ_1 be a counterclockwise rotation by $\pi/2$ about the origin. Let τ_2 be a counterclockwise rotation by $\pi/2$ about the point $(1, 0)$. Show that $\tau_1 \circ \tau_2$ is a rotation.

25.6. Another way to think about orientation is with normal vectors formed by cross products. Label the three points $O = (0, 0)$, $P = (1, 0)$, and $Q = (0, 1)$ and let T be an isometry. Form the vectors

v_x**:** the vector from O to P,
v_y**:** the vector from O to Q,
w_x**:** the vector from $T(O)$ to $T(P)$, and
w_y**:** the vector from $T(O)$ to $T(Q)$.

Compare the cross products $v_1 \times v_2$ and $T(v_1) \times T(v_2)$, where T is

- a reflection across a line through O,
- a rotation around O,
- a translation.

25.7. Let T be an orientation-preserving isometry. Prove that T is a rotation if and only if there exist points P and Q so that $|PT(P)| \neq |QT(Q)|$.

25.8. Let t be a translation and r be a rotation. Prove that $t \circ r$ and $r \circ t$ are rotations.

25.9. Consider the matrix equation

$$T\begin{pmatrix} x \\ y \end{pmatrix} = M\begin{pmatrix} x \\ y \end{pmatrix}$$

(where M is a 2×2 matrix) for (a) a reflection across a line through the origin and (b) a rotation around the origin. Show that for a reflection, $\det(M) = -1$ and that for a rotation, $\det(M) = 1$. In this way, the determinant of M captures information about orientation.

The remaining exercises look at surfaces that can be formed by bending and warping a flat sheet and gluing its sides together. More complete investigations can be found in many places. For instance, Massey has a nice write-up in the first chapter of *A Basic Course in Algebraic Topology* [Mas91].

25.10. Let S be the square with vertices $(0, 0)$, $(1, 0)$, $(0, 1)$, and $(1, 1)$. Orient each of those edges with vectors

$\vec{a}$: pointing from $(0, 0)$ to $(1, 0)$
$\vec{b}$: pointing from $(0, 0)$ to $(0, 1)$
$\vec{A}$: pointing from $(0, 1)$ to $(1, 1)$
$\vec{B}$: pointing from $(1, 0)$ to $(1, 1)$.

Imagine that a square S is made from a flexible material. Show that by bending and warping S, and gluing $\vec{a}$ to $\vec{A}$ and $\vec{b}$ to $\vec{B}$ so that they are oriented consistently, the resulting shape, a *torus*, can be made to look like an like an inner tube.

25.11. Let S be the square in the last exercise, with $\vec{a}$, $\vec{b}$, and $\vec{A}$ oriented as before. Orient $\vec{B}$ so that it points from $(1, 1)$ to $(1, 0)$. The resulting shape, a *Klein bottle* cannot be embedded in three-dimensional space without a self-intersection. Show that it is a non-orientable surface. Hint: show that it contains a Möbius strip.

25.12. Let S be the octagon $P_1 P_2 P_3 \cdots P_8$. Glue the following vectors along its edges, matching the orientation of those vectors:

- $\overrightarrow{P_1 P_2}$ with $\overrightarrow{P_4 P_3}$,
- $\overrightarrow{P_2 P_3}$ with $\overrightarrow{P_5 P_4}$,
- $\overrightarrow{P_5 P_6}$ with $\overrightarrow{P_8 P_7}$, and
- $\overrightarrow{P_6 P_7}$ with $\overrightarrow{P_1 P_8}$.

Show that the result can be deformed to form a inner-tube shape with two holes (a "two-holed torus").

37

Non-Euclidean Parallels

From here on out, let's assume that Playfair's axiom is false. That means that our geometry is not Euclidean. It means our triangle angle sums are strictly less than π. It means that Saccheri quadrilaterals are not rectangles, because rectangles do not exist, and so the summit angles are acute (not right). And other absurdities.

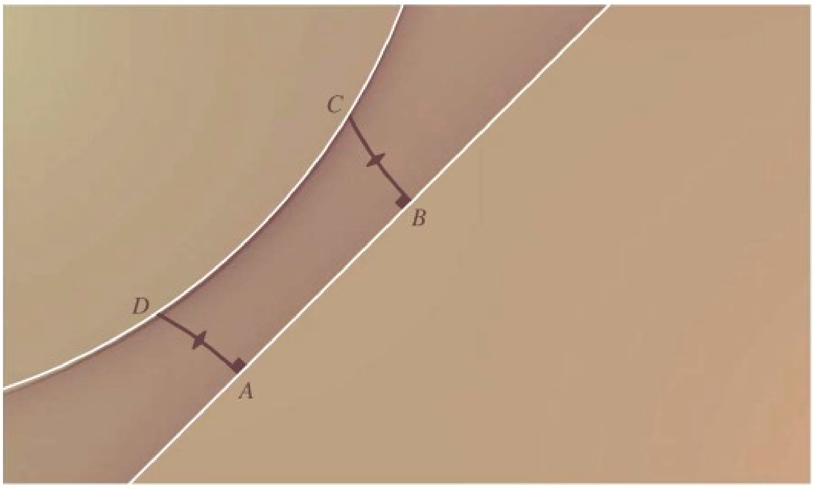


Figure 1. The base and summit of a Saccheri quadrilateral are on parallel lines.

It may have been implied, but in the last chapter we never proved that the base and summit of a Saccheri quadrilateral are parallel.

Exercise 37.1 Let $\square ABCD$ be a Saccheri quadrilateral with base AB and summit CD. Prove that $\overleftrightarrow{AB}$ and $\overleftrightarrow{CD}$ are parallel.

In this section, we will explore parallels more systematically. By the end of it, we should have a better sense of what to look for in a non-Euclidean geometry. To start, let's see that non-Euclidean behavior is pervasive, and not just an anomaly that occurs at a few isolated points.

Theorem 37.1 *Let ℓ be a line and let P be a point that is not on ℓ. Then there are infinitely many lines through P that are parallel to ℓ.*

Proof There are two pieces to this proof. First that there are always at least two parallels. Then that there are infinitely many.

Part 1, that there are (at least) two parallels. Drop the perpendicular from P to ℓ, and mark its intersection with ℓ as Q. Let ℓ' be the line through P that is perpendicular to PQ. According to the alternate interior angle theorem, ℓ' is parallel to ℓ. Now suppose that it is the only parallel. To get a contradiction, we are going to build a Saccheri quadrilateral and see that it would have to be a rectangle. Pick a point on ℓ other than Q and label it R. On the line through R that is perpendicular to ℓ, mark the point S so that $RS \simeq PQ$ (choose S on the same side of ℓ as P). Then $\square PQRS$ is a Saccheri quadrilateral with base QR and summit PS. According to exercise 37.1, $\overline{PS}$ and $\overline{QR} = \ell$ are parallel. But there is only one line through P that is parallel to ℓ, namely ℓ'. Therefore $\overline{PS} = \ell'$. In $\square PQRS$, the summit angle at P is a right angle; and the other summit angle must be congruent to it. Therefore all four angles of $\square PQRS$ are right angles and it is a rectangle. There are no rectangles in non-Euclidean geometry, so there must be more than one parallel to ℓ that passes through P.

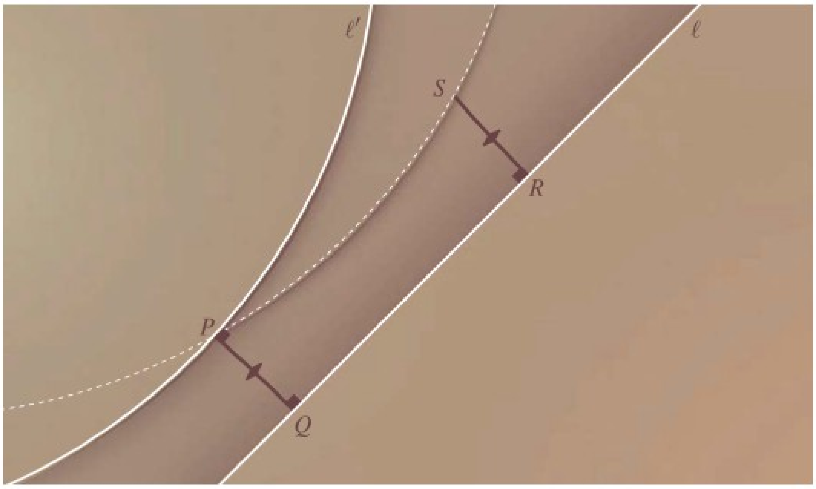

Figure 2. If there are no rectangles, then there must be at least two lines through P that are parallel to $\overline{QR}$.

Part 2, that there are infinitely many parallels. Let ℓ_1 and ℓ_2 be two lines through P that are parallel to ℓ. We can box-in P by surrounding it with more labeled points:

A, A' **:** on ℓ_1 so that $A * P * A'$,
B **:** on ℓ_2 and on the same side of PQ as A,
B' **:** on ℓ_2 and on the same side of PQ as A' (so $B * P * B'$).

Let C be a point on the segment AB. We will argue that $\overline{PC}$ is also parallel to ℓ. Suppose $\overline{PC}$ intersects ℓ at a point D. Then one of $\overrightarrow{PA}$, $\overrightarrow{PA'}$, $\overrightarrow{PB}$, or $\overrightarrow{PB'}$ would have to lie in the interior of

$\angle QPD$. According to the crossbar theorem, the ray would have to intersect QD. This cannot happen since ℓ_1 and ℓ_2 (which contain all four rays) are parallel to ℓ.

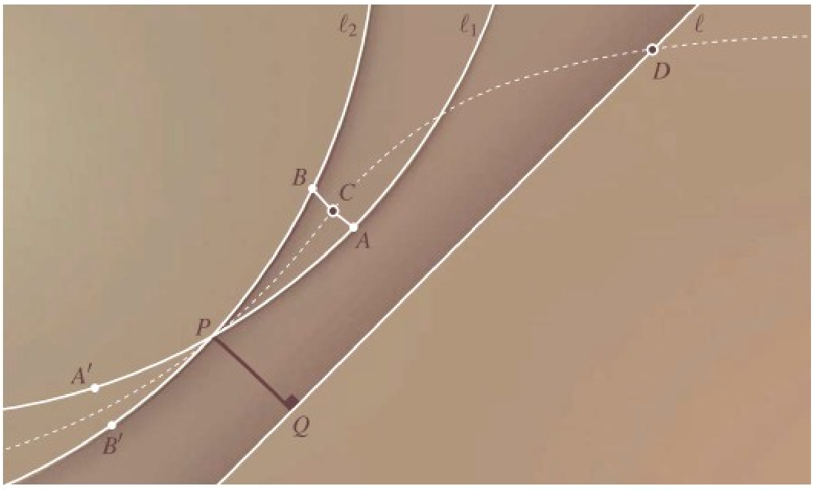

Figure 3. Given two parallels through P, we can find infinitely more between them. □

In Euclidean geometry, parallel lines are everywhere equidistant, so we can measure the distance between them with a single number. Non-Euclidean geometry is not so simple. Given parallel lines ℓ_1 and ℓ_2 in non-Euclidean geometry, the distance from a point P on ℓ_2 to the line ℓ_1 is measured as usual: drop a perpendicular from P to ℓ_1 and mark its foot (the intersection with ℓ_1) as F_P. Then the distance from P to ℓ_1 is $|PF_P|$.

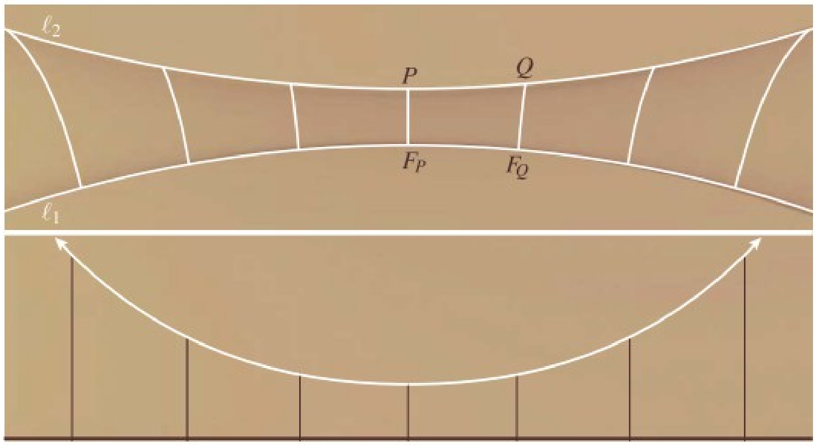

Figure 4. We can view the distance between parallel lines ℓ_1 and ℓ_2 as a function of the points on ℓ_2.

We can define a function $f : \ell_2 \to \mathbb{R}$ by setting $f(P)$ to be the distance from P to ℓ_1. The rest of this chapter investigates it. Before we go any further, we need the following lemma (note its similarity to the theorem in the last chapter that compared the length of the summit to the length of the base).

Lemma 37.2 *Let ℓ_1 and ℓ_2 be parallel lines, let P and Q be points on ℓ_2, and let F_P and F_Q be the respective feet of the perpendiculars on ℓ_1. Then $|F_PF_Q| < |PQ|$.*

Exercise 37.2 Prove the lemma.

Theorem 37.3 *The function f measuring the distance from points of ℓ_2 to the line ℓ_1 is continuous.*

Proof It is always possible to drop a perpendicular from a point P on ℓ_2 to the line ℓ_1, and it is always possible to measure the distance from P to its foot F_P, so the function f is always defined. For f to be continuous at the point P, we need a bit more: as a point Q on ℓ_2 approaches P, the value of $f(Q)$ must approach $f(P)$. To be more precise,

> For every $\epsilon > 0$, there must be a $\delta > 0$ so that if $|PQ| < \delta$ then $|f(P) - f(Q)| < \epsilon$.

The verification of this hinges on a few simple geometric observations that follow from the triangle inequality.

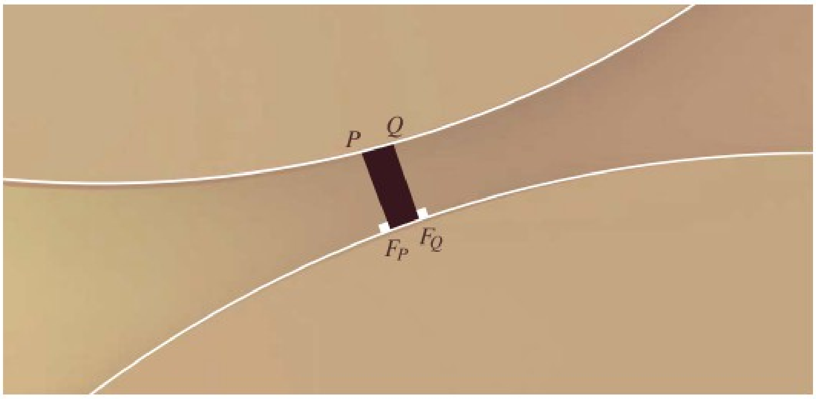

Figure 5. To show that f is continuous, consider two points P and Q that are close to one another.

- $|PF_P| \le |PQ| + |QF_Q| + |F_PF_Q|$.
- $|QF_Q| \le |PQ| + |PF_P| + |F_PF_Q| \implies |PF_P| \ge |QF_Q| - |PQ| - |F_PF_Q|$.
- Therefore

$$|QF_Q| - |PQ| - |F_PF_Q| \le |PF_P| \le |PQ| + |QF_Q| + |F_PF_Q|.$$

- Subtract $|QF_Q|$:

$$-|PQ| - |F_PF_Q| \le |PF_P| - |QF_Q| \le |PQ| + |F_PF_Q|.$$

- We don't know whether $|PF_P| > |QF_Q|$ or if it is the other way around. Either way, we can say that

$$\big||PF_P| - |QF_Q|\big| \leq |PQ| + |F_PF_Q|.$$

With that information, verifying continuity is straightforward. Fix $\epsilon > 0$ and put $\delta = \epsilon/2$. If $|PQ| < \delta = \epsilon/2$, then $|F_PF_Q| < \epsilon/2$ as well (according to lemma 37.2), and so

$$|f(P) - f(Q)| = \big||PF_P| - |QF_Q|\big| \leq |PQ| + |F_PF_Q| < \epsilon/2 + \epsilon/2 = \epsilon.$$

Therefore f is continuous at P. Since P was an arbitrary point on ℓ_2, f is continuous on all of ℓ_2. □

Theorem 37.4 *For a real number r, $|\{f^{-1}(r)\}| \leq 2$. That is, there are at most two points on ℓ_2 that are at a distance r from ℓ_1.*

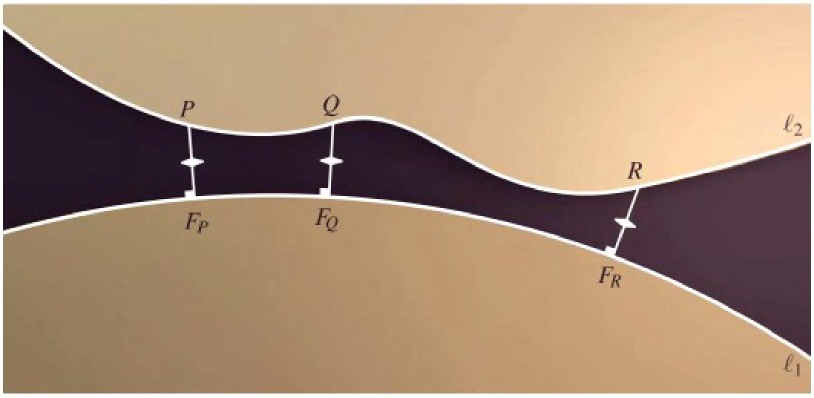

Figure 6. It is not possible for all of P, Q, and R to be the same distance from ℓ_1.

Proof Suppose that there is a real number r so that $|\{f^{-1}(r)\}| > 2$. Then there are (at least) three distinct points P, Q, and R on ℓ_2 with $P * Q * R$ so that $f(P) = f(Q) = f(R) = r$. If we label the feet of their respective perpendiculars as F_P, F_Q, and F_R, then

$$|PF_P| = |QF_Q| = |RF_R| = r.$$

Thus $\square F_PF_QQP$ and $\square F_QF_RRQ$ are Saccheri quadrilaterals. They cannot be rectangles, though, so their summit angles $\angle PQF_Q$ and $\angle RQF_Q$ must be acute. But the angles are supplementary so they cannot both be acute. □

Theorem 37.5 *The function f has no local maxima and at most one local minimum.*

Proof Suppose that f has a local maximum at a point B. Then, since f is continuous, for a sufficiently small value positive value ϵ, there are points A and C on either side of B so that

$$f(A) = f(C) = f(B) - \epsilon.$$

Let F_A, F_B, and F_C be the feet of the perpendiculars to ℓ_1 from A, B, and C respectively. Then

$$|AF_A| = f(A) = f(C) = |CF_C|$$

so $\square F_A F_C C A$ is a Saccheri quadrilateral with base $F_A F_C$. The segment BF_B connects the summit to the base and is perpendicular to the base. We saw at the end of the last chapter that such segments cannot be longer than the legs. But the legs of this Saccheri quadrilateral are AF_A and CF_C, and they are shorter (by ϵ) than BF_B. This is a contradiction, and so f cannot have a local maximum.

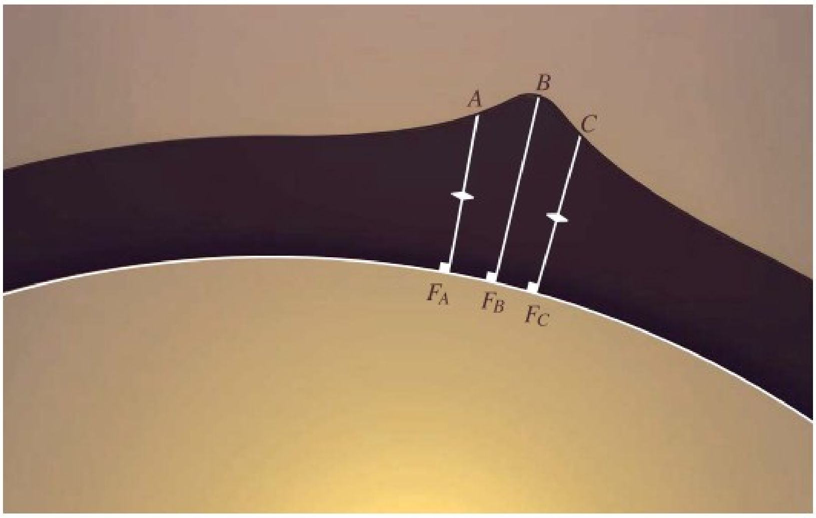

Figure 7. It is not possible for f to have a local maximum (as is suggested here at the point B).

The second part of the theorem follows immediately: if f had more than one minimum, then, because it is continuous, it would have a local maximum in between them. ☐

Theorem 37.6 *Let P and Q be points on ℓ_2 and suppose that $f(Q) > f(P)$. Then f approaches infinity along $\overrightarrow{PQ}$.*

It should be clear that the value of f continues to increase past Q. If at some point it began to decrease, then we would have found a local maximum, and we have just seen that f has none. But could it be that f continues to grow, but is bounded above? Is there an upper bound that f approaches in the limit but never surpasses? This is a more delicate question. The strategy of the proof is to build a wall of congruent Saccheri quadrilaterals that appears to contain $\overrightarrow{PQ}$, and then see why that cannot happen.

Proof Suppose that f does have an upper bound so that it approaches but never exceeds a number k. Starting from the point F_Q, the foot of the perpendicular from Q, mark off congruent segments along ℓ_1 on the same side of PF_P as $\overrightarrow{PQ}$. That is, label points F_i so that

$$F_Q = F_0 * F_1 * F_2 * F_3 * \cdots$$

and so that the segments F_iF_{i+1} are congruent. Above each point F_i (on the same side of ℓ_1 as ℓ_2), erect a perpendicular segment F_iP_i of length k. Then each $\square F_iF_{i+1}P_{i+1}P_i$ is a Saccheri quadrilateral, and by SASAS they are all congruent.

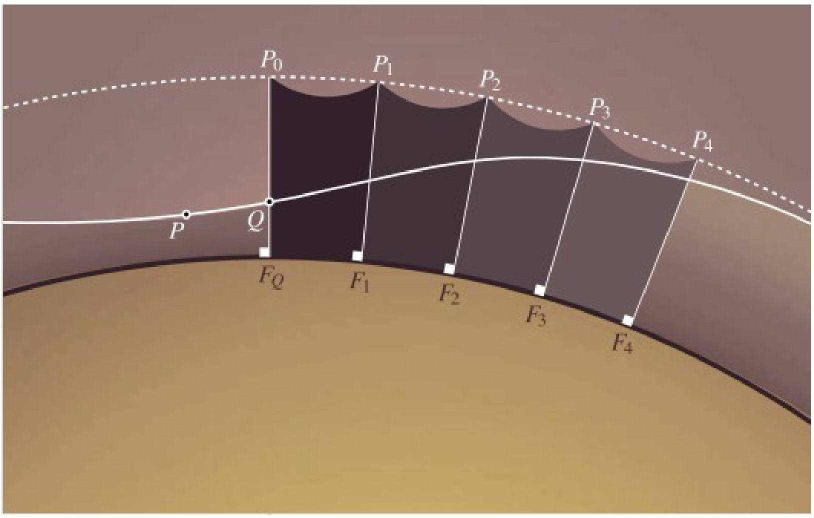

Figure 8. It is not possible for f to level off at some asymptotic value, as suggested here.

Their altitudes are shorter than their legs, by an amount that we can call ϵ (since the quadrilaterals are congruent, the discrepancy will be the same for all of them). Now let's get back to $\overrightarrow{PQ}$. For a while, it may run below the summits of the quadrilaterals we have assembled. But f has a limiting value of k along it, so eventually there is a point beyond which f is greater than $k - \epsilon$. Look beyond that point, at the interaction of $\overrightarrow{PQ}$ with one of the summits P_nP_{n+1}. Points P_n and P_{n+1} are on the opposite side of ℓ_2 from ℓ_1. But the altitude between them is on the same side of ℓ_2 as ℓ_1. This would imply that ℓ_2 intersects P_nP_{n+1} twice. Two distinct lines can intersect only once, so this is a contradiction. ☐

Looking in the other direction, if $f(Q) > f(P)$, then $f(P) < f(Q)$, and it is natural to wonder what happens as we progress along $\overrightarrow{QP}$. Does the distance to ℓ_2 continue to decrease, or does it at some point begin to increase again?

Definition 37.7 If f achieves a minimum, then ℓ_1 and ℓ_2 are called *divergent* parallels. If instead f approaches zero, then ℓ_1 and ℓ_2 are called *asymptotic* parallels.

If ℓ_1 and ℓ_2 are divergent parallels, then once $\overrightarrow{QP}$ has crossed over the minimum value, the value of f will begin to go up. Once that happens, by the previous result, f will go to infinity. Both types of parallels exist in non-Euclidean geometry. The base and summit of a Saccheri quadrilateral are divergent parallels. Asymptotic parallels are more elusive, but one of the exercises outlines a proof of their existence. Beyond that, there is one more obvious question: are there any parallels that are neither divergent nor asymptotic? Suppose ℓ_1 and ℓ_2 are not divergent. Then f does not achieve its minimum. It is easy then to pick points P and Q

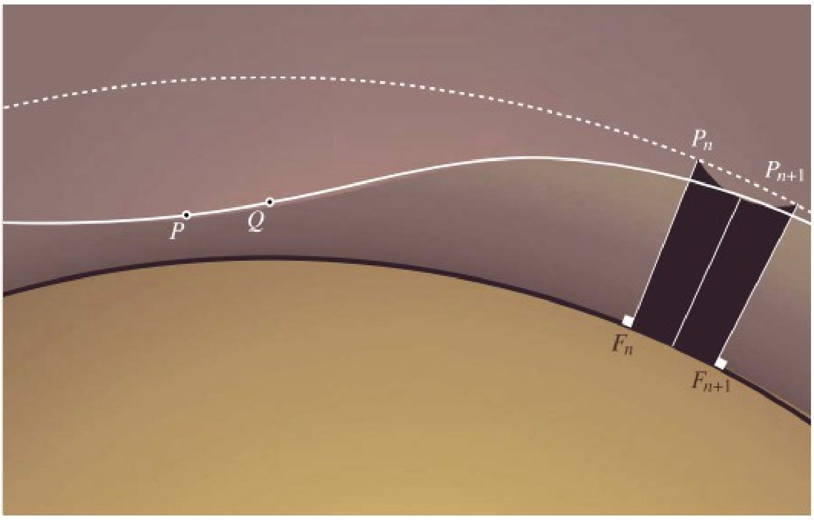

Figure 9. If $\overrightarrow{PQ}$ approached an asymptote, it would eventually intersect the summit of a constructed Saccheri quadrilateral more than once.

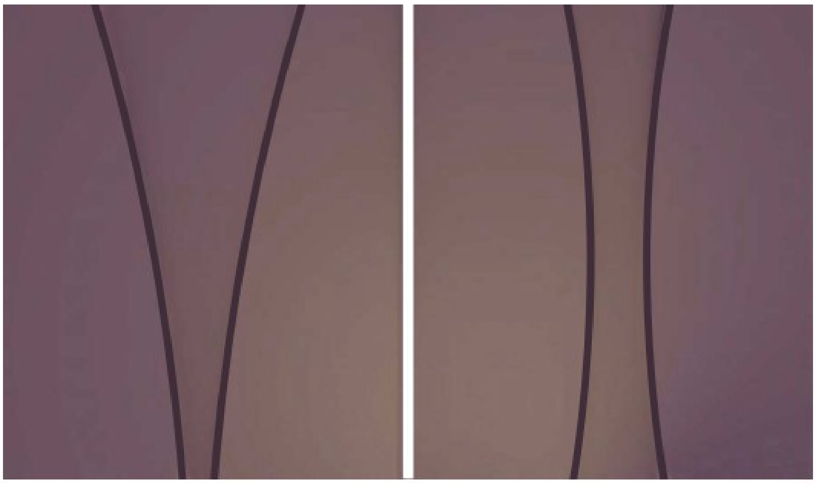

Figure 10. (l) asymptotic parallels; (r) divergent parallels.

so that $f(P) < f(Q)$, so f must continue to decrease past P as we move out along $\overrightarrow{QP}$. By definition, the lines are asymptotic if the value of f decreases to zero. Is it possible that the value of f is always decreasing, but never drops below some positive number k? No. The argument against a nonzero lower bound is essentially the same as the argument against an upper bound in the proof above.

Theorem 37.8 *If ℓ_1 and ℓ_2 are parallel, then they are either divergent or asymptotic.*

Exercise 37.3 Prove theorem 37.8.

The results of this chapter should give you some sense of the look of non-Euclidean geometry. But can such a geometry exist? If we want to answer YES, we need to find a model that meets all the requirements of neutral geometry, and has the non-Euclidean characteristics. In the next chapters, we will look at such models.

37.1 Exercises

37.4. Let r_1 and r_2 be two non-opposite rays with endpoint A. Label point B and C on r_1 and B' and C' on r_2 so that $A * B * C$ and $A * B' * C'$. Prove that the angle sum of $\triangle ACC'$ is less than the angle sum of $\triangle ABB'$.

37.5. Suppose that ℓ_1 and ℓ_2 are divergent parallels. Let P be the point on ℓ_2 that is the minimum distance from ℓ_1, and let Q be the foot of the perpendicular from P. Prove that QP intersects ℓ_2 at a right angle.

37.6. Let ℓ be a line and let P be a point that is not on ℓ. Prove that there is a line through P which is asymptotic to ℓ. Hint: let r_1 and r_2 be rays from P, one that intersects ℓ and one that is along a divergent parallel to ℓ. Let A be a point on r_1 and B be a point on r_2. A point Q on AB falls into one of two sets: either PQ is parallel to ℓ or it isn't. By Dedekind's axiom, there is a point Q_0 that separates those two sets. Show that PQ_0 is an asymptotic parallel.

37.7. Suppose that lines ℓ_1 and ℓ_2 intersect at a point O. Suppose that P and Q are on ℓ_2 so that $O * P * Q$, and that F_P and F_Q are the feet of the perpendiculars, from P and Q respectively, to ℓ_1. Prove that $|PF_P| < |QF_Q|$.

37.8. Let r_1 and r_2 be two rays with a common endpoint O. Prove that for a positive real number x, there is a point P on r_1 so that $d(P, r_2) > x$.

The Pseudosphere

In time, some geometers began to doubt that Playfair's axiom could be proved using only the axioms of neutral geometry. So they began to search for a model of a neutral geometry that would exhibit non-Euclidean behavior. In such a geometry parallel lines would have to bend away from one another. Viewed from a Euclidean perspective, the non-Euclidean plane would look warped. One idea was to use a curved surface as the model. In it, points would be modeled by the points on the surface, while lines will be modeled by geodesics on the surface. The distance between two points would be measured as the arc length of the geodesic connecting them, and the angle between two geodesics would be the angle between their tangent vectors at the point of intersection. The undefined terms *on*, *between*, and *congruent* would then be defined in the obvious way.

A geodesic is (roughly speaking) the shortest path between two points. For example, the geodesics on a plane are lines. Geodesics on a sphere are *great circles*, circles on the sphere whose centers coincide with the center of the sphere. Neither the plane nor the sphere works as a model for non-Euclidean geometry. The plane is flat and the sphere, while warped, seems to be warped in the wrong way because the great circles bend toward one another rather than away.

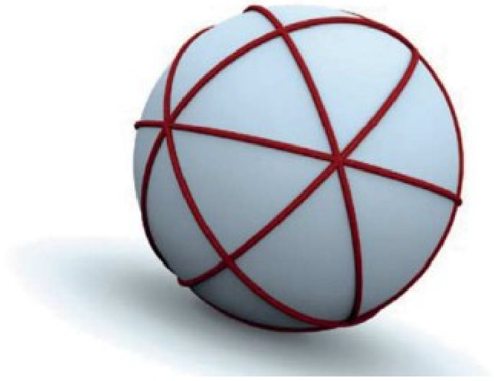

Figure 1. Some geodesics (great circles) on a sphere.

There are, however, some surfaces that exhibit the right kind of warping, those with constant negative Gaussian curvature. One is called the pseudosphere. The purpose of this chapter is to find equations for it. We will have to use differential geometry in order to do so, so this chapter is advanced. My primary reference for this is Spivak's five volume Differential Geometry series, the calculations are in volume 3 [Spi99b].

We will get into the details as this chapter unfolds, but there are two parts to a surface of constant negative curvature: the constant part and the negative part. The curvature has to be constant so that the model will be "isotropic", that is it looks the same at every point. Without this requirement, the surface won't satisfy all of the neutral axioms. The curvature has to be negative so that parallels will bend away from one another as we would expect in a non-Euclidean geometry.

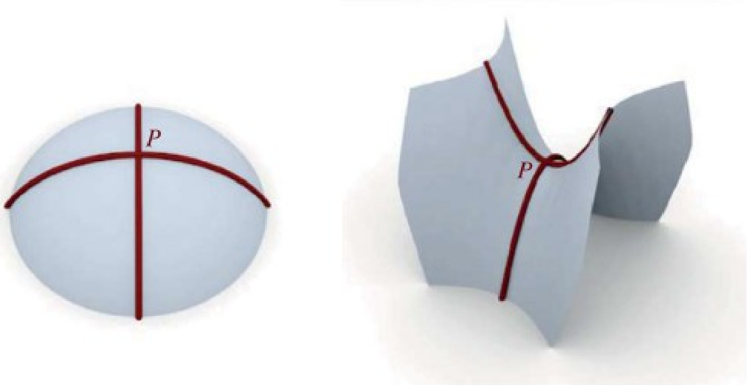

Figure 2. The curves are geodesics on the surfaces. On the left, P is a point of positive curvature. On the right, P is a point of negative curvature. For negatively curved surfaces, the geodesics bend away from each other.

38.1 Surfaces

There are several ways to describe a surface in $\mathbb{R}^3$. Perhaps the most elementary is when one variable can be written as a function of the other two such as $z = f(x, y)$. Because that form can be limiting, a more flexible approach is to parametrize the surface, writing coordinates as a function of two variables:

$$X(s, t) = (f(s, t), g(s, t), h(s, t)).$$

Given a surface S parametrized by $X(s, t)$, assuming that the surface is relatively smooth and that the parametrization function is relatively well-behaved, we can compute partial derivatives

$$\begin{aligned} X_s &= \left.\frac{\partial X}{\partial s}\right|_{(s_0,t_0)} = \langle f_s(s_0, t_0),\ g_s(s_0, t_0),\ h_s(s_0, t_0)\rangle\,, \\ X_t &= \left.\frac{\partial X}{\partial t}\right|_{(s_0,t_0)} = \langle f_t(s_0, t_0),\ g_t(s_0, t_0),\ h_t(s_0, t_0)\rangle \end{aligned}$$

at a point $P = X(s_0, t_0)$ on S. The results are vectors that point in the direction of an infinitesimal change in s and an infinitesimal change in t. They form a basis for T_P, the *tangent plane* to S at P.

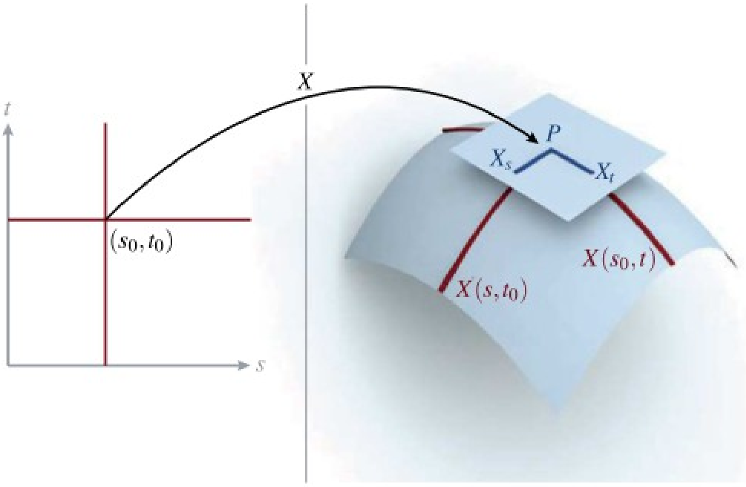

Figure 3. The parametrization X maps the st-domain space to the surface. The partial derivatives $X_s(s_0, t_0)$ and $X_t(s_0, t_0)$ form a basis for the tangent plane to the surface at P.

In the domain space, the line through (s_0, t_0) in the direction of the vector $\langle a, b\rangle$ can be parametrized as

$$\rho(w) = (s_0 + aw, t_0 + bw).$$

Then $X(\rho(w))$ is a curve on S,

$$X(\rho(w)) = \Big(f(s_0 + aw, t_0 + bw),\ g(s_0 + aw, t_0 + bw),\ h(s_0 + aw, t_0 + bw)\Big),$$

and the tangent vector at P can be computed by the chain rule:

$$\begin{aligned}[X(\rho(w))]' &= \langle f_s \cdot a + f_t \cdot b,\ g_s \cdot a + g_t \cdot b,\ h_s \cdot a + h_t \cdot b\rangle \\ &= a\langle f_s, g_s, h_s\rangle + b\langle f_t, g_t, h_t\rangle \\ &= aX_s + bX_t.\end{aligned}$$

Therefore, the vectors of the tangent plane T_P are all tangent vectors to parametrized curves on S that pass through P. So T_P is the best linear approximation to S in an infinitesimally small neighborhood around P.

Let's turn now to specifics. There are several surfaces that meet the constant negative curvature requirement. The one we are after, the pseudosphere, is relatively easy to work with because it is a surface of revolution. Start with a curve $\mathcal{C}$ in the yz-plane, parametrized as

$$r(t) = \big(0,\ y(t),\ z(t)\big).$$

It will simplify calculations if we place another restriction on the parametrization, and require that $\mathcal{C}$ be parametrized by arc length. That is, choose a parametrization that moves along $\mathcal{C}$ at a constant speed of 1, so that

$$\sqrt{[y'(t)]^2 + [z'(t)]^2} = 1.$$

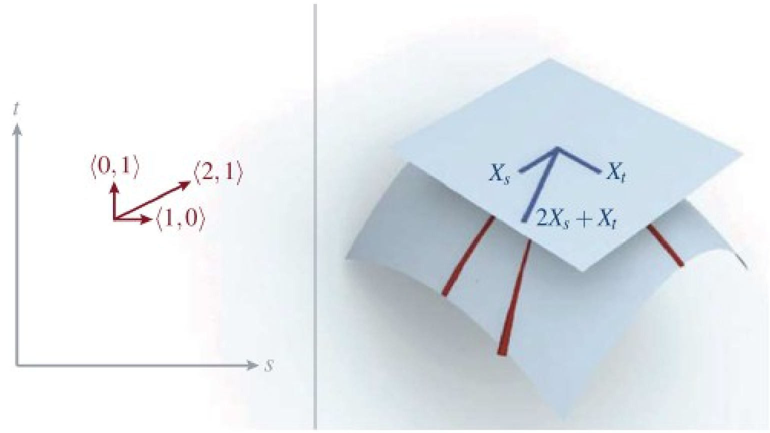

Figure 4. Any tangent vector in the tangent plane can be written as a linear combination of X_s and X_t.

Revolving $\mathcal{C}$ around the y-axis will generate a surface of revolution that can be parametrized as

$$X(s,t) = \big(z(t)\sin s,\ y(t),\ z(t)\cos s\big), \quad 0 \le s \le 2\pi.$$

At a point on this surface, the partial derivatives are

$$\begin{aligned} X_s &= \Big\langle z(t)\cos s,\ 0,\ -z(t)\sin s\Big\rangle \\ X_t &= \Big\langle z'(t)\sin s,\ y'(t),\ z'(t)\cos s\Big\rangle. \end{aligned}$$

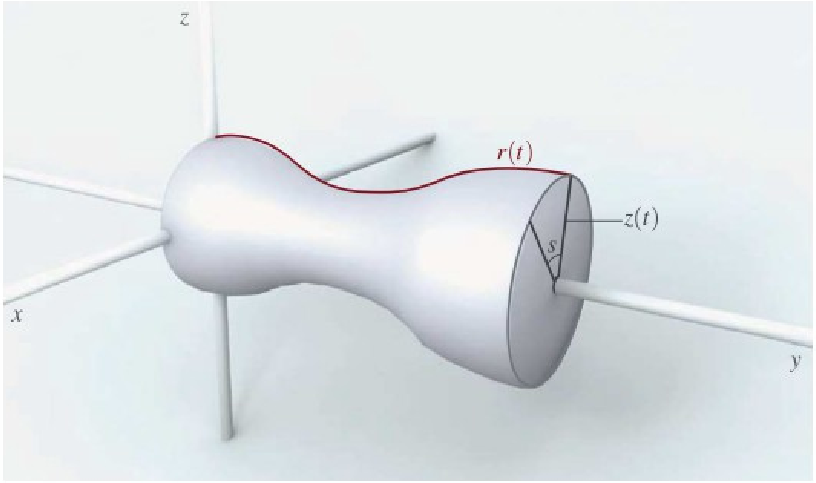

Figure 5. Form a surface by revolving the curve $r(t) = \langle 0, y(t), z(t)\rangle$ around the y-axis.

38.2 Maps between surfaces. The Gauss map

Because surfaces are now the objects of study, we consider maps between them. Let $f : S_1 \to S_2$ be a map from the points of a surface, S_1, to the points of another surface, S_2. Let P be a point on the first surface. The tangent plane T_P is the best linear approximation to S_1 around P. Likewise, on S_2, the tangent plane $T_{f(P)}$ is the best linear approximation to S_2 around $f(P)$. We want to define a linear map between the tangent planes $df : T_P \to T_{f(P)}$ that best approximates f near the points.

Let $X : D \to S_1$ be a parametrization of S_1 with $X(s_0, t_0) = P$. Every vector in T_P can be written as a linear combination $aX_s + bX_t$ and is therefore the tangent vector to the curve $X(\rho(w))$ where $\rho(w) = (s_0 + aw, t_0 + bw)$. The composition $f \circ X : D \to S_2$ is not likely to be a parametrization of S_2 since it will not typically be a bijection. Nevertheless, we can calculate the partial derivatives $(f \circ X)_s$ and $(f \circ X)_t$. A parametrized line $\rho(w)$ in D is mapped to a curve $f \circ X(\rho(w))$ on S_2, whose tangent vector at $f(P)$ is (by the chain rule)

$$\begin{aligned}[f \circ X(\rho(w))]' &= (f \circ X)_s \cdot \frac{ds}{dw} + (f \circ X)_t \cdot \frac{dt}{dw} \\ &= (f \circ X)_s \cdot a + (f \circ X)_t \cdot b.\end{aligned}$$

We define the differential of f at P, $df : T_P \to T_{f(P)}$, by

$$df(aX_s + bX_t) = a(f \circ X)_s + b(f \circ X)_t.$$

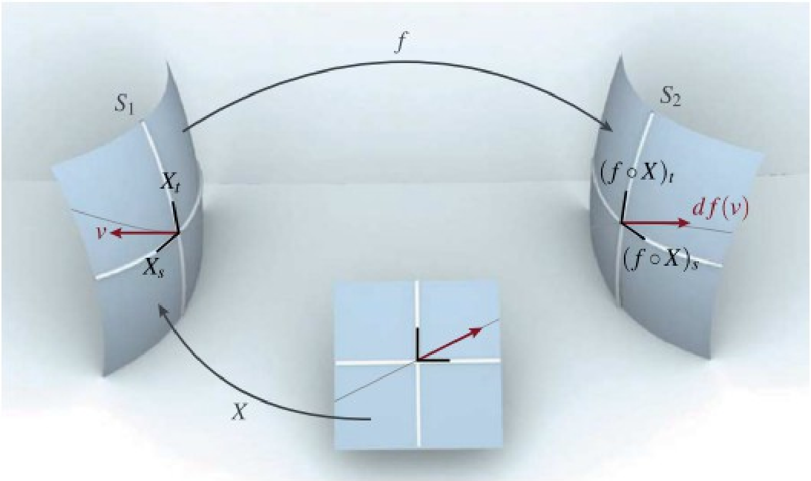

Figure 6. A map $f : S_1 \to S_2$ between two surfaces S_1 and S_2. The differential df is the map between tangent planes.

Gauss's idea was to use a particular map between surfaces, now called the Gauss map, to study curvature. The basic idea is simple and elegant. Imagine moving in a small neighborhood around a point P on a surface S, with an eye on the tangent plane as you do so. The tangent plane balances on the surface like a surfboard, and so as the surface bends, the tangent plane must turn. The more the tangent plane has to turn to keep up with the surface, the more highly curved the surface is. We can measure how fast the tangent plane is turning by looking at the rate of change of its unit normal vector (it is tempting to try to extend the surfboard analogy, and to call the unit normal vector the surfer on the surfboard, but that assumes the surfer is always perpendicular to the board).

Definition 38.1 Let $\mathbb{S}$ denote the sphere of radius one centered at the origin. For a point P on a smooth surface S, let $n(P)$ be the unit normal vector to S at P. If the tail of $n(P)$ is translated to the origin, then its head will be at a point $\nu(P)$ on $\mathbb{S}$. The *Gauss map* $\nu : S \to \mathbb{S}$ is defined by $P \mapsto \nu(P)$.

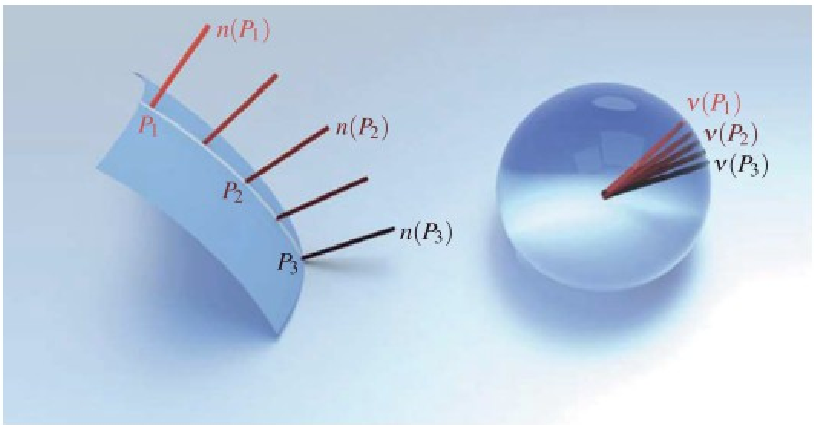

Figure 7. The Gauss map $\nu : S \to \mathbb{S}$.

The Gauss map may be complicated. However, the curvature at a point P only depends on what is happening near P, and there ν can be replaced by its linear approximation $d\nu$. The differential of the Gauss map has the advantage over the differentials of other maps that the tangent planes T_P and $T_{\nu(P)}$ are parallel. Because they have the same vectors in them, $\{X_s, X_t\}$ is a basis of T_P and of $T_{\nu(P)}$. In it, $d\nu$ can be written as a 2×2 matrix.

Let's now compute the Gauss map and its differential for our surface of revolution. To do that, we need to know the unit normal vector. The cross product of X_s and X_t is perpendicular to both of them, so it is a normal vector to the tangent plane:

$$\begin{aligned} N &= X_s \times X_t \\ &= \begin{vmatrix} i & j & k \\ z(t)\cos s & 0 & -z(t)\sin s \\ z'(t)\sin s & y'(t) & z'(t)\cos s \end{vmatrix} \\ &= \left\langle y'(t)z(t)\sin s,\ -z(t)z'(t)\cos^2 s - z(t)z'(t)\sin^2 s,\ y'(t)z(t)\cos s \right\rangle \\ &= \left\langle y'(t)z(t)\sin s,\ -z(t)z'(t),\ y'(t)z(t)\cos s \right\rangle. \end{aligned}$$

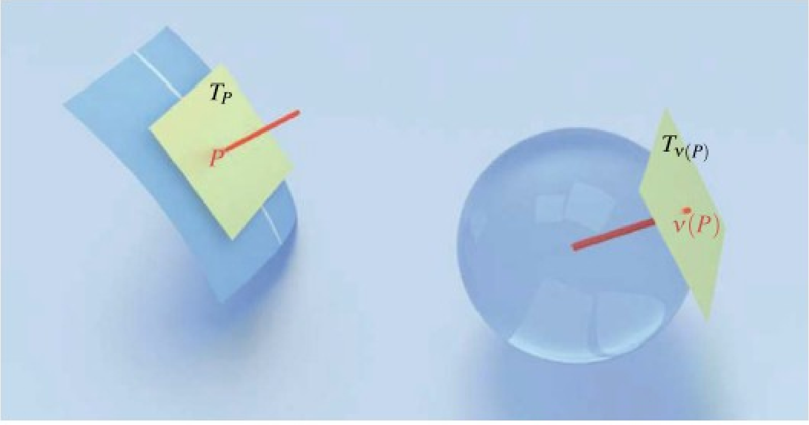

Figure 8. The differential of the Gauss map.

It may not be a unit vector, so we need to divide by its length

$$\begin{aligned}|N| &= \sqrt{\big(y'(t)z(t)\sin s\big)^2 + \big(-z(t)z'(t)\big)^2 + \big(y'(t)z(t)\cos s\big)^2}\\ &= \sqrt{\big(y'(t)z(t)\big)^2 + \big(-z(t)z'(t)\big)^2}\\ &= z(t)\sqrt{\big(y'(t)\big)^2 + \big(z'(t)\big)^2}\\ &= z(t).\end{aligned}$$

The last step takes advantage of the fact that $\mathcal{C}$ is parametrized by arc length. The unit normal is then

$$n = \frac{N}{|N|} = \Big\langle y'(t)\sin s,\ -z'(t),\ y'(t)\cos s\Big\rangle.$$

This calculation gives us the Gauss map as well. If $P = X(s,t)$, then

$$\nu(P) = \big(y'(t)\sin s,\ -z'(t),\ y'(t)\cos s\big).$$

Now let's find the $d\nu$ matrix. Compute the partial derivatives,

$$\begin{aligned}(\nu\circ X)_s &= \Big\langle y'(t)\cos s,\ 0,\ -y'(t)\sin s\Big\rangle\\ (\nu\circ X)_t &= \Big\langle y''(t)\sin s,\ -z''(t),\ y''(t)\cos s\Big\rangle.\end{aligned}$$

We rewrite them as linear combinations of the basis elements X_s and X_t, where

$$\begin{aligned}X_s &= \Big\langle z(t)\cos s,\ 0,\ -z(t)\sin s\Big\rangle\\ X_t &= \Big\langle z'(t)\sin s,\ y'(t),\ z'(t)\cos s\Big\rangle.\end{aligned}$$

The first is easy:

$$\begin{aligned}(\nu \circ X)_s &= \langle y'(t)\cos s,\ 0,\ -y'(t)\sin s\rangle \\ &= \frac{y'(t)}{z(t)} \cdot \Big\langle z(t)\cos s, 0, -z(t)\sin s\Big\rangle \\ &= \frac{y'(t)}{z(t)} \cdot X_s.\end{aligned}$$

The second requires a trick. Because $\mathcal{C}$ is parametrized by arc length,

$$[y'(t)]^2 + [z'(t)]^2 = 1.$$

If we differentiate with respect to t and solve for y'', we get

$$2y'(t)y''(t) + 2z'(t)z''(t) = 0 \implies y''(t) = -\frac{z'(t)z''(t)}{y'(t)}.$$

Substitute to get

$$\begin{aligned}(\nu \circ X)_t &= \Big\langle y''(t)\sin s,\ -z''(t),\ y''(t)\cos s\Big\rangle \\ &= \Big\langle -\frac{z'(t)z''(t)}{y'(t)}\sin s,\ -z''(t),\ -\frac{z'(t)z''(t)}{y'(t)}\cos s\Big\rangle \\ &= -\frac{z''(t)}{y'(t)} \cdot \Big\langle z'(t)\sin s,\ y'(t),\ z'(t)\cos s\Big\rangle \\ &= -\frac{z''(t)}{y'(t)} \cdot X_t.\end{aligned}$$

Therefore

$$\begin{aligned}d\nu(aX_s + bX_t) &= a(\nu \circ X)_s + b(\nu \circ X)_t \\ &= a(y'/z)X_s + b(-z''/y')X_t.\end{aligned}$$

In the $\{X_s, X_t\}$ basis, $d\nu$ has the matrix form

$$d\nu \begin{pmatrix} a \\ b \end{pmatrix} = \begin{pmatrix} y'/z & 0 \\ 0 & -z''/y' \end{pmatrix} \begin{pmatrix} a \\ b \end{pmatrix}.$$

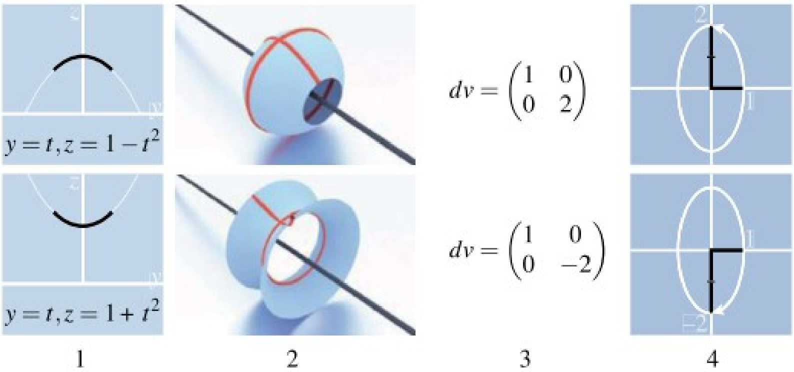
38.3 Gaussian curvature

The *Gaussian curvature* $K(P)$ of S at the point P is defined to be the determinant of the $d\nu$ matrix at P. In our case

$$K(P) = -\frac{y'(t)}{z(t)} \cdot \frac{-z''(t)}{y'(t)} = -\frac{z''(t)}{z(t)}.$$

What is the geometric significance of that number?

Why we want K to be negative. The $d\nu$ matrix is a symmetric matrix, which is obvious in our example, and true in general. Therefore it has real eigenvalues, and K, its determinant, is their product. If we apply the $d\nu$ map to the circle of unit vectors $\langle\cos\theta, \sin\theta\rangle$, we get a set of vectors that trace out an ellipse. Because the dv matrix is symmetric, the eigenvectors are along the major and minor axes of the ellipse, and the corresponding eigenvalues are the signed distances from the origin to the ellipse along the axes. This is true in general, and easy to see in our example. The eigenvectors point in the directions of maximum and minimum curvature, then, and the corresponding eigenvalues are the curvatures in those directions (they are called the principal curvatures). If K is negative, then one of the eigenvalues is positive and the other is negative. So in the direction of one eigenvector, the surface will bend towards the normal vector $n(P)$; in the direction of the other, the surface will bend away from $n(P)$. Hence, negative K will make the surface bend so that lines on it diverge.



$$dv = \begin{pmatrix} 1 & 0 \\ 0 & 2 \end{pmatrix}$$

$$dv = \begin{pmatrix} 1 & 0 \\ 0 & -2 \end{pmatrix}$$

Figure 9. (1) A curve is (2) revolved around the y-axis. We calculate (3) the dv matrix, and can then (4) see its effects on the unit circle.

Why we want $|K|$ to be constant. The magnitude of $\det(dv)$ is the factor by which dv scales area. The dv map will transform a 1×1 square into a parallelogram with an area of $|\det(dv)|$, and since dv is linear, all other areas will follow suit. In our example, the parallelogram is a rectangle, so this is clear. In a small region (say of size ϵ) near P, the dv map is a good approximation of v, and so v also approximately scales area by $|\det(dv)|$. To get a sense of the scaling near P, consider the circle of points that are a distance of ϵ from P on the surface—a "circle" on the surface—and look at its circumference. In the plane that circumference is $2\pi\epsilon$, but on a curved surface it is not. The ratio depends on the curvature at P. Intuitively that is clear because if $|\det(dv)|$ is large, then v will wrap the circle farther around $\mathbb{S}$ than if it is small. For instance, consider the points P and Q shown in figure 10.

Both are points of positive curvature, but the curvature at P is larger than the curvature at Q. Let C_P and C_Q be circles of radius ϵ, centered at P and Q respectively. While both circles have the same radius, the circumference of C_P is smaller than the circumference of C_Q. As a model for neutral geometry, this would create the following problem. The circumference of a circle is the limit of perimeters of regular inscribed polygons. Since C_P and C_Q have the same radius, a regular n-gon inscribed in C_P is congruent to a regular n-gon inscribed in C_Q. Hence their perimeters would be the same, and so the circumferences of C_P and C_Q, as limits of them, should be the same (the Bertrand-Diquet-Puiseux theorem gives a precise relationship between the curvature and the circumference/radius ratio and that is a place to look if you want a more rigorous explanation [Spi99a]).

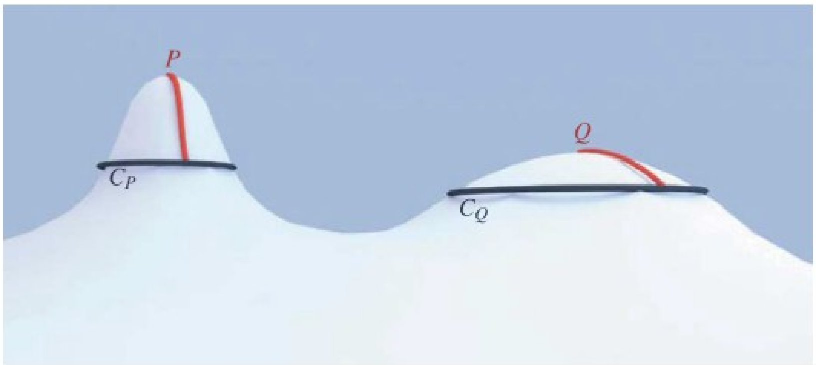


Figure 10. The curvature is greater at P than it is at Q. A circle centered at P of radius ϵ would have a smaller circumference than a circle centered at Q with the same radius.

38.4 The tractrix and pseudosphere

So it comes down to this: we want the curvature K to be a negative constant, say $K = -1$. That is,

$$-\frac{z''(t)}{z(t)} = -1 \implies z''(t) = z(t).$$

One solution to this differential equation (not the only one) is $z(t) = e^{t}$. What then, is $y(t)$? We get

$$\begin{aligned} (y'(t))^2 + (z'(t))^2 &= 1 \\ (y'(t))^2 + e^{2t} &= 1 \\ y'(t) &= -\sqrt{1 - e^{2t}} \\ y(t) &= \int -\sqrt{1 - e^{2t}}\, dt \end{aligned}$$

(the solution curve comes in two pieces corresponding to the positive and negative roots and the negative root is the one that gives the standard piece). We leave evaluating the integral as an exercise.

Exercise 38.1 Show that

$$\int -\sqrt{1 - e^{2t}}\, dt = \ln\left(\frac{1 + \sqrt{1 - e^{2t}}}{e^t}\right) - \sqrt{1 - e^{2t}} + C.$$

Any value for C will work, so put $C = 0$. For the term inside the square root to be positive, t must be between $-\infty$ and zero. The result is a parametrization of $\mathcal{C}$. Let's go ahead and do one more step and write y directly in terms of z. It is easy since $z = e^t$:

$$y = \ln\left(\frac{1 + \sqrt{1 - z^2}}{z}\right) - \sqrt{1 - z^2}, \quad 0 < z \le 1.$$

The curve is called the *tractrix*. Its graph is shown in figure 11. Rotating the tractrix around the y-axis generates the pseudosphere, shown in figure 12.

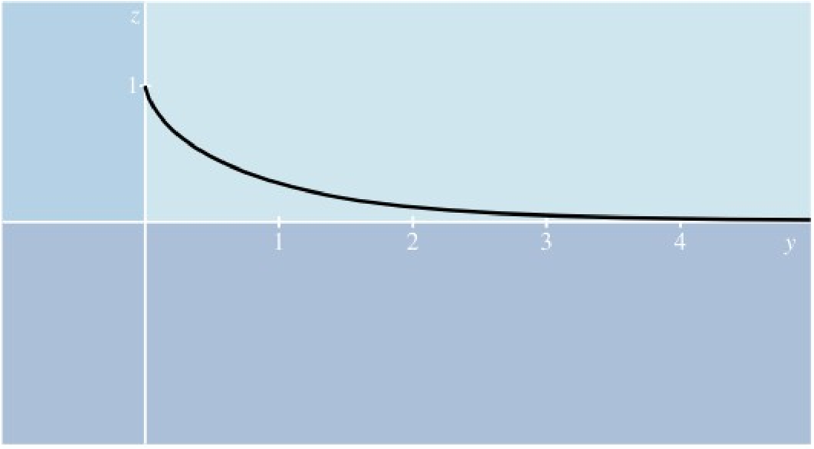

Figure 11. The graph of the tractrix (for positive y).

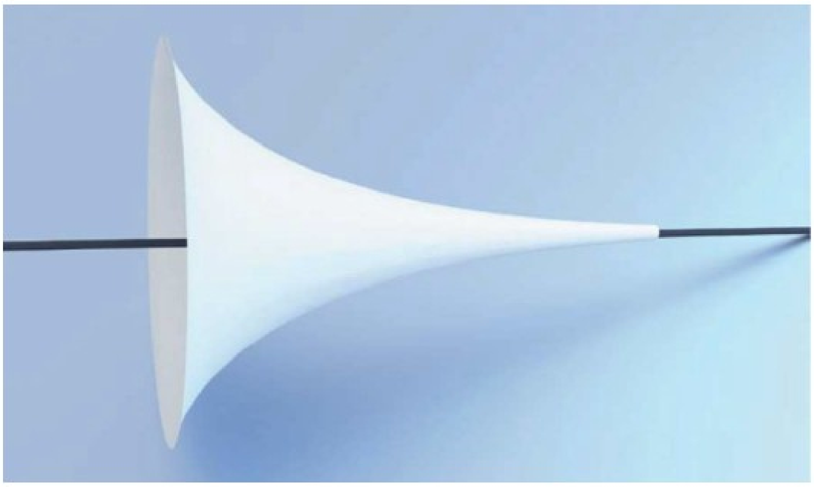

Figure 12. The pseudosphere.

The pseudosphere models a non-Euclidean neutral geometry locally, but globally there are some problems. One is apparent already: the pseudosphere ends at $y = 0$ where the tractrix has a vertical tangent. A neutral geometry plane cannot just stop like that. It is probably reasonable to hope that some other $K = -1$ surface (not a surface of revolution) would avoid this problem, but unfortunately this is not the case. Hilbert proved that no complete regular surface with constant negative curvature can be smoothly embedded in $\mathbb{R}^3$ [Spi99b]. In spite of its limitations, we will stick with the pseudosphere for a few more chapters. It will show the way to another model without the limitations.

38.5 Exercises

38.2. A torus can be realized as a surface of revolution formed by revolving a circle with radius a and center $(b, 0)$ around the y-axis (where $b > a$). Parametrize the surface.

38.3. Verify that the Gaussian curvature of the plane $z = 0$ is zero.

38.4. Show that the cylinder $x^2 + y^2 = 1$ has Gaussian curvature of zero.

38.5. Show that the Gaussian curvature of a sphere of radius r is $1/r^2$ (use spherical coordinates).

38.6. Compute the Gaussian curvature of the saddle surface $z = x^2 - y^2$ at the point $(0, 0, 0)$.

38.7. Let $P = (y_0, z_0)$ be a point on the tractrix. Let ℓ be the tangent line to the tractrix at P, and let $Q = (y_1, 0)$ be its intersection with the y-axis. Show that the distance from P to Q is 1 (so the distance from P to Q is independent of the coordinates of P).

39

Geodesics on the Pseudosphere

In the last chapter, we found a parametrization of the pseudosphere, a surface with constant negative curvature. The plan was to use that surface as a model for a non-Euclidean neutral geometry in which lines are represented by geodesics along the surface. The goal of this chapter is to calculate the geodesics.

39.1 Geodesics, the theory

Roughly, a geodesic between two points on a surface is the shortest path on the surface that connects them. To be more precise, we will talk about the calculus of variations. Let S be a surface parametrized by $X : D \to \mathbb{R}^3$ where

$$X(s,t) = (f(s,t), g(s,t), h(s,t))$$

and consider a parametrized curve $\rho(w)$ in the domain D (it can then be projected onto the surface S by X). We want to perturb $\rho(w)$ to see if the arc length of the curve on S increases or decreases. If the arc length always increases, no matter the variation, then $\rho(w)$ is a geodesic. What are the mechanics of perturbing?

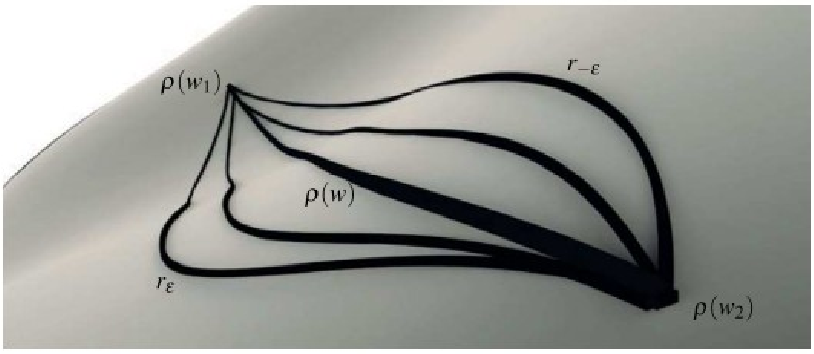

Figure 1. Some variations of the curve $\rho(w)$.

Definition 39.1 Let $\rho : [w_1, w_2] \to D$ be a parametrized curve in a domain D. A family of curves in D

$$\{r_v : [w_1, w_2] \longrightarrow D\}, \quad -\epsilon < v < \epsilon,$$

is a (smooth) *variation of* ρ if $R(w, v) = r_v(w)$ is a smooth map that satisfies:

- $R(w_1, v) = \rho(w_1)$ for all v; i.e., they all start at the same point,
- $R(w_2, v) = \rho(w_2)$ for all v; i.e., they all end at the same point,
- $R(w, 0) = \rho(w)$ (at $v = 0$, the original curve, unperturbed).

In general the length of a parametric curve $r(t)$ is calculated by integrating $|r'(t)|$. In our situation, the X map projects r_v of a variation onto the surface S, where we can calculate its arc length L as a function of v:

$$L(v) = \int_{w_1}^{w_2} \left|X(r_v(w))\right| dw = \int_{w_1}^{w_2} \sqrt{\left[X(r_v(w))\right]' \cdot \left[X(r_v(w))\right]'}\, dw.$$

For $\rho(w) = R(w, 0)$ to be a geodesic, $v = 0$ must be a local minimum of $L(v)$. This has to happen for every such variation.

Definition 39.2 Suppose that S is a surface parametrized by $X : D \longrightarrow \mathbb{R}^3$ and ρ is a parametrized curve in D. Then $X(\rho)$ is a *geodesic* of S if for every variation r_v of $\rho(w)$, $L(v)$, the length of $X(r_v)$, has a local minimum at $v = 0$.

Finding the local minimum across a perturbation requires locating the critical points, which requires computing the derivative with respect to v, of $L(v)$. We need to be careful with the variables: the integral is with respect to w, but the derivative is with respect to v. There is a trick that simplifies future calculations. The arc length integral involves a square root, which tends to make things difficult. There is, however, a related energy integral

$$\mathcal{E}(v) = \frac{1}{2} \int_{w_1}^{w_2} \left[X(r_v(w))\right]' \cdot \left[X(r_v(w))\right]' dw$$

that has the same critical points as L but not the square root (this is a commonly used trick in optimization problems; the calculations are not fundamentally different, but they are cleaned up). So to find the geodesics, we can solve the simple-looking equation

$$\frac{d}{dv}\mathcal{E}(v)\bigg|_{v=0} = 0.$$

Alas, it is not as simple as it looks.

39.2 Geodesics, the calculations

In the last chapter, we parametrized the pseudosphere as a surface of revolution

$$X(s, t) = \big(z(t)\sin s,\ y(t),\ z(t)\cos s\big), \quad 0 \le s \le 2\pi,$$

and found the equation for y in terms of z that would give the surface constant negative curvature. The result was the tractrix:

$$y = \ln\left(\frac{1+\sqrt{1-z^2}}{z}\right) - \sqrt{1-z^2}, \quad 0 < z \leq 1.$$

The tractrix came to us in a parametrized form where $z = e^t$, for $-\infty < t \leq 0$. We again need a parametrization of the tractrix, but this time a different one. Put $z(t) = 1/t$ with $1 \leq t < \infty$. Then

$$\begin{aligned} y(t) &= \ln\left(\frac{1+\sqrt{1-(1/t)^2}}{1/t}\right) - \sqrt{1-(1/t)^2} \\ &= \ln\left(t + t\sqrt{1-(1/t)^2}\right) - \sqrt{1-(1/t)^2} \\ &= \ln\left(t + \sqrt{t^2-1}\right) - \sqrt{1-(1/t)^2}. \end{aligned}$$

In this parametrization, X is the map from $D = [0, 2\pi) \times [1, \infty)$ to $\mathbb{R}^3$ given by

$$X(s,t) = \left(\frac{1}{t}\sin s,\ \ln\left(t+\sqrt{t^2-1}\right) - \sqrt{1-(1/t)^2},\ \frac{1}{t}\cos s\right).$$

Our goal is to find curves $\rho(w)$ in D so that $X(\rho(w))$ is a geodesic, i.e., curves that minimize energy. That calculation generates a pair of differential equations that $\rho(w)$ must satisfy. Solving the system will give the equations of the geodesics of the pseudosphere.

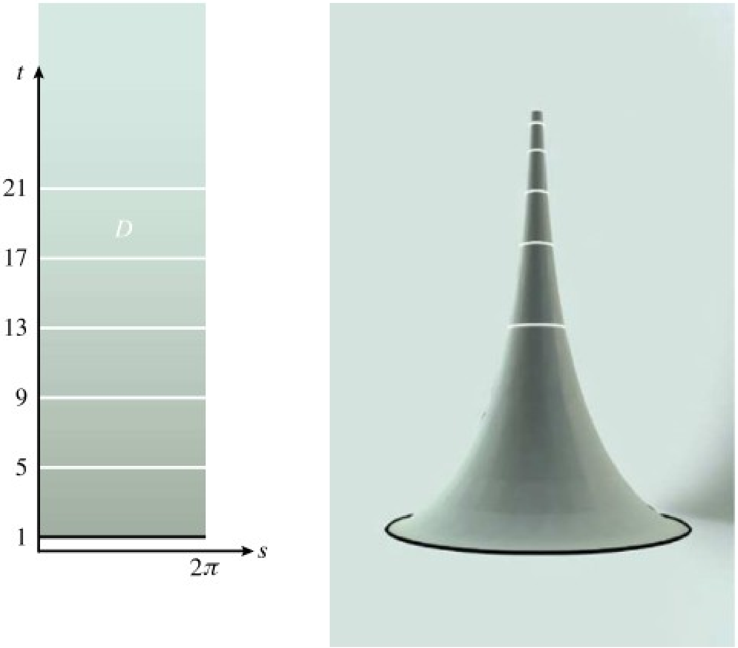

Figure 2. The domain D that is projected onto the pseudosphere by the parametrization X.

Given a variation $r_v(w)$, the energy integral is

$$\mathcal{E}(v) = \frac{1}{2}\int_{w_1}^{w_2} \frac{\partial X}{\partial w}\cdot\frac{\partial X}{\partial w}\,dw.$$

We need to find $\partial X/\partial w$. It may be helpful to review our variables. Because

$$X = \big(z(t)\sin s,\ y(t),\ z(t)\cos s\big),$$

X depends on s and t, which depend upon v and w (for the first calculation, we are setting up an integral to calculate the length of one curve in the variation, so the v variable is held constant). We have found y and z in terms of t, and it might be tempting to substitute now, but it is better to wait. We can use the chain rule to calculate

$$\begin{aligned}\frac{\partial X}{\partial w} &= \Big\langle \frac{\partial}{\partial s}(z\sin s)\cdot\frac{\partial s}{\partial w} + \frac{\partial}{\partial t}(z\sin s)\cdot\frac{\partial t}{\partial w},\ \frac{dy}{dt}\frac{\partial t}{\partial w},\\ &\qquad\qquad \frac{\partial}{\partial s}(z\cos s)\cdot\frac{\partial s}{\partial w} + \frac{\partial}{\partial t}(z\cos s)\cdot\frac{\partial t}{\partial w}\Big\rangle\\ &= \Big\langle z\cos s\frac{\partial s}{\partial w} + \sin s\frac{dz}{dt}\frac{\partial t}{\partial w},\ \frac{dy}{dt}\frac{\partial t}{\partial w},\ -z\sin s\frac{\partial s}{\partial w} + \cos s\frac{dz}{dt}\frac{\partial t}{\partial w}\Big\rangle,\end{aligned}$$

and then

$$\begin{aligned}\frac{\partial X}{\partial w}\cdot\frac{\partial X}{\partial w} &= \left[z\cos s\frac{\partial s}{\partial w} + \sin s\frac{dz}{dt}\frac{\partial t}{\partial w}\right]^2 + \left[\frac{dy}{dt}\frac{\partial t}{\partial w}\right]^2 + \left[-z\sin s\frac{\partial s}{\partial w} + \cos s\frac{dz}{dt}\frac{\partial t}{\partial w}\right]^2.\\ &= \left[z^2\cos^2 s\left(\frac{\partial s}{\partial w}\right)^2 + 2z\sin s\cos s\frac{\partial s}{\partial w}\frac{dz}{dt}\frac{\partial t}{\partial w} + \sin^2 s\left(\frac{dz}{dt}\frac{\partial t}{\partial w}\right)^2\right] + \left[\frac{dy}{dt}\frac{\partial t}{\partial w}\right]^2\\ &\quad + \left[z^2\sin^2 s\left(\frac{\partial s}{\partial w}\right)^2 - 2z\sin s\cos s\frac{\partial s}{\partial w}\frac{dz}{dt}\frac{\partial t}{\partial w} + \cos^2 s\left(\frac{dz}{dt}\frac{\partial t}{\partial w}\right)^2\right].\end{aligned}$$

Thanks to the Pythagorean identity $\sin^2 x + \cos^2 x = 1$, this simplifies to

$$\frac{\partial X}{\partial w}\cdot\frac{\partial X}{\partial w} = z^2\left(\frac{\partial s}{\partial w}\right)^2 + \left(\frac{dz}{dt}\frac{\partial t}{\partial w}\right)^2 + \left(\frac{dy}{dt}\frac{\partial t}{\partial w}\right)^2.$$

Now we can substitute y and z. We know $z = 1/t$, so $dz/dt = -1/t^2$. The dy/dt term is a little more difficult.

Lemma 39.3 *The derivative of*

$$y(t) = \ln(t + \sqrt{t^2 - 1}) - \sqrt{1 - (1/t)^2}, \quad t \geq 1,$$

is $y'(t) = \sqrt{t^2 - 1}/t^2$, *and thus* $[y'(t)]^2 = t^{-2} - t^{-4}$.

Exercise 39.1 Verify lemma 39.3.

Substituting,

$$\begin{aligned}\frac{\partial X}{\partial w}\cdot\frac{\partial X}{\partial w} &= \frac{1}{t^2}\left(\frac{\partial s}{\partial w}\right)^2+\frac{1}{t^4}\left(\frac{\partial t}{\partial w}\right)^2+\left(\frac{1}{t^2}-\frac{1}{t^4}\right)\left(\frac{\partial t}{\partial w}\right)^2\\ &= \frac{1}{t^2}\left[\left(\frac{\partial s}{\partial w}\right)^2+\left(\frac{\partial t}{\partial w}\right)^2\right].\end{aligned}$$

We have our energy function. For a variation $\{r_v(w)\}$ of ρ,

$$\mathcal{E}(v)=\frac{1}{2}\int_{w_1}^{w_2}\frac{1}{t^2}\left[\left(\frac{\partial s}{\partial w}\right)^2+\left(\frac{\partial t}{\partial w}\right)^2\right]dw.$$

The geodesics will be critical points of the function. To find them, let's differentiate with respect to v (use the product rule):

$$\begin{aligned}\frac{d\mathcal{E}}{dv} &= \frac{d}{dv}\left(\frac{1}{2}\int_{w_1}^{w_2}\frac{1}{t^2}\left[\left(\frac{\partial s}{\partial w}\right)^2+\left(\frac{\partial t}{\partial w}\right)^2\right]dw\right)\\ &= \frac{1}{2}\int_{w_1}^{w_2}\frac{\partial}{\partial v}\left(\frac{1}{t^2}\cdot\left[\left(\frac{\partial s}{\partial w}\right)^2+\left(\frac{\partial t}{\partial w}\right)^2\right]\right)dw\\ &= \frac{1}{2}\int_{w_1}^{w_2}\frac{1}{t^2}\left[2\frac{\partial s}{\partial w}\frac{\partial^2 s}{\partial w\partial v}+2\frac{\partial t}{\partial w}\frac{\partial^2 t}{\partial w\partial v}\right]-\frac{2}{t^3}\frac{\partial t}{\partial v}\left[\left(\frac{\partial s}{\partial w}\right)^2+\left(\frac{\partial t}{\partial w}\right)^2\right]dw\\ &= \int_{w_1}^{w_2}\frac{1}{t^2}\frac{\partial s}{\partial w}\frac{\partial^2 s}{\partial w\partial v}+\frac{1}{t^2}\frac{\partial t}{\partial w}\frac{\partial^2 t}{\partial w\partial v}-\frac{1}{t^3}\left[\left(\frac{\partial s}{\partial w}\right)^2+\left(\frac{\partial t}{\partial w}\right)^2\right]\frac{\partial t}{\partial v}\,dw.\end{aligned}$$

The variation variable is v so we have very little control over it. Therefore, it makes sense to try to isolate the v terms as much as possible. The mixed partials are a challenge, but fortunately there is a trick.

Lemma 39.4

$$\int_{w_1}^{w_2}\frac{1}{t^2}\frac{\partial s}{\partial w}\frac{\partial^2 s}{\partial w\partial v}\,dw=\int_{w_1}^{w_2}\frac{1}{t^3}\left[2\frac{\partial s}{\partial w}\frac{\partial t}{\partial w}-t\frac{\partial^2 s}{\partial w^2}\right]\frac{\partial s}{\partial v}\,dw$$

$$\int_{w_1}^{w_2}\frac{1}{t^2}\frac{\partial t}{\partial w}\frac{\partial^2 t}{\partial w\partial v}\,dw=\int_{w_1}^{w_2}\frac{1}{t^3}\left[2\left(\frac{\partial t}{\partial w}\right)^2-t\frac{\partial^2 t}{\partial w^2}\right]\frac{\partial t}{\partial v}\,dw.$$

Proof Both formulas are an application of integration by parts. We will do the first calculation, and leave the similar second calculation as an exercise. Put

$$U=\frac{1}{t^2}\cdot\frac{\partial s}{\partial w},\qquad dU=\left(\frac{1}{t^2}\frac{\partial^2 s}{\partial w^2}-\frac{2}{t^3}\frac{\partial t}{\partial w}\frac{\partial s}{\partial w}\right)dw,$$

$$dV=\frac{\partial^2 s}{\partial w\partial v}\,dw,\qquad V=\frac{\partial s}{\partial v},$$

so that

$$\int_{w_1}^{w_2} \frac{1}{t^2}\frac{\partial s}{\partial w}\frac{\partial^2 s}{\partial w \partial v}\,dw = \left(\frac{1}{t^2}\frac{\partial s}{\partial w}\frac{\partial s}{\partial v}\right)\Bigg|_{w_1}^{w_2} - \int_{w_1}^{w_2} \frac{\partial s}{\partial v}\left[\frac{1}{t^2}\frac{\partial^2 s}{\partial w^2} - \frac{2}{t^3}\frac{\partial t}{\partial w}\frac{\partial s}{\partial w}\right] dw.$$

The variation is fixed at both endpoints, so $\partial s/\partial v(w_1) = \partial s/\partial v(w_2) = 0$. The first term contributes nothing, so

$$\begin{aligned}\int_{w_1}^{w_2} \frac{1}{t^2}\frac{\partial s}{\partial w}\frac{\partial^2 s}{\partial w \partial v}\,dw &= 0 - \int_{w_1}^{w_2} \frac{\partial s}{\partial v}\left[\frac{1}{t^2}\frac{\partial^2 s}{\partial w^2} - \frac{2}{t^3}\frac{\partial t}{\partial w}\frac{\partial s}{\partial w}\right] dw \\ &= \int_{w_1}^{w_2} \frac{1}{t^3}\left[2\frac{\partial t}{\partial w}\frac{\partial s}{\partial w} - t\frac{\partial^2 s}{\partial w^2}\right]\frac{\partial s}{\partial v}\,dw.\end{aligned}$$

□

Exercise 39.2 Verify the second equation in the last lemma.

Substitute into $d\mathcal{E}/dv$ to get

$$\begin{aligned}\frac{d\mathcal{E}}{dv} &= \int_{w_1}^{w_2} \frac{1}{t^3}\left[2\frac{\partial s}{\partial w}\frac{\partial t}{\partial w} - t\frac{\partial^2 s}{\partial w^2}\right]\frac{\partial s}{\partial v} + \frac{1}{t^3}\left[2\left(\frac{\partial t}{\partial w}\right)^2 - t\frac{\partial^2 t}{\partial w^2}\right]\frac{\partial t}{\partial v} \\ &\qquad - \frac{1}{t^3}\left[\left(\frac{\partial s}{\partial w}\right)^2 + \left(\frac{\partial t}{\partial w}\right)^2\right]\frac{\partial t}{\partial v}\,dw \\ &= \int_{w_1}^{w_2} \frac{1}{t^3}\left[2\frac{\partial s}{\partial w}\frac{\partial t}{\partial w} - t\frac{\partial^2 s}{\partial w^2}\right]\frac{\partial s}{\partial v} + \frac{1}{t^3}\left[\left(\frac{\partial t}{\partial w}\right)^2 - t\frac{\partial^2 t}{\partial w^2} - \left(\frac{\partial s}{\partial w}\right)^2\right]\frac{\partial t}{\partial v}\,dw.\end{aligned}$$

The critical points of $\mathcal{E}(v)$ occur when the integral is zero. Still, we know little about $\partial s/\partial v$ and $\partial t/\partial v$. There may be some variations where the $\partial s/\partial v$ and $\partial t/\partial v$ components cancel each other out. But geodesics occur only when energy is minimized for all variations. The only way to guarantee this regardless of variation is if when $v = 0$, at $\rho(v)$,

- $2\dfrac{ds}{dw}\dfrac{dt}{dw} - t\dfrac{d^2 s}{dw^2} = 0$, and
- $\left(\dfrac{dt}{dw}\right)^2 - t\dfrac{d^2 t}{dw^2} - \left(\dfrac{ds}{dw}\right)^2 = 0$,

the differential equations that describe a geodesic ρ. The next step is to put them into a more useful form (one that does not involve second derivatives) with the following lemmas.

Lemma 39.5 *If*

$$2\frac{ds}{dw}\frac{dt}{dw} - t\frac{d^2 s}{dw^2} = 0,$$

then s'/t^2 is a constant.

Proof Assuming as given that

$$-ts'' + 2t's' = 0,$$

use the quotient rule to compute the derivative of s'/t^2:

$$\left(\frac{s'}{t^2}\right)' = \frac{t^2 s'' - s' \cdot 2tt'}{(t^2)^2} = \frac{ts'' - 2s't'}{t^3} = 0.$$

Since the derivative of s'/t^2 is zero, s'/t^2 is a constant. ☐

Lemma 39.6 *If*

$$2\frac{ds}{dw}\frac{dt}{dw} - t\frac{d^2 s}{dw^2} = 0 \quad \textit{and} \quad \left(\frac{dt}{dw}\right)^2 - t\frac{d^2 t}{dw^2} - \left(\frac{ds}{dw}\right)^2 = 0,$$

then $(s')^2 + (t')^2 = Ct^2$ *for some constant* C.

Proof Multiply both sides of the second equation by -1 to get $(s')^2 - (t')^2 + tt'' = 0$. Then add $(s')^2 + (t')^2$ to both sides and multiply by t':

$$\begin{aligned} (s')^2 - (t')^2 + tt'' &= 0 \\ 2(s')^2 + tt'' &= (s')^2 + (t')^2 \\ 2(s')^2 t' + tt't'' &= [(s')^2 + (t')^2]t'. \end{aligned}$$

According to the first equation, $2s't' = ts''$ so

$$\begin{aligned} s'(ts'') + tt't'' &= [(s')^2 + (t')^2]t' \\ t[s's'' + t't''] &= [(s')^2 + (t')^2]t' \\ [s's'' + t't'']/[(s')^2 + (t')^2] &= t'/t. \end{aligned}$$

Integrate with respect to w. On the right

$$\int \frac{t'}{t}\, dw = \ln(t) + C_1.$$

The left hand side is similar: put $u = (s')^2 + (t')^2$ so that $du = (2s's'' + 2t't'')\, dw$. Then

$$\int \frac{s's'' + t't''}{(s')^2 + (t')^2}\, dw = \int \frac{1/2}{u}\, du = \frac{1}{2}\ln|u| + C_2 = \frac{1}{2}\ln\left((s')^2 + (t')^2\right) + C_2.$$

Combining, we get

$$\begin{aligned} \tfrac{1}{2}\ln\left((s')^2 + (t')^2\right) + C_2 &= \ln(t) + C_1 \\ \ln\left((s')^2 + (t')^2\right) &= 2\ln(t) + 2C_1 - 2C_2 \\ (s')^2 + (t')^2 &= e^{\ln(t^2) + 2C_1 - 2C_2} \\ (s')^2 + (t')^2 &= Ct^2 \end{aligned}$$

where $C = e^{2C_1 - 2C_2}$. ☐

The constant C eventually gets wrapped into other constants, so there is no harm in assuming that $C = 1$ now. Doing that means

$$X(\rho)' \cdot X(\rho)' = \frac{1}{t^2}\left[(s')^2 + (t')^2\right] = \frac{1}{t^2} \cdot t^2 = 1.$$

The parametrized curve $X(\rho)$ on the pseudosphere moves at a constant speed of 1, so the curve is parametrized by arc length.

Now let's assume that a curve ρ satisfies the differential equations, and try to see what ρ will look like. Assuming $s'/t^2 = k$ for some constant k, write $s' = kt^2$. There is one case where this is easy: if $k = 0$, then $s' = 0$, so s is a constant, so ρ is a vertical line in D.

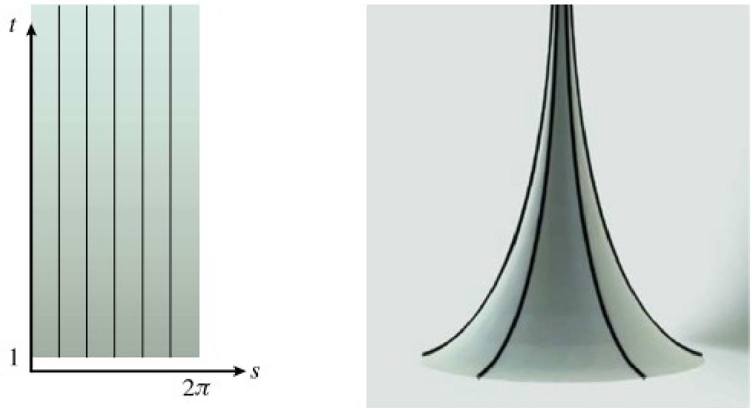

Figure 3. Geodesics on the pseudosphere that are projections of vertical lines.

If $k \neq 0$, the calculation is more difficult. Start by substituting $s' = kt^2$ into the second equation:

$$\begin{aligned}(s')^2 + (t')^2 = t^2 &\implies (kt^2)^2 + (t')^2 = t^2\\ &\implies (t')^2 = t^2 - k^2t^4\\ &\implies t' = \sqrt{t^2 - k^2t^4} = t\sqrt{1 - k^2t^2}.\end{aligned}$$

Since s and t are functions of w, we can eliminate w to get a single differential equation relating s and t:

$$\frac{ds}{dt} = \frac{ds/dw}{dt/dw} = \frac{kt^2}{t\sqrt{1 - k^2t^2}} = \frac{kt}{\sqrt{1 - k^2t^2}}.$$

Integrating gives s in terms of t, the equations of the geodesics.

Lemma 39.7 *If $k \neq 0$, then*

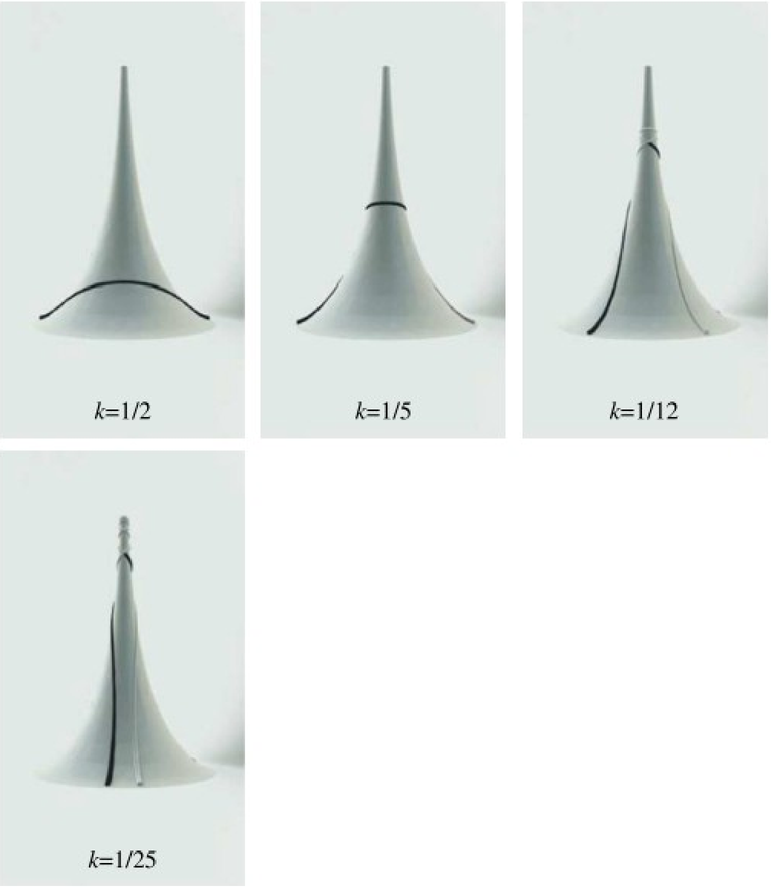
$$\int \frac{kt}{\sqrt{1 - k^2t^2}}\,dt = -\frac{1}{k}\sqrt{1 - k^2t^2} + C.$$

Proof Let $u = 1 - k^2t^2$ so $du = -2k^2t\,dt$ and

$$\begin{aligned}\int \frac{kt}{\sqrt{1-k^2t^2}}\,dt &= \int \frac{-1/(2k)}{\sqrt{u}}\,du \\ &= -\frac{1}{2k}\int u^{-1/2}\,du \\ &= -\frac{1}{2k}2u^{1/2} + C \\ &= -\frac{1}{k}\sqrt{1-k^2t^2} + C.\end{aligned}$$ ☐

Therefore, if ρ is a geodesic, it satisfies

$$s = -\frac{1}{k}\sqrt{1-k^2t^2} + C \implies k(s-C) = -\sqrt{1-k^2t^2}.$$



k=1/2

k=1/5

k=1/12

k=1/25

Figure 4. Geodesics on the pseudosphere that are the projections of half-circles. The projection of the entire half-circle is shown. The portion that lies in the domain D is shaded black. Extending the curves beyond D creates self-intersections that would be undesirable in a model for a non-Euclidean neutral geometry.

Square both sides:

$$\begin{aligned} k^2(s-C)^2 &= 1-k^2t^2 \\ k^2(s-C)^2+k^2t^2 &= 1 \\ (s-C)^2+t^2 &= (1/k)^2. \end{aligned}$$

The curves in D that project to geodesics on the pseudosphere are circles that are centered on the s-axis (or at least the portions of them that lie in D).

The geodesics reveal another problem with the pseudosphere model. When the circles ρ reach the edge of D, the corresponding geodesics on the pseudosphere just stop. It is easy to get around that problem by extending D horizontally so that X wraps around the pseudosphere more than once. But then the geodesics cross over themselves, creating undesirable self-intersections.

39.3 References

Spivak discusses geodesics in the third volume of his *Comprehensive Introduction to Differential Geometry* [Spi99b], but my approach here more closely follows Thorpe's *Elementary Topics in Differential Geometry* [Tho79].

39.4 Exercises

39.3. The standard parameterization (in terms of sine and cosine) of the circle $(s-C)^2+t^2=(1/k)^2$ does not satisfy the differential equation for the arc length criterion or either of the differential equations for the geodesic criterion. The parametrization that works is

$$s(w)=\frac{1}{k}\tanh(w), \quad t(w)=\frac{1}{k}\operatorname{sech}(w).$$

Verify that the parametrization satisfies the differential equations (the $\operatorname{sech}(w)$ and $\tanh(w)$ functions are covered in chapter 44 if you are not familiar with them).

39.4. Show that lines are geodesics in the plane $z=0$.

39.5. Show that the circle $r(t)=\langle\cos t, \sin t, k\rangle$ (k constant) is a geodesic on the cylinder $x^2+y^2=1$. Show that the vertical line $r(t)=\langle 1, 0, t\rangle$ is also a geodesic on the cylinder.

39.6. Show that the equatorial circle $r(t)=\langle\cos t, \sin t, 0\rangle$ is a geodesic on the sphere $x^2+y^2+z^2=1$.

46

Hyperbolic Area

When we developed Euclidean area in chapter 30, we described it as a positive real number associated with each polygon so that

- congruent polygons would have the same area,
- if a polygon could be broken into smaller pieces, the area of that polygon would be the sum of the areas of the pieces, and
- the area of a rectangle would be given by the formula $A = bh$.

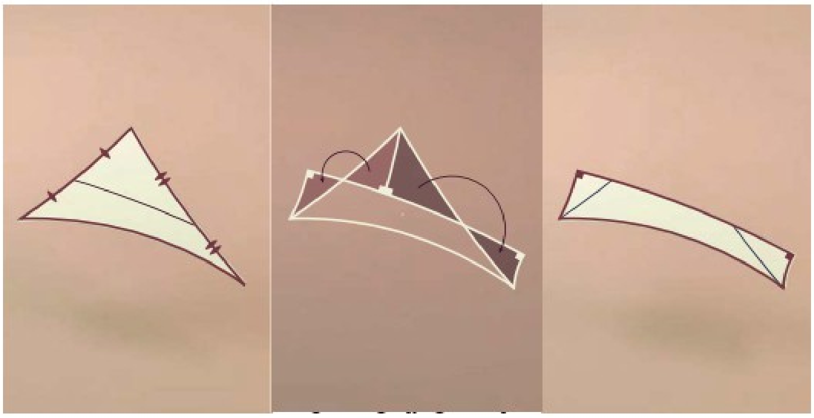


Figure 1. A triangle can be cut and the pieces rearranged to form a Saccheri quadrilateral. The triangle and the Saccheri quadrilateral should have the same area.

Hyperbolic area should retain the first two properties, but the last one isn't going to work because there are no rectangles. Hyperbolic area will have to be built from some other shape. The obvious choice is a triangle (and you could argue that it would have been better to build up Euclidean areas from triangles as well). The area of a Euclidean triangle is $A = bh/2$ but the formula doesn't work in the hyperbolic realm (a specific example is investigated in the exercises). So where can we look to find the formula for the area of a hyperbolic triangle? We will go back to the pseudosphere.

46.1 Area on the pseudosphere

In multivariable calculus the area $\mathscr{A}$ of a parametrized surface $\Omega = X(D)$ can be calculated as the double integral

$$\mathscr{A} = \iint_{\Omega} 1\, d\sigma = \iint_{D} |N| dt ds$$

where $|N|$ is the length of the normal vector. We have parametrized the pseudosphere by

$$X(s,t) = \left(\frac{\sin s}{t},\ \ln(t + \sqrt{t^2 - 1}) - \sqrt{1 - \frac{1}{t^2}},\ \frac{\cos s}{t} \right),$$

where $0 \le s \le 2\pi$ and $1 \le t < \infty$. The restriction on t is essential, but the $[0, 2\pi]$ restriction on s is there just to ensure that the domain wraps around the pseudosphere only once. That horizontal constraint is fairly restricting but we can ignore it, so long as we understand that this will cause X to wrap around the pseudosphere repeatedly.

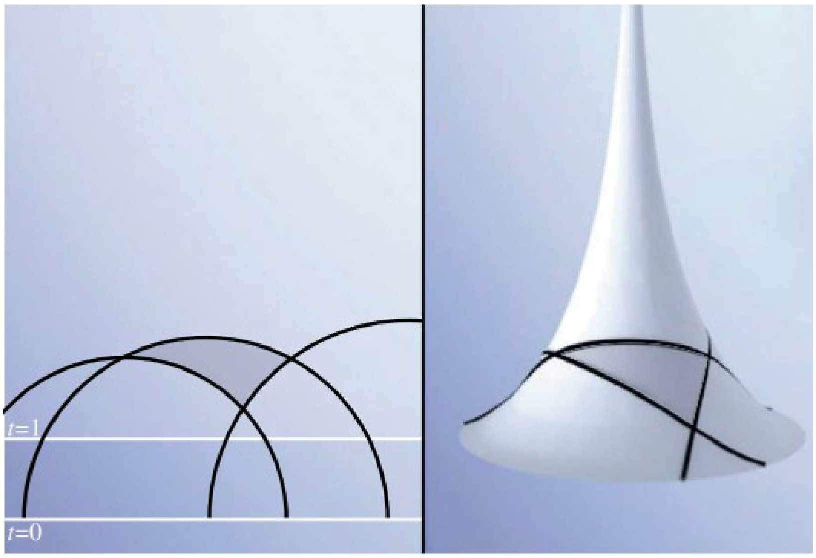

Figure 2. The projection of a triangle from the UHP to the pseudosphere.

The N vector is the cross product of the partial derivatives,

$$X_s = \left\langle \frac{\cos s}{t},\ 0,\ -\frac{\sin s}{t} \right\rangle$$
$$X_t = \left\langle -\frac{\sin s}{t^2},\ \frac{\sqrt{t^2 - 1}}{t^2},\ -\frac{\cos s}{t^2} \right\rangle$$

(the calculation of $\partial y/\partial t$ in X_t was an exercise in chapter 39). Then

$$\begin{aligned}
N &= \begin{vmatrix} i & j & k \\ \dfrac{\cos s}{t} & 0 & -\dfrac{\sin s}{t} \\ -\dfrac{\sin s}{t^2} & \dfrac{\sqrt{t^2-1}}{t^2} & -\dfrac{\cos t}{t^2} \end{vmatrix} \\
&= \left\langle \frac{\sin s}{t} \cdot \frac{\sqrt{t^2-1}}{t^2},\ \frac{\sin s}{t} \cdot \frac{\sin s}{t^2} + \frac{\cos s}{t} \frac{\cos s}{t^2},\ \frac{\cos s}{t} \cdot \frac{\sqrt{t^2-1}}{t^2} \right\rangle \\
&= \left\langle \frac{\sin s\sqrt{t^2-1}}{t^3},\ \frac{1}{t^3},\ \frac{\cos s\sqrt{t^2-1}}{t^3} \right\rangle,
\end{aligned}$$

and so

$$\begin{aligned}
|N| &= (N \cdot N)^{1/2} \\
&= \left[\frac{\sin^2 s(t^2-1) + 1 + \cos^2 s(t^2-1)}{t^6} \right]^{1/2} \\
&= \frac{[(t^2-1)+1]^{1/2}}{t^3} \\
&= 1/t^2.
\end{aligned}$$

Substitution yields a pleasant integral:

$$\mathscr{A} = \iint_D \frac{1}{t^2}\, ds dt.$$

We are not interested in the surface area of the pseudosphere as a whole. We want to know the areas of hyperbolic triangles on it. For that, the tricky part is to set up the proper domain D to cover them. We proceed in several steps.

Lemma 46.1 *Let*

$$D = \{(s,t) \big| (s^2+t^2) < r^2,\ 0 \le a \le s \le b,\ t \ge 1\},$$

an approximately quadrilateral region in the UHP. Then the area of $X(D)$ *is*

$$\mathscr{A} = (b-a) + (\sin^{-1}(a/r) - \sin^{-1}(b/r)).$$

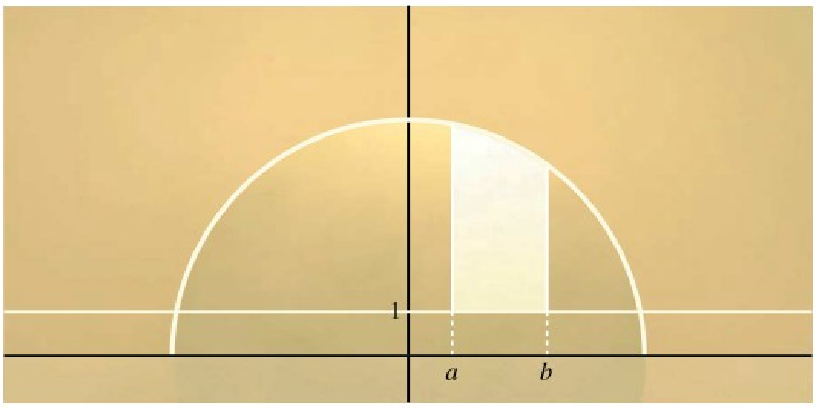

Figure 3. The first domain, with $0 \leq a \leq b$.

Proof This is a straightforward calculation.

$$
\begin{aligned}
\mathscr{A} &= \iint_D \frac{1}{t^2}\, ds dt \\
&= \int_a^b \int_1^{\sqrt{r^2-s^2}} \frac{1}{t^2}\, dt ds \\
&= \int_a^b -\frac{1}{t}\Big|_1^{\sqrt{r^2-s^2}} ds \\
&= \int_a^b 1 - \frac{1}{\sqrt{r^2-s^2}}\, ds \\
&= \int_a^b 1\, ds - \int_a^b \frac{1}{\sqrt{r^2-s^2}}\, ds \\
&= (b-a) - \int_a^b \frac{1}{\sqrt{r^2-s^2}}\, ds.
\end{aligned}
$$

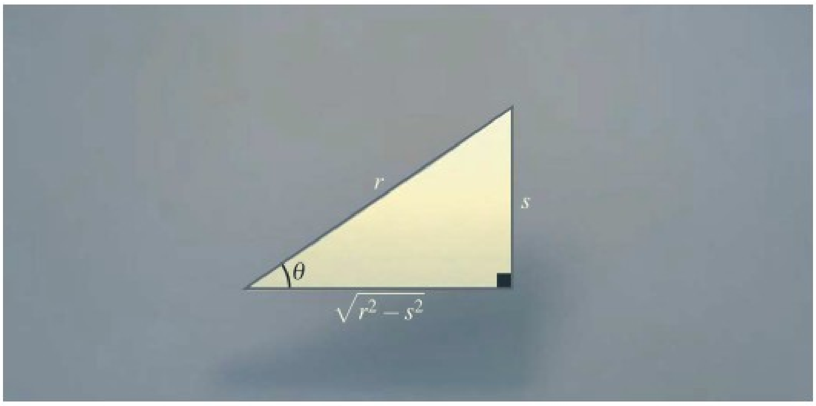

Figure 4. A trigonometric substitution.

Use trigonometric substitution: put $s = r\sin\theta$, so that $\sqrt{r^2 - s^2} = r\cos\theta$ and $ds = r\cos\theta\, d\theta$. Then

$$\begin{aligned}
\mathscr{A} &= (b-a) - \int_{s=a}^{s=b} \frac{r\cos\theta}{r\cos\theta}\, d\theta \\
&= (b-a) - \left(\theta\Big|_{s=a}^{s=b}\right) \\
&= (b-a) - \left(\sin^{-1}(s/r)\Big|_a^b\right) \\
&= (b-a) - \left[\sin^{-1}(b/r) - \sin^{-1}(a/r)\right] \\
&= (b-a) + \sin^{-1}(a/r) - \sin^{-1}(b/r).
\end{aligned}$$

□

The previous lemma ended with two inverse sine functions. They can be rewritten in a more useful form.

Lemma 46.2 *Let D be the same region as in the previous lemma, but now label its top-most vertices*

$$A = (a, \sqrt{r^2 - a^2}) \text{ and } B = (b, \sqrt{r^2 - b^2}).$$

Then

$$\mathscr{A} = (b-a) + (\pi - (\angle A) - (\angle B)),$$

where $(\angle A)$ and $(\angle B)$ are computed by measuring the angles between the vertical lines and the tangent lines to D at A and B.

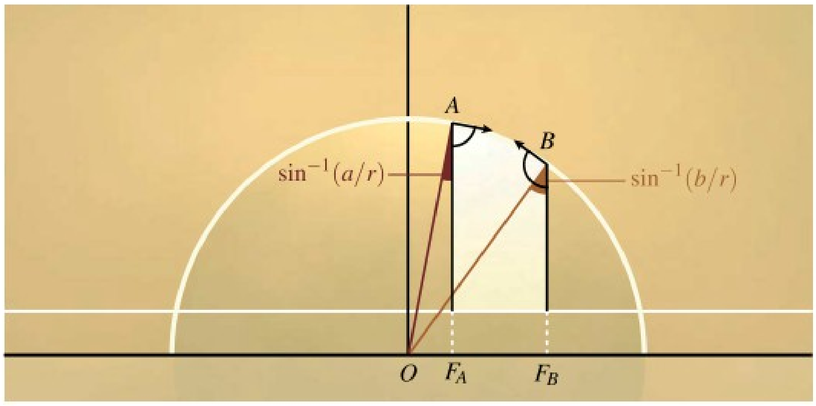

Figure 5. Relating the area to the measures of $\angle A$ and $\angle B$.

Proof We start with labels: let O be the origin, $F_A = (a, 0)$, and $F_B = (b, 0)$. The right triangle $\triangle OF_AA$ has hypotenuse r and a side of length a, so

$$\sin(\angle OAF_A) = \frac{a}{r} \implies (\angle OAF_A) = \sin^{-1}(a/r).$$

This angle is complementary to $\angle A$, so $\sin^{-1}(a/r) = \pi/2 - (\angle A)$. The behavior at B is different. Again

$$\sin(\angle OBF_B) = \frac{b}{r} \implies (\angle OBF_B) = \sin^{-1}(b/r),$$

but this time $\sin^{-1}(b/r) = (\angle B) - \pi/2$. Substituting into the formula for $\mathscr{A}$,

$$\begin{aligned}\mathscr{A} &= (b-a) + (\pi/2 - (\angle A)) - ((\angle B) - \pi/2)\\ &= (b-a) + (\pi - (\angle A) - (\angle B)).\end{aligned}$$

□

In the first two lemmas, we put restrictions on D that are not really necessary: that a and b have to be positive, and that the circle must be centered at the origin. Now let's remove them in the next two lemmas.

Lemma 46.3 *If*

$$D = \left\{(s,t)\middle|(s^2+t^2) < r^2,\ a \le s \le b,\ t \ge 1\right\},$$

then $\mathscr{A} = (b-a) + (\pi - (\angle A) - (\angle B))$.

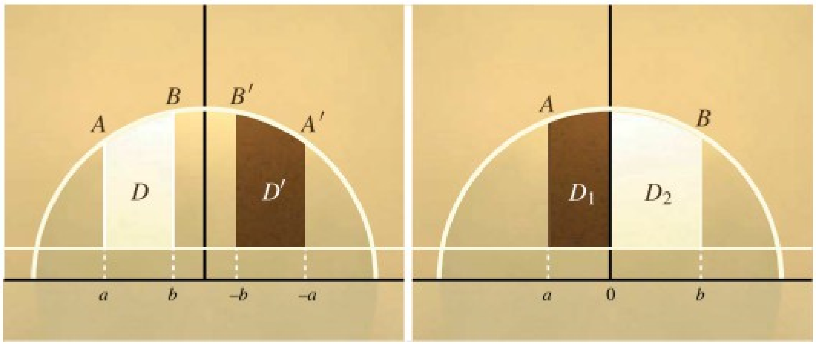

Figure 6. Extending to other types of domains: (l) $a \le b \le 0$ and (r) $a \le 0 \le b$.

Proof Step 1. Suppose that $a < b \le 0$. The reflection across the vertical axis will transform D into a congruent shape D', mapping A to A' and B to B'. The area of $X(D')$ is the same as the area of $X(D)$, though, and $\angle A \simeq \angle A'$ and $\angle B \simeq \angle B'$, so

$$\begin{aligned}\mathscr{A}(D) &= \mathscr{A}(D')\\ &= ((-a) - (-b)) + (\pi - (\angle B') - (\angle A'))\\ &= (b-a) + (\pi - (\angle A) - (\angle B)).\end{aligned}$$

Step 2. Suppose that $a < 0 < b$. Then D can be broken up into two smaller regions, D_1 from $x = a$ to $x = 0$, and D_2 from $x = 0$ to $x = b$. We have

$$\begin{aligned}\mathscr{A}(D_1) &= (0-a) + (\pi - (\angle A) - \pi/2) = -a + \pi/2 - (\angle A)\\ \mathscr{A}(D_2) &= (b-0) + (\pi - \pi/2 - (\angle B)) = b + \pi/2 - (\angle B),\end{aligned}$$

and so

$$\begin{aligned}\mathscr{A}(D) &= \mathscr{A}(D_1) + \mathscr{A}(D_2)\\ &= (-a + \pi/2 - (\angle A)) + (b + \pi/2 - (\angle B))\\ &= (b - a) + (\pi - (\angle A) - (\angle B)).\end{aligned}$$ □

Lemma 46.4 *If*

$$D = \left\{(s,t)\big|(s-h)^2 + t^2 < r^2,\ a \le s \le b,\ t \ge 1\right\},$$

then $\mathscr{A} = (b - a) + (\pi - (\angle A) - (\angle B))$.

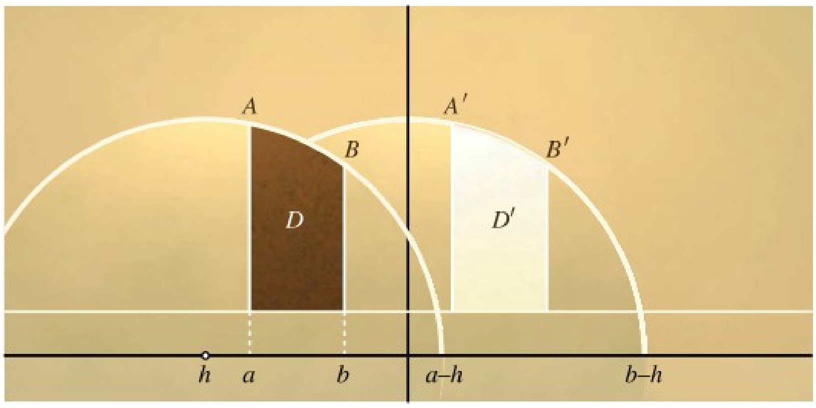

Figure 7. Extending to other types of domains: circles that are not centered at the origin.

Proof The horizontal translation by $-h$ shifts D to a congruent domain D' whose bounding circle is centered at the origin, mapping A to A' and B to B'. It does not alter area: the area of $X(D)$ is the same as the area of $X(D')$. Nor does it alter angle measures, so $(\angle A) = (\angle A')$ and $(\angle B) = (\angle B')$. Therefore

$$\begin{aligned}\mathscr{A}(D) &= \mathscr{A}(D')\\ &= ((b-h) - (a-h)) + (\pi - (\angle A') - (\angle B'))\\ &= (b - a) + (\pi - (\angle A) - (\angle B)).\end{aligned}$$ □

Now we can cut apart and piece together domains to find the area of a triangle.

Theorem 46.5 *For* $\triangle ABC$ *in the UHP, the area of* $X(\triangle ABC)$ *is*

$$\mathscr{A} = \pi - (\angle A) - (\angle B) - (\angle C).$$

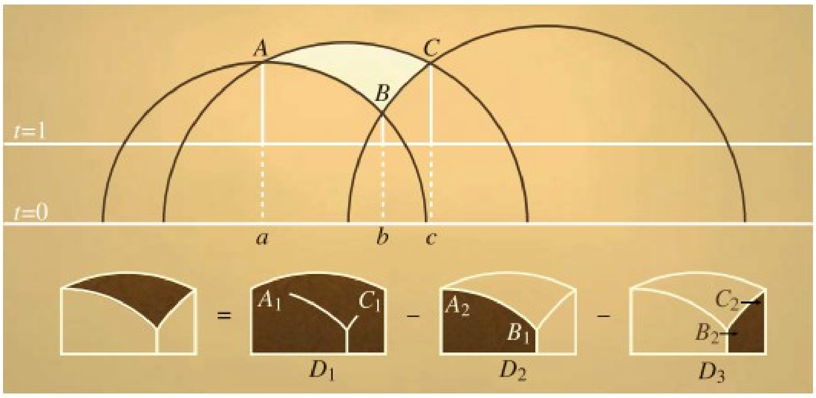

Figure 8. Calculating the area of a hyperbolic triangle.

Proof There are a few configurations. We will look at just one, as illustrated and labeled in figure 8. In this case, the area of $X(\triangle ABC)$ is

$$\mathscr{A}(\triangle ABC) = \mathscr{A}(D_1) - \mathscr{A}(D_2) - \mathscr{A}(D_3)$$

where

$$\begin{aligned}
\mathscr{A}(D_1) &= (c-a) + [\pi - (\angle A_1) - (\angle C_1)] \\
\mathscr{A}(D_2) &= (b-a) + [\pi - (\angle A_2) - (\angle B_1)] \\
\mathscr{A}(D_3) &= (c-b) + [\pi - (\angle B_2) - (\angle C_2)],
\end{aligned}$$

and so

$$\begin{aligned}
\mathscr{A}(\triangle ABC) &= (c-a) + [\pi - (\angle A_1) - (\angle C_1)] \\
&\quad - (b-a) - [\pi - (\angle A_2) - (\angle B_1)] \\
&\quad - (c-b) - [\pi - (\angle B_2) - (\angle C_2)] \\
&= [(\angle A_2) - (\angle A_1)] + [(\angle B_2) + (\angle B_1)] + [(\angle C_2) - (\angle C_1)] - \pi \\
&= -(\angle A) + [2\pi - (\angle B)] - (\angle C) - \pi \\
&= \pi - (\angle A) - (\angle B) - (\angle C).
\end{aligned}$$

□

46.2 Areas of polygons in the Poincaré disk

The UHP model inherits its metrical properties from the pseudosphere, so $\triangle ABC$ in the UHP should also have area $\pi - (\angle A) - (\angle B) - (\angle C)$. The map $\sigma \circ \rho$ from the UHP to D is conformal, so the image of $\triangle ABC$ in D will have the same angles. Therefore, the pseudosphere area calculation carries over directly to suggest an area formula in the Poincaré disk.

Definition 46.6 The area of $\triangle ABC$ is $\pi - (\angle A) - (\angle B) - (\angle C)$.

In spite of all the calculations that have led to this point, this is still (I think) a little surprising. We are saying that triangle areas are calculated entirely in terms of angle sums! The

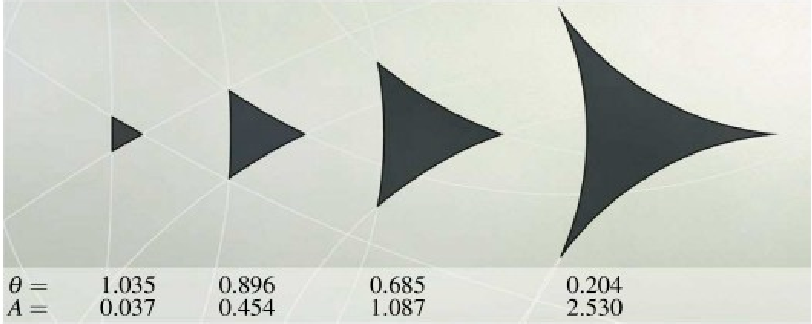

Figure 9. Hyperbolic areas of equilateral triangles, given by the formula $\mathscr{A} = \pi - 3\theta$.

term $\pi - (\angle A) - (\angle B) - (\angle C)$ is called the *defect* of the triangle. In Euclidean geometry, it would always be zero, so the defect measures how far the triangle deviates from a Euclidean triangle. This formula is saying that small triangles (in the sense of area) are the ones with small defects. That jibes with the general principal of the last lesson, that Euclidean and hyperbolic geometry look approximately the same for small objects, but diverge from one another for bigger objects. It also means that no hyperbolic triangle can have an area greater than π! Surprising or not, it turns out that the formula meets the requirements of an area function.

In chapter 31, we found a formula for the area of a general simple polygon, using an inductive argument. It was based on the idea that a simple polygon can be split into smaller pieces, and then the area of the whole is the sum of the areas of the pieces (every simple polygon can be triangulated and its area is the sum of the areas of the triangles). The key to the argument was that every simple polygon with more than three sides has a diagonal (theorem 31.1) that breaks the polygon into two smaller pieces. The argument for the existence of a diagonal works just fine in hyperbolic geometry.

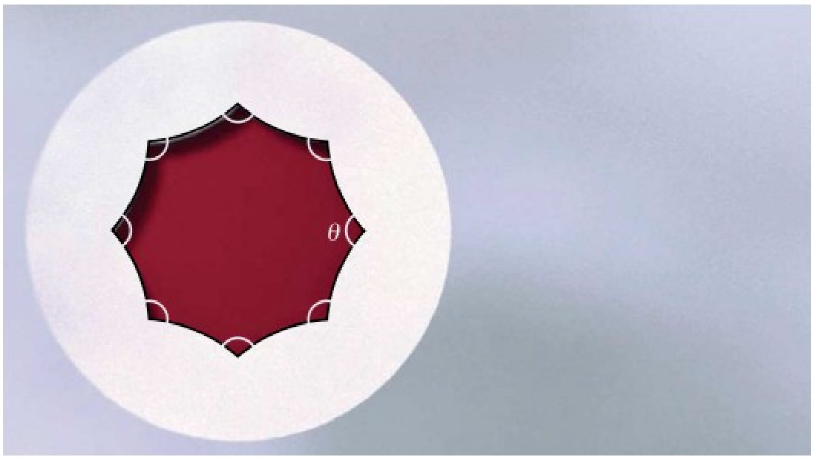

Figure 10. The area of a regular octagon with interior angle θ is $\mathscr{A} = 6\pi - 8\theta$.

Exercise 46.1 Check the proof of theorem 31.1 to make sure that it is still valid in hyperbolic geometry.

Theorem 46.7 *The area of a simple polygon* $\mathcal{P} = P_1P_2\cdots P_n$ *is*

$$(n-2)\pi - \sum_{i=1}^{n}(\angle P_i).$$

Proof As in the Euclidean case, we proceed by induction on the number of sides of $\mathcal{P}$. The base case consists of polygons of three sides: triangles. For them, the formula matches the defect formula. Now assume that polygons with n or fewer sides have areas that are given by the formula, and consider an $(n+1)$-sided polygon $\mathcal{P} = P_1P_2\cdots P_{n+1}$. It has a diagonal cutting $\mathcal{P}$ into two smaller pieces $\mathcal{P}_A$ and $\mathcal{P}_B$. To simplify the notation, let's relabel the vertices of $\mathcal{P}$ so that

$$\begin{aligned}\mathcal{P}_A &= P_1P_2\cdots P_j\\ \mathcal{P}_B &= P_1P_jP_{j+1}\cdots P_{n+1}.\end{aligned}$$

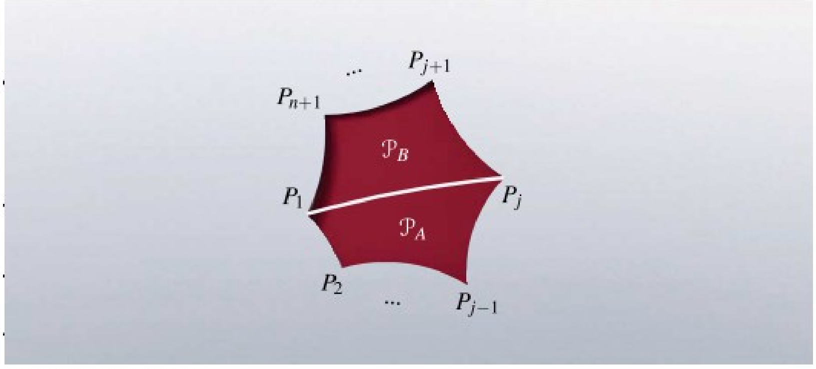

Figure 11. To prove the area formula, we use an inductive proof, cutting the polygon into two smaller pieces with a diagonal.

Between $\mathcal{P}_A$ and $\mathcal{P}_B$, there are $n+3$ sides (the $n+1$ original sides and the diagonal that is counted twice because it occurs in both pieces). The first piece, $\mathcal{P}_A$, has j of the sides. The other piece, $\mathcal{P}_B$, must have the remaining $n+3-j$ sides. According to the inductive hypothesis,

$$\begin{aligned}\mathscr{A}(\mathcal{P}_A) &= (j-2)\pi - \left[(\angle P_jP_1P_2) + \sum_{i=2}^{j-1}(\angle P_i) + (\angle P_{j-1}P_jP_1)\right]\\ \mathscr{A}(\mathcal{P}_B) &= (n+1-j)\pi - \left[(\angle P_1P_jP_{j+1}) + \sum_{i=j+1}^{n+1}(\angle P_i) + (\angle P_{n+1}P_1P_j)\right].\end{aligned}$$

Then

$$\begin{aligned}\mathscr{A}(\mathcal{P}) &= \mathscr{A}(\mathcal{P}_A) + \mathscr{A}(\mathcal{P}_B)\\ &= (n-1)\pi - \left[(\angle P_1) + \sum_{i=2}^{j-1}(\angle P_i) + (\angle P_j) + \sum_{i=j+1}^{n+1}(\angle P_i)\right]\\ &= ((n+1)-2)\pi - \sum_{i=1}^{n+1}(\angle P_i),\end{aligned}$$

as needed. By induction, this is a valid formula for any simple polygon. □

Now that we have this formula for the area of a general polygon, we can check that it satisfies the requirements of an area function.

Exercise 46.2 Verify that the formula assigns to every simple polygon a positive real number. Verify that the formula assigns the same number to two congruent polygons.

The last requirement, that the area of the whole is the sum of the areas of the pieces, is more complicated to verify. The next exercise confirms it in a few specific cases.

Exercise 46.3 Let D be a point in the interior of $\triangle ABC$. Prove that

$$\mathscr{A}(\triangle ABC) = \mathscr{A}(\triangle ABD) + \mathscr{A}(\triangle BCD) + \mathscr{A}(\triangle ACD).$$

Given a convex quadrilateral $\square ABCD$, let $A * E * B$ and $C * F * D$. Prove that

$$\mathscr{A}(\square ABCD) = \mathscr{A}(\square AEFD) + \mathscr{A}(\square BEFC).$$

46.3 Area of a circle

To end the chapter, let's use the formula for the area of a polygon to find the area of a circle. The formula depends upon two things. One is lemma 45.6, that as n approaches infinity, $n\sin(x/n)$ approaches x. The other is a kind of hyperbolic cofactor identity:

Lemma 46.8 *Let α and β be the two acute angles in a right triangle and let a be the length of the side opposite α. Then*

$$\cos\alpha = \sin\beta \cdot \cosh a.$$

Exercise 46.4 Prove the lemma. Hint: to get started, rewrite the cosine term in terms of hyperbolic tangents.

The derivation of the area formula for circles is like the derivation of the circumference formula: we approximate the circle with regular inscribed polygons and then take a limit as the number of sides approaches infinity. The area formula would seem to make this easy, since it only depends on the interior angles and all the interior angles of a regular polygon are congruent. It turns out that there are some computational complications with this approach, and so we will instead do something a little less direct.

Theorem 46.9 *The area of a circle with radius r is*

$$\mathscr{A} = 2\pi(\cosh r - 1).$$

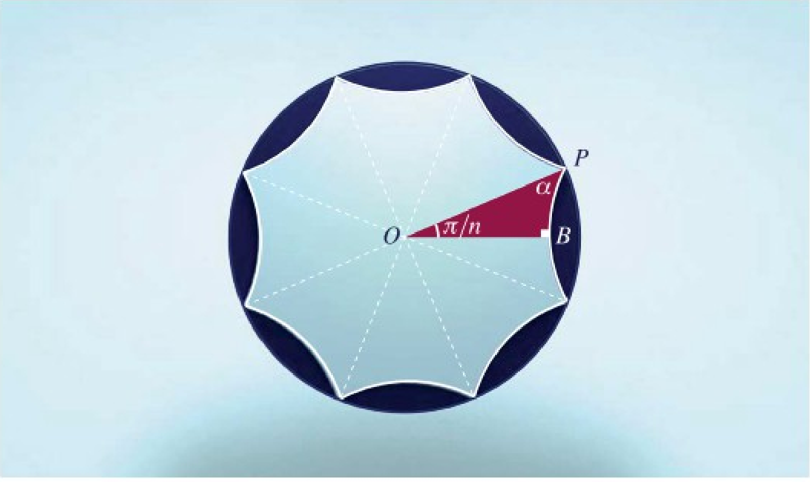

Figure 12. Use inscribed regular polygons to approximate the area inside a circle.

Proof Write $\mathscr{A}$ for the area of a circle with radius r. Let $\mathscr{A}_n$ denote the area of a regular n-gon $\mathcal{P}_n$ inscribed in the circle. It can be broken up into $2n$ right triangles each of which is congruent to $\triangle OPB$, where O is the center of the circle, P is one of the vertices of the n-gon, and B is the right angle. The angle at P is the key. Let's say it has a measure of α. Then each interior angle of $\mathcal{P}_n$ has a measure of 2α and therefore

$$\mathscr{A}_n = (n-2)\pi - \sum_{i=1}^{n} 2\alpha = (n-2)\pi - 2n\alpha.$$

Rather than trying to find the value of α, we solve the equation for α:

$$2n\alpha = (n-2)\pi - \mathscr{A}_n \implies \alpha = \pi/2 - \pi/n - \mathscr{A}_n/2n.$$

The trick is to look not at α itself, but instead at $\cos\alpha$. There are two ways we can work with that expression. One way is to use the cofactor identity in lemma 46.8. In $\triangle OPB$, the angle at O measures π/n. Therefore

$$\cos\alpha = \sin(\pi/n)\cosh(|OB|).$$

The other way is via the traditional cofactor identity:

$$\begin{aligned} \cos\alpha &= \cos\left(\frac{\pi}{2} - \frac{\pi}{n} - \frac{\mathscr{A}_n}{2n}\right) \\ &= \cos\left(\frac{\pi}{2} - \left(\frac{\pi}{n} + \frac{\mathscr{A}_n}{2n}\right)\right) \\ &= \sin\left(\frac{\pi}{n} + \frac{\mathscr{A}_n}{2n}\right). \end{aligned}$$

Setting them equal we get

$$\sin(\pi/n)\cosh(|OB|) = \sin\left(\frac{\pi}{n} + \frac{\mathscr{A}_n}{2n}\right).$$

As n approaches infinity, both sides of the equation approach zero, but if we multiply by n, then

$$n\sin(\pi/n)\cosh(|OB|) = n\sin\left(\frac{\pi + \mathscr{A}_n/2}{n}\right).$$

As n approaches infinity,

- $|OB|$ approaches r ,
- $\mathscr{A}_n$ approaches $\mathscr{A}$,
- the small angle formula describes what happens to the sine terms.

The result is

$$\pi \cdot \cosh(r) = \pi + \mathscr{A}/2,$$

and we can solve for $\mathscr{A}$:

$$\mathscr{A}/2 = \pi\cosh r - \pi \implies \mathscr{A} = 2\pi(\cosh r - 1). \qquad \square$$

The formula looks different from the Euclidean one. Look, though, at what happens when it is rewritten using the Taylor series for hyperbolic cosine:

$$\begin{aligned}\mathscr{A} &= 2\pi\left(\left(\sum_{n=0}^{\infty}\frac{r^{2n}}{(2n)!}\right) - 1\right)\\ &= 2\pi\left(\left(1 + \frac{r^2}{2!} + \frac{r^4}{4!} + \cdots\right) - 1\right)\\ &= 2\pi\left(\frac{r^2}{2} + \frac{r^4}{24} + \cdots\right)\\ &= \pi r^2 + \frac{\pi r^4}{12} + \cdots.\end{aligned}$$

For small values of r, the later terms in the series contribute very little to the value of $\mathscr{A}$. That is, when $r \approx 0$, $\mathscr{A} \approx \pi r^2$. Once again, the hyperbolic world appears to be similar to the Euclidean world when it is viewed at a small enough scale.

46.4 Exercises

46.5. A torus is formed by revolving the circle

$$(x-b)^2 + y^2 = a^2, \quad 0 < a < b,$$

around the y-axis (see exercise 38.2 in lesson 38). Compute the surface area of the torus.

46.6. Let $\triangle ABC$ be a right triangle with vertices $A = 0$, $B = 0.5$, and $C = 0.5i$. First consider AB to be its base, and calculate the lengths of its base and height. Then consider BC as the base, and calculate the lengths of the base and height. Observe that the values of $bh/2$ are not the same.

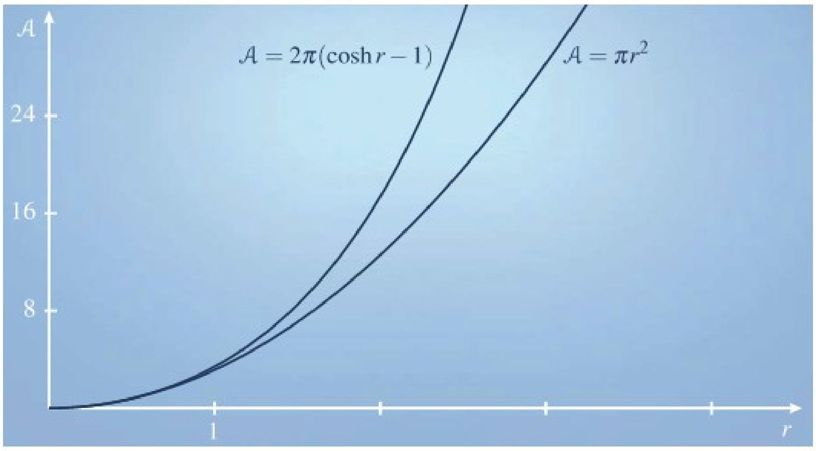

Figure 13. Comparisons of the areas of hyperbolic and Euclidean circles as a function of their radii.

46.7. Compute the hyperbolic area of the triangle with vertices $A = 0$, $B = 0.5$, and $C = 0.5i$.

46.8. In the proof of the formula for the area of a triangle, we considered the case where the vertex B is below AC. Show that the formula is valid if B is above AC.

46.9. Let R be a regular quadrilateral inscribed in a circle of radius r. Find a formula for the area of R as a function of r.

46.10. Prove that there are circles that cannot be contained in the interior of any triangle.

46.11. What is the area of the convex quadrilateral $\square ABCD$ with $A = 0.25 + 0i$, $B = 0 + 0i$, $C = 0 + 0.25i$ and right angles at A, B, and C (see exercise 45.6)?

46.12. What is the area of the Saccheri quadrilateral $\square EFGH$ that has summit vertices $E = (-1/3) + (1/3)i$ and $F = (1/3) + (1/3)i$ and its base along the real axis (see exercise 45.10)?

46.13. Suppose that $\triangle ABC$ is decomposed into a collection of smaller triangles $\{T_i\}$. Explain why the area of $\triangle ABC$ is the sum of their areas. You will need to use Euler's formula for planar polygons, that $v - e + f = 1$, where v is the total number of vertices, e is the total number of edges, and f is the total number of faces in the decomposition.

Chapter 6

Models for the Hyperbolic Plane

6.1 Introduction

The role of models in geometry is tied to the subject's historical connection to axiomatics. While *The Elements* of Euclid is the archetype of an axiomatic system, the real plane, $\mathbb{R}^2$, is the archetype of a model for an axiomatic system, in this case, that of the Euclidean plane. The existence of a model for an axiomatic system is proof that the system is consistent.

We have seen that Euclidean and hyperbolic geometries share so much that we might think of hyperbolic geometry as nearly Euclidean. Indeed, Theorem 2.28 implies that when we look at a region of the hyperbolic plane that is sufficiently small, the angular defect of a triangle is so small as to be indetectable. In practical terms, if space were hyperbolic, our perception of space as Euclidean may be correct, if human scale is "sufficiently small."

Carl Friedrich Gauss (1777–1855) claimed to have discovered, and secreted, Bolyai's and Lobachevsky's results years before the latter two made their work public. He may well have. Gauss was the leading mathematician of his time and he worked on a broad array of problems, among them the problem of the parallels. His influence was such that he could make or break a career and he probably broke Bolyai's career—and spirit—by brushing off the younger man's work when he saw it by saying, in effect, "Yes this is great work. I know because I did it years ago." The story is that he kept his work on non-Euclidean geometries secret because he feared the outcry that would attend its public release.

As we work through our discussion, we will see that the connections between Euclidean and hyperbolic geometries go beyond formalities. Models for the hyperbolic plane and for the Euclidean plane can be constructed from one another. Establishing this was the critical step in the resolution of the problem of the parallels. The relative consistency of hyperbolic geometry meant that the axioms for hyperbolic geometry are consistent if and only if the axioms

M. I. Dillon, *Geometry Through History*,
https://doi.org/10.1007/978-3-319-74135-2_6

for Euclidean geometry are consistent. Understanding this is what enabled the mathematics community to move on, once and for all, from the problem of the parallels.

6.2 Beltrami

Eugenio Beltrami (1835–1900) in 1868 published two articles about hyperbolic geometry and surfaces of constant negative curvature. In the first, he described how to realize the geometry of Lobachevsky on a surface of negative curvature. The date is significant: 1868 is also the year in which Riemann's work on geometry was published.

Georg Bernhard Riemann (1826–1866) studied with Gauss in Göttingen and received his doctoral degree there in 1851. To teach in the university, Riemann had to complete a second project called the *habilitation*. The habilitation culminated in a lecture to the faculty, its topic chosen by the examiners from among different subjects supplied by the candidate. Riemann's topic, chosen by Gauss, was foundations of geometry. The lecture he gave included ideas about generalized surfaces called manifolds, higher-dimensional spaces, and the notion that a surface has intrinsic properties, that is, properties that are independent of any surrounding space. Riemann's work was to have an enormous impact on the mathematics of the nineteenth and twentieth centuries. Indeed, its influence is still felt today. Before the force of his blow could be fully effected, though, Riemann's ideas had to circulate through the community. By 1868, they were known well enough abroad to give Beltrami the fortitude to go ahead with his account about realizing Lobachevsky's geometry. (See [10] and [17].)

The discovery and dissemination of ideas associated to the resolution of the parallel postulate is a story rich in irony and this part of the tale is no exception. Lambert, the eighteenth century mathematician whom we met in the context of ibn al-Haytham-Lambert quadrilaterals, is associated with several ideas in mathematics, among them the problem of the parallels. Quite apart from that, he also studied and developed the theory of hyperbolic trigonometric functions. Though Lambert viewed his assault on the problem of the parallel postulate as a failure, his hyperbolic trigonometry turned out to be a key element in work leading up to Beltrami's first model of a non-Euclidean plane. While Lambert had both things in his hands—the problem of the parallels and hyperbolic trigonometry—the connection between the two escaped him entirely. It would be another 100 years before the problem of the parallels was resolved. (See [17] for details.)

Beltrami's paper starts with an analytic description of a line element on a surface of *constant negative curvature*. There is not a great deal that we will say about this; we want simply to establish some context. Curvature, by which we mean *Gaussian curvature*, is a measure of how a surface bends. As expected, a plane has zero curvature but so does the surface of a cylinder: A cylinder can be "uwrapped" and laid flat on a plane. A sphere has constant positive curvature: constant, because the curvature does not change from point

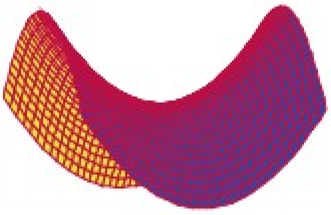

Figure 6.1: A saddle has negative curvature

to point, positive, because if you make a cut in a sphere in an attempt to lay it flat on the plane, pieces of the sphere on either side of the cut have to be pulled apart. The surface of a sphere has too little "material" to form something flat. A hyperbolic paraboloid—a saddle—has negative curvature. (See Fig. 6.1.) If you make a cut in a saddle in an attempt to lay it flat on the plane, pieces of the saddle on either side of the cut have to be pulled together: The surface has too much "material" to form something flat.

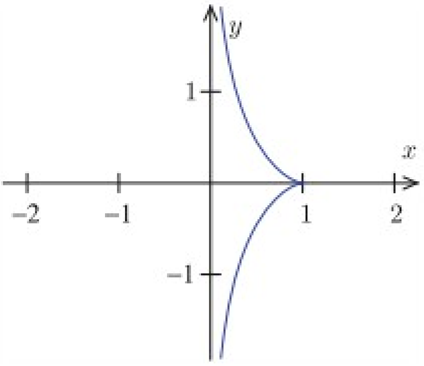

Figure 6.2: The tractrix defined by $x = 1/\cosh t, y = t - \tanh t$

The *pseudosphere*, or *tractoid*, is a surface of constant negative curvature that can be generated by rotating a curve called a *tractrix* about its vertical axis. (See Fig. 6.2.) Beltrami identified a particular region on this surface, and used differential geometry to establish that Lobachevsky's geometry is realized there. An important device in his discussion is the fact that the region of interest on the surface can be mapped onto an open disk in the plane. The circle defining the disk in the plane is the *limit circle*. (See Fig. 6.3.) Its points correspond to points "at infinity" on the surface, indicated in pink in Fig. 6.3. Points outside

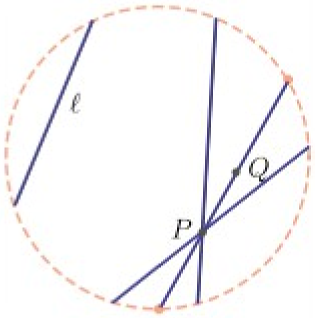

Figure 6.3: The Klein-Beltrami model for the hyperbolic plane

the disk are not part of the model. Lines on the surface are represented by chords of the limit circle. In Fig. 6.3, the line determined by points P and Q is shown, as are several parallels to the line ℓ through the point P. This is the model often referred to as the *Klein-Beltrami model* for the hyperbolic plane.

If Beltrami's work established the relative consistency of Euclidean and non-Euclidean geometry—that is, hyperbolic geometry—Klein's work established the relative consistency of projective geometry, spherical geometry, Euclidean geometry, and non-Euclidean geometry. [28] At this point in our tale, though, the most accessible model for a hyperbolic plane is the Poincaré disk.

Henri Poincaré (1854–1912) started working in hyperbolic geometry when he was thinking about quadratic forms, solutions to certain differential equations, and complex analysis, areas of mathematics that at that time, were not seen as part of geometry. Poincaré's random insight was that the transformations he had been working on were also transformations of the hyperbolic plane. Once his eyes were opened, Poincaré saw the relevance of non-Euclidean geometry all over mathematics. He quickly set about bringing hyperbolic geometry to bear in several different areas of mathematics, including number theory. Non-Euclidean geometry, which until Poincaré's time had seemed a bizarre curiosity, was suddenly everywhere. Poincaré's work might properly signal the true arrival of hyperbolic geometry into mainstream mathematics. (See [28].)

6.3 The Poincaré Disk

There are two models attributed to Poincaré: the upper half-plane model and the disk model. We study the disk model. Like the upper half-plane model, the disk model is constructed within the Euclidean plane, which we designate $\mathcal{E}$. Since $\mathcal{E}$ is modeled by $\mathbb{R}^2$, and we will be concerned with certain mappings from $\mathcal{E}$ to $\mathbb{R}$, calculus is available to us and we employ it to study the Poincaré disk.

Let $\mathcal{C}$ be the circle with center O and radius 1. The choice of 1 for the radius of $\mathcal{C}$ is arbitrary. Let $\mathcal{D}$ be the open disk in $\mathcal{E}$ associated to $\mathcal{C}$. $\mathcal{D}$ is the foundation for our model of a hyperbolic plane. When we think of $\mathcal{D}$ as modeling the hyperbolic plane, we designate it $\mathcal{P}$.

The points of $\mathcal{P}$ are the points of $\mathcal{D}$. Lines in the Poincaré disk are of two types: **type-1 lines** are intersections of diameters of $\mathcal{C}$ with $\mathcal{D}$, and **type-2 lines** are intersections of circles orthogonal to $\mathcal{C}$ with $\mathcal{D}$.

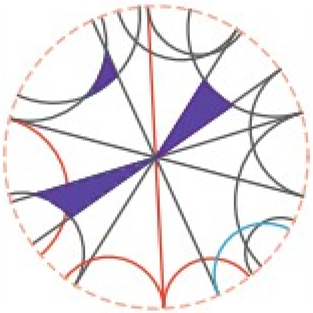

Figure 6.4: The Poincaré disk model

Proceeding through our discussion, we will be dealing with $\mathcal{D}$ sometimes as a subset of $\mathcal{E}$—which, when convenient, we can model using $\mathbb{R}^2$, with which we have some familiarity—and sometimes as modeling $\mathcal{P}$, which we are endeavoring to understand. Going forward, every subset of $\mathcal{D}$ wears two hats: one Euclidean, and one hyperbolic. We must be careful to distinguish which hat it wears when we pick up an object to discuss its nature.

We continue to refer to Euclidean lines simply as lines. Following [23], we refer to type-1 and type-2 lines together as **L-lines** ("L" for Lobachevsky).

A goal for us right now is understanding what it means for one point to be between two other points in our model, $\mathcal{P}$. Once we establish that we have a well-behaved notion of betweenness in $\mathcal{P}$, we will have license to talk about L-segments. In other words, if A and B are points on an L-line ℓ, then the associated L-segment is the collection of points $X \in \ell$ so that $X = A$, or $A * X * B$, or $X = B$.

Angles in $\mathcal{P}$ are identical to angles in $\mathcal{E}$. The Euclidean tangents at the point of intersection of two L-lines determine the angles formed by the L-lines.

Figure 6.4 shows some L-lines and regions in $\mathcal{P}$. The red L-lines are all parallel. The light blue arc, a type-2 line, is parallel to three of the red L-lines, but not to the fourth. This is significant: In a neutral plane, transitivity of parallelism is one of the conditions equivalent to the parallel postulate. That parallelism is not transitive is thus a defining feature of a hyperbolic plane. Three points in $\mathcal{P}$ that do not lie on a single L-line determine an **L-triangle**. The filled areas in the figure are regions enclosed by L-triangles.

Our first task is to show that $\mathcal{P}$ satisfies the first postulate of Euclid, that is, Axioms I.1–2 of Hilbert. These are the only incidence axioms we need. The

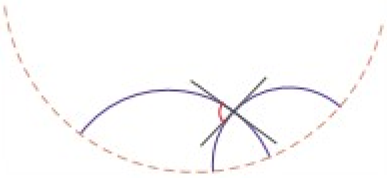

Figure 6.5: An angle between L-lines is an angle between their tangents

others are either automatic, since our model employs Euclidean points, or irrelevant, since we are discussing a plane.

Lemma 6.1. Two points in $\mathcal{P}$ determine a unique L-line.

Proof. Let P and Q be points in $\mathcal{P}$. If P belongs to a Euclidean diameter of $\mathcal{C}$ that runs through Q, then that diameter determines a unique type-1 line containing P and Q. Suppose in this case that there were also a type-2 line containing P and Q. That L-line would be determined by a circle $\mathcal{C}'$ in $\mathcal{E}$ orthogonal to $\mathcal{C}$. By Lemma 5.21, both P and Q would have to be different from O. Under inversion through $\mathcal{C}$, $\overline{PQ} \setminus O$ is mapped to itself. As an orthogonal to $\mathcal{C}$, $\mathcal{C}'$ is also mapped to itself under inversion through $\mathcal{C}$. If the $\mathcal{C}$ inverses of P and Q are P' and Q' respectively, this means P, Q, P', Q' would belong both to a line in $\mathcal{E}$ and to a circle in $\mathcal{E}$, a violation of Prop. III.10. We conclude that if P and Q lie on a diameter of $\mathcal{C}$, there is a unique L-line that contains the two points.

Next suppose P and Q do not lie on a diameter of $\mathcal{C}$. In this case neither P nor Q can be O. We must show that there is a single type-2 line containing them. Let P' be the $\mathcal{C}$ inverse of P so that the Euclidean line determined by P and P' is $\overline{OP}$. Then P, Q, and P' are noncollinear, so by Prop. III.10, they determine a unique circle, $\mathcal{C}'$. By Theorem 5.24, $\mathcal{C}$ and $\mathcal{C}'$ are orthogonal, thus, in this case, P and Q determine a type-2 line. Also by Theorem 5.24, any circle orthogonal to $\mathcal{C}$ and containing P and Q must contain their inverses, so the L-line determined by P and Q is unique, again by Prop. III.10. □

Let ℓ be an L-line in $\mathcal{P}$. In $\mathcal{E}$, the Euclidean arc or line segment that determines ℓ intersects $\mathcal{C}$ in two points. We call these the **points at infinity** of ℓ. Note that these are Euclidean points that are not in $\mathcal{P}$.

We can establish that both the axioms of order and the continuous nature of a line hold in $\mathcal{P}$ by coordinatizing L-lines using $\mathbb{R}$. Once we coordinatize lines, several of Hilbert's axioms will be verified immediately.

First, we consider a notion of non-Euclidean distance in $\mathcal{P}$.

Distance in the Poincaré Disk

A measure of distance on a set that conforms to our understanding of how distance ought to work is usually defined by a *metric*.

Definition 6.2. A **metric** on a set $\mathcal{S}$ is a mapping $d : \mathcal{S} \times \mathcal{S} \to \mathbb{R}$ that satisfies the following for all x, y, z in $\mathcal{S}$:

(1) $d(x, y) \geq 0$ with equality only if $x = y$;

(2) $d(x, y) = d(y, x)$;

(3) $d(x, z) \leq d(x, y) + d(y, z)$.

When $\mathcal{S}$ has a metric d, $(\mathcal{S}, d)$ is a **metric space**.

The last condition of Definition 6.2 is a version of Euclid's Triangle Inequality, Prop. I.20. In this case, the inequality is not strict because x, y, z are not necessarily vertices of a triangle. Going forward, we use "triangle inequality" to refer to condition (3) in Definition 6.2, or to

$$|a + b| \leq |a| + |b|,$$

the triangle inequality as it arises in $\mathbb{R}$, or to the inequality in the next lemma.

Lemma 6.3. Let x, y, z be points in a metric space $(\mathcal{S}, d)$. Then

$$d(x, y) \geq |d(x, z) - d(y, z)|.$$

Proof. Since $d(x, z) \leq d(x, y) + d(y, z)$, we have $d(x, z) - d(y, z) \leq d(x, y)$. On the other hand, $d(y, z) \leq d(x, y) + d(x, z)$ implies $d(y, z) - d(x, z) \leq d(x, y)$. Putting the two together, we get the result. □

The archetype for a metric space is $\mathbb{R}^n$ with

$$d(P, Q) = \sqrt{\sum_{i=1}^{n} (x_i - y_i)^2} \tag{6.1}$$

where $P = (x_1, x_2, \ldots, x_n)$ and $Q = (y_1, y_2, \ldots, y_n)$. Notice that in $\mathbb{R}$, (6.1) becomes

$$d(x, y) = |x - y|.$$

Proofs that (6.1) satisfies the triangle inequality abound in the literature. We leave it as an exercise to prove the case for $n = 1$. Equation (6.1) defines the **Euclidean metric** on $\mathbb{R}^n$.

Lemma 6.4. Let $(\mathcal{S}, d)$ be a metric space. Let $A \subseteq \mathcal{S}$. Then (A, d) is also a metric space.

Proof. Let $x, y \in A$. Since $x, y \in \mathcal{S}$, properties (1) and (2) of Definition 6.2 hold. Now let z be an element in A as well. Since x, y, z all belong to $\mathcal{S}$, property (3) of Definition 6.2 must hold as well. □

Since $\mathcal{D}$ is a subset of a metric space, $\mathbb{R}^2$, it is also a metric space under the Euclidean metric. The problem with this is that Postulate II will not hold in this metric space. We need a metric on $\mathcal{P}$ that will allow us to stretch line segments indefinitely.

Definition 6.5. Let P and Q be points in $\mathcal{P}$, and let ℓ be the L-line they determine. Let S and T be the points at infinity of ℓ. The **L-distance between P and Q** is

$$L(P,Q) = \left| \ln \frac{|PS|/|PT|}{|QS|/|QT|} \right| \tag{6.2}$$

where $|PS|$ is the Euclidean distance between points P and S, (or the Euclidean length of PS), and ln is the natural logarithm.

Theorem 6.6. *L is a metric on $\mathcal{P}$.*

Proof. Notice first that when $P = Q$, $\frac{|PS|/|PT|}{|QS|/|QT|} = 1$, and $\ln 1 = 0$. Note further that by the definition, the L-distance between points is always nonnegative.

The triangle inequality and condition (2) of Definition 6.2 are easy to show using properties of logarithms and absolute values. Likewise, if P, Q determine a type-1 line, it is easy to show that $L(P,Q) = 0$ implies $P = Q$. We leave those verifications to the exercises. We must show that condition (1) holds if P, Q determine a type-2 line.

Suppose then that $P \neq Q$ lie on a type-2 line in $\mathcal{P}$. Notice that $\overrightarrow{SP}$ and $\overrightarrow{SQ}$ must be different, otherwise S, P, Q would lie on both a line and a circle, in violation of Prop. III.10. Since $\overrightarrow{SQ}$ and $\overrightarrow{SP}$ lie on the same side of ST, $\angle TSP$ and $\angle TSQ$ must be different.

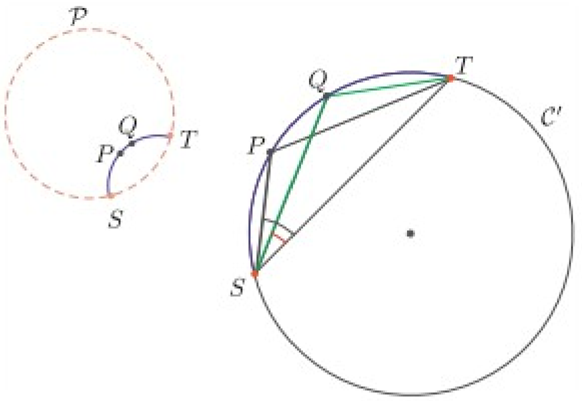

Figure 6.6: A type-2 line in $\mathcal{P}$ and the underlying set in $\mathcal{E}$

Assume now that $L(P,Q) = 0$. We then have

$$\frac{|PS|/|PT|}{|QS|/|QT|} = 1, \text{ that is, } \frac{|PS|}{|QS|} = \frac{|PT|}{|QT|}.$$

By Prop. III.21, $\angle SPT \cong \angle SQT$. We thus have SAS for similar Euclidean triangles (Prop. VI.6) $\Delta STP \sim \Delta STQ$. That implies $\angle TSP \cong \angle TSQ$, which is a contradiction. We conclude that if $L(P, Q) = 0$, then $P = Q$ as desired. $\square$

As we proceed through our discussion, $|PQ|$ will always designate the Euclidean length of the line segment PQ, or equivalently, the Euclidean distance between P and Q.

The notion of a metric allows us to consider what it means for mappings to be continuous on spaces that are more general than $\mathbb{R}$ with the Euclidean metric.

Definition 6.7. Let f be a mapping from a metric space $(\mathcal{S}_1, d_1)$ to a metric space $(\mathcal{S}_2, d_2)$. Then f is **continuous at a point** $x \in \mathcal{S}_1$ provided for any real number $\epsilon > 0$ there is a real number $\delta > 0$ so that if for some $y \in \mathcal{S}_1$, $d_1(x, y) < \delta$, then $d_2(f(x), f(y)) < \epsilon$.

Continuous mappings on metric spaces have many of the properties we are used to from calculus. We have to be careful, though, to bear in mind that an arbitrary metric space may not come equipped with operations such as addition or multiplication, for example. In general, a sum of mappings between metric spaces may not make sense. Composition of mappings, though, makes sense as long as the domain of the second mapping contains the range of the first.

Lemma 6.8. Let $(\mathcal{S}_1, d_1)$, $(\mathcal{S}_2, d_2)$, and $(\mathcal{S}_3, d_3)$ be metric spaces. Let $f : \mathcal{S}_1 \to \mathcal{S}_2$ be a continuous mapping and let $g : \mathcal{R} \to \mathcal{S}_3$ be a continuous mapping, where $\mathcal{R} \subseteq f(\mathcal{S}_1)$. Then $g \circ f$ is a continuous mapping from $\mathcal{S}_1$ to $\mathcal{S}_3$.

Proof. Let x be in $\mathcal{S}_1$. Given $\epsilon > 0$, we must produce $\delta > 0$ so that if $d_1(x, y) < \delta$ for $y \in \mathcal{S}_1$, then $d_3(g(f(x)), g(f(y))) < \epsilon$.

Since g is continuous, we know there is $\xi > 0$ so that if $d_2(f(x), f(y)) < \xi$ for $f(y) \in f(\mathcal{S}_1)$, then $d_3(g(f(x)), g(f(y))) < \epsilon$. With that ξ fixed, we can in turn choose $\delta > 0$ so that if $d_1(x, y) < \delta$ for some $y \in \mathcal{S}_1$, then $d_2(f(x), f(y)) < \xi$, from which it follows that $d_3(g(f(x)), g(f(y))) < \epsilon$, as was to be shown. $\square$

Now that we have a metric on $\mathcal{P}$ and a notion of continuity, we can approach the problem of coordinatizing L-lines using $\mathbb{R}$. We start by considering the same problem in the more familiar setting of $\mathbb{R}^2$.

Let ℓ be the line in $\mathbb{R}^2$ that passes through points (x_0, y_0) and (a, b). When we think about identifying the points of ℓ with the points of $\mathbb{R}$, we are usually thinking of something more than just a point-by-point correspondence. An "identification" should show some respect to distances between points of ℓ and distances between corresponding points of $\mathbb{R}$. Even so, there are many different ways to make this sort of identification using a parametrization. We can parametrize ℓ with a variable t and then think of a point X on ℓ as identified with the associated $t \in \mathbb{R}$. For example,

$$x = x_0 + t(a - x_0),\ y = y_0 + t(b - y_0),\ t \in \mathbb{R}. \tag{6.3}$$

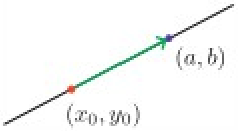

Figure 6.7: A line in $\mathbb{R}^2$ with a "starting point" and a direction

Here the point (x_0, y_0) is identified with 0, and the point (a, b) is identified with 1. The vector $\mathbf{v} =< a - x_0, b - y_0 >$ (shown in Fig. 6.7 in green) determines the positive direction on ℓ: As t increases, the associated points on ℓ can be found farther to the right of (x_0, y_0). Note, moreover, that points on ℓ that are close, are associated to values of t that are also close. Equation (6.3) thus gives us a way of assigning coordinates to the points on ℓ, so that distances between coordinates of points bear a certain fidelity to distances between points on ℓ.

Let us make this more precise.

Definition 6.9. A **coordinatization** of a curve $\mathcal{S}$ in a space with a metric d is a continuous bijective mapping $f : \mathcal{S} \to \mathbb{R}$.

The bijectivity condition guarantees a point-by-point correspondence between $\mathcal{S}$ and $\mathbb{R}$. The continuity condition guarantees that a coordinatization respects the notions of nearness on the curve $\mathcal{S}$ and in $\mathbb{R}$.

We get to our coordinatization through a sequence of lemmas.

Lemma 6.10. *Let ℓ be an L-line in $\mathcal{P}$. Let T, S be the points at infinity of ℓ. Let $|ST| = \tau$. Define $R : \ell \to \mathbb{R}$ by $R(X) = |XT|$. If we view ℓ as a subset of $\mathbb{R}^2$ with the Euclidean metric, then R is a continuous bijective mapping of ℓ onto the interval $(0, \tau) \subset \mathbb{R}$.*

Proof. Let everything be as hypothesized and suppose X is fixed on ℓ. Let $\epsilon > 0$ be given. If we take $\delta = \epsilon$, then if $|XY| < \delta$ for some $Y \in \ell$, Lemma 6.3 gives us

$$d(R(X), R(Y)) = ||XT| - |YT|| \leq |XY| < \epsilon,$$

which shows that R is continuous.

Next we show that R is bijective onto $(0, \tau)$. The case in which ℓ is a type-1 line is routine and we leave it to the reader. Suppose then that ℓ is a type-2 line.

To show that R is one-to-one we suppose it is not and seek a contradiction. Suppose then that for two different points X, Y on ℓ, $R(X) = R(Y)$. Since $|XT| = |YT|$, ΔXYT is isosceles. By Exercise 5.4.7, the median of ΔXYT from T (shown in red in Fig. 6.8) is the perpendicular bisector of XY. But XY is a chord of $\mathcal{C}'$, the Euclidean circle that determines ℓ. By Corollary 5.2, the perpendicular bisector of XY passes through the center of $\mathcal{C}'$. Since it also passes through T and a point on $\widehat{ST}$, that means the center of $\mathcal{C}'$ is interior to

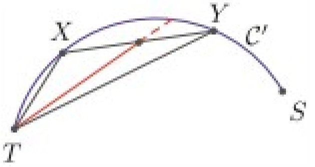

Figure 6.8: $|XT| = |YT|$ implies ΔXYT is isosceles

$\mathcal{C}$, the circle that determines $\mathcal{P}$. By Lemma 5.21 that is impossible because $\mathcal{C}'$ and $\mathcal{C}$ are orthogonal. We conclude that R is indeed one-to-one.

Finally, we show that R is onto the interval $(0, \tau)$. Notice that for $X \in \ell$, $|XT| \leq |XS| + |ST|$ so $|XT| < |ST|$. This shows that $R(X) \in (0, \tau)$. Let $\rho \in (0, \tau)$. Consider the circle in $\mathcal{E}$ centered at T with radius ρ. That circle must intersect $\widehat{ST}$ at some point X. It follows that $R(X) = \rho$, which establishes that R is onto $(0, \tau)$ and completes the proof. ☐

The proof of our next major result benefits from a theorem we learn in middle school or high school. This is close to Prop. II.11, 13, although Euclid does not mention cosines.

> **The Law of Cosines** Let a, b, c be the lengths of sides of a triangle and suppose the side with length a subtends the angle α. Then
>
> $$a^2 = b^2 + c^2 - 2bc \cos \alpha.$$

Lemma 6.11. Let ℓ be an L-line in $\mathcal{P}$ with points at infinity S and T. Let $\tau = |ST|$. If ℓ is a type-2 line, let $\varphi = \angle TXS$, for any X on ℓ. If ℓ is a type-1 line, let $\varphi = \pi$. If $x = |XT|$ and $y = |XS|$, then

$$y = x \cos \varphi + \sqrt{\tau^2 - x^2 \sin^2 \varphi}.$$

Proof. When ℓ is a type-1 line, $\cos \varphi = -1$ and $\sin^2 \varphi = 0$. The result in this case follows nearly immediately.

Suppose ℓ is a type-2 line determined by a circle $\mathcal{C}'$. Since the base on the circumference of $\mathcal{C}'$ for $\widehat{ST}$ is the major arc associated to ST, φ is obtuse, so $\cos \varphi < 0$. (The verification that φ is obtuse is left as an exercise.)

The Law of Cosines gives us $\tau^2 = x^2 + y^2 - 2xy \cos \varphi$ so that

$$y^2 - (2x \cos \varphi) y + (x^2 - \tau^2) = 0.$$

By the quadratic formula,

$$y = \frac{2x \cos \varphi \pm \sqrt{4x^2 \cos^2 \varphi - 4(x^2 - \tau^2)}}{2} = x \cos \varphi \pm \sqrt{x^2(\cos^2 \varphi - 1) + \tau^2}.$$

Since $\cos\varphi < 0$, the positive square root must be what gives us y. Note too that $\cos^2\varphi - 1 = -\sin^2\varphi$. This implies the result. $\square$

Notice that by Prop. III.21, the angle φ in Lemma 6.11 is constant.

Now we dust off a few more tools from single variable calculus.

Recall that an *algebraic function* is a mapping from a subset of $\mathbb{R}$ to $\mathbb{R}$ that is defined using arithmetic (addition, subtraction, multiplication, and division), powers, and roots. Examples of algebraic functions are polynomials, rational functions, $f(x) = \sqrt{x}$, and $g(x) = \sqrt[3]{\frac{x^2+1}{3x^2+5}}$. Trigonometric functions, hyperbolic functions, exponentials, and logarithms are examples of non-algebraic functions. Algebraic functions are continuous on their domains.

Recall also the following important theorem from Calculus I.

Theorem 6.12 (Intermediate Value Theorem). Let f be a continuous function from an interval $I \subseteq \mathbb{R}$ to $\mathbb{R}$. If $f(a) < f(b)$ for some a, b in I, then for any $y \in (f(a), f(b))$ there is x between a and b so that $f(x) = y$.

Lemma 6.13. Let ℓ be an L-line in $\mathcal{P}$ with points at infinity S and T. Let $\tau = |ST|$. If ℓ is a type-2 line, let $\varphi = \angle TXS$, for any X on ℓ. If ℓ is a type-1 line, let $\varphi = \pi$. For $x \in (0, \tau)$, define

$$g(x) = \frac{x}{x\cos\varphi + \sqrt{\tau^2 - x^2\sin^2\varphi}}.$$

Then g is a continuous bijection from $(0, \tau)$ onto $\mathbb{R}_+$.

Proof. That g is continuous on its domain follows from the fact that g is algebraic in x. (Note that τ, and φ are constants so $\cos\varphi$ and $\sin\varphi$ are also constants.) In Lemma 6.11 we established that the denominator of g is $|XS|$, thus for $x \in (0, \tau)$, it also lies strictly between 0 and τ. This confirms that g is defined and continuous on all of $(0, \tau)$.

Note that g is differentiable on its domain with

$$g'(x) = \frac{\tau^2}{(x\cos\varphi + \sqrt{\tau^2 - x^2\sin^2\varphi})^2\sqrt{\tau^2 - x^2\sin^2\varphi}}.$$

As $g'(x) > 0$ for all $x \in (0, \tau)$, g is strictly increasing. This shows that g is one-to-one.

Next notice that

$$\lim_{x\to 0^+} g(x) = 0,$$

and that

$$\lim_{x\to\tau^-} g(x) = \lim_{x\to\tau^-} \frac{1}{\cos\varphi + \sqrt{\frac{\tau^2}{x^2} - \sin^2\varphi}}.$$

Since $\cos\varphi < 0$, and $\sqrt{1 - \sin^2\varphi} = |\cos\varphi|$, the denominator $\cos\varphi + \sqrt{\frac{\tau^2}{x^2} - \sin^2\varphi}$ approaches 0 from above as x approaches τ from below, thus $\lim_{x\to\tau^-} g(x) = \infty$. By the Intermediate Value Theorem, g must assume all values in $\mathbb{R}_+$, thus, g is onto $\mathbb{R}_+$. $\square$

Theorem 6.14. Let ℓ be an L-line in $\mathcal{P}$. Let P be a fixed point on ℓ and suppose S and T are the points at infinity of ℓ. Let

$$f(X) = \ln \frac{|PS|/|PT|}{|XS|/|XT|}. \tag{6.4}$$

Then f is a coordinatization of ℓ by $\mathbb{R}$.

Proof. Let everything be as hypothesized.

We may view f as a composition, $f = f_1 \circ f_2$, where $f_2 : \ell \to \mathbb{R}_+$ by $f_2(X) = \frac{|PS|/|PT|}{|XS|/|XT|}$, and $f_1 : \mathbb{R}_+ \to \mathbb{R}$ is the natural logarithm function. Bijectivity and continuity of $f : \ell \to \mathbb{R}$ will follow if we show that f_1 and f_2 are both bijective and continuous.

By our calculus courses, we know that the natural logarithm is a bijective continuous mapping from $\mathbb{R}_+$ onto $\mathbb{R}$, so we need only address the qualifications of f_2. Notice that

$$f_2 = \frac{|PS|}{|PT|} g \circ R,$$

where $|PS|/|PT|$ is a constant, $R : \ell \to (0, \tau)$, $\tau = |ST|$, is the mapping we discussed in Lemma 6.10, and $g : (0, \tau) \to \mathbb{R}_+$ is the mapping from Lemma 6.13. As f_2 is the composition of continuous bijections, it must also be a continuous bijection. We leave the details underlying that statement to the reader. □

Suppose now that ℓ is an L-line with the line coordinatization f given (6.4). We can order the points on ℓ according to their coordinates: For points A, B, C on ℓ, say B is between A and C provided $f(A) < f(B) < f(C)$ or $f(C) < f(B) < f(A)$. That Hilbert's axioms of line order and continuity apply in $\mathcal{P}$ then follows from properties of $\mathbb{R}$, properties one studies, for instance, in a first course in real analysis. It is not too difficult, and we leave it as an exercise, to show that Pasch's Axiom holds in $\mathcal{P}$.

The L-metric on $\mathcal{P}$ allows us to define congruence of segments: L-segments AB and CD are congruent if and only if $L(A, B) = L(C, D)$. Since we are transferring the problem of comparing segments to the problem of comparing numbers, difficulties that Hilbert had to manage disappear. For instance, congruence of segments is an equivalence relation because equality of numbers is an equivalence relation. Angles in $\mathcal{P}$ are identical to angles in $\mathcal{E}$, so the axioms that apply to angle congruence in $\mathcal{E}$ carry over to $\mathcal{P}$. Note that once Hilbert's axioms are established, the associated theorems follow. We do not have to prove any of them.

Determining that SAS holds in $(\mathcal{P}, L)$ is more interesting. This is where congruence of segments and congruence of angles meet, as it were. Our strategy for proving SAS involves the use of L-line reflections.

L-Reflections on $\mathcal{P}$

Definition 6.15. The **type-1 reflections** on $\mathcal{P}$ are Euclidean reflections determined by type-1 lines. The **type-2 reflections** on $\mathcal{P}$ are circular inversions determined by type-2 lines. The type-1 and type-2 reflections together are called **L-reflections** on $\mathcal{P}$.

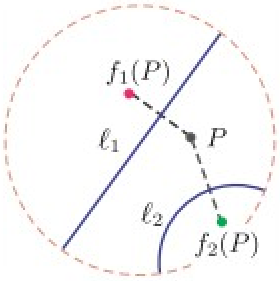

Figure 6.9: Two types of L-reflections

Just as Euclidean reflection leaves Euclidean distance unchanged, a type-2 reflection on $\mathcal{P}$ leaves L-distance unchanged. To understand this, we take a moment to consider the ratio of Euclidean segment lengths in (6.2). That ratio is the **planar cross ratio** of Euclidean points P, Q, S, T.

Lemma 6.16. The planar cross ratio of points in $\mathcal{E} \setminus O$ is invariant under circular inversion of $\mathcal{E} \setminus O$.

Proof. Consider points P, Q, S, T in $\mathcal{E} \setminus O$ and let P', Q', S', T' be their respective images under an inversion with radius a and center O. Assuming noncollinearity, we have the following four pairs of similar triangles, by Observation 5.16: $\Delta POS \sim \Delta S'OP'$, $\Delta POT \sim \Delta T'OP'$, $\Delta QOS \sim \Delta S'OQ'$, and $\Delta QOT \sim \Delta T'OQ'$. It follows that

$$\frac{|PS|}{|OP|} = \frac{|P'S'|}{|OS'|}, \text{ and } \frac{|PT|}{|OP|} = \frac{|P'T'|}{|OT'|}. \tag{6.5}$$

Dividing the second equation into the first we get

$$\frac{|PS|}{|PT|} = \frac{|P'S'|}{|P'T'|}\frac{|OT'|}{|OS'|}.$$

Similarly,

$$\frac{|QS|}{|QT|} = \frac{|Q'S'|}{|Q'T'|}\frac{|OT'|}{|OS'|}.$$

Dividing the latter two equations, we get

$$\frac{|PS|}{|PT|}\frac{|QT|}{|QS|} = \frac{|P'S'|}{|P'T'|}\frac{|Q'T'|}{|Q'S'|},$$

as desired.

Next, consider what happens if O, P, S are collinear. We may assume the points are labeled so that $|PS| = |OS| - |OP|$ and $|P'S'| = |OP'| - |OS'|$. Then $|PS||OS'| = a^2 - |OP||OS'|$, and $|P'S'||OP| = a^2 - |OS'||OP|$ so $|PS||OS'| = |P'S'||OP|$ implying that the first statement in (6.5) is still true. Thus, if any of the four "triangles" is not actually a triangle, we get the same equations and we can still conclude that the planar cross ratio is unchanged by inversion. □

Theorem 6.17. The L-metric is invariant under circular inversion.

Proof. The proof is immediate by Lemma 6.16. □

We study Euclidean reflections and rotations in some detail in later chapters after developing the requisite algebraic machinery. For now, we simply observe that under reflection across a diagonal, as well as rotation about its center, $\mathcal{P}$ is mapped to itself, L-lines are mapped to L-lines, and Euclidean length and angle are preserved. Our intuition tells us this must be so, and for now, we leave it at that.

Since Euclidean length is preserved, L-length is also preserved under type-1 reflections. (We leave the verification as an exercise.) Theorem 5.23 implies that a type-2 reflection on $\mathcal{P}$ leaves $\mathcal{P}$ fixed as a set. By Lemma 5.25, angles formed by L-lines are unchanged by inversion. L-reflections, then, map $\mathcal{P}$ to $\mathcal{P}$, and respect L-length and angle. The next result is less obvious.

Lemma 6.18. A type-2 reflection of $\mathcal{P}$ maps L-lines to L-lines.

Proof. We continue to use $\mathcal{C}$, with center O and radius 1, as the circle in $\mathcal{E}$ defining $\mathcal{P}$. Let ℓ be a type-2 line in $\mathcal{P}$ with underlying circle $\mathcal{C}'$ with center A and radius a. From Exercise 5.3.9, we know that $\mathcal{C}$ and $\mathcal{C}'$ are orthogonal if and only if

$$a^2 + 1 = b^2, \tag{6.6}$$

where $b = |OA|$.

Fix a coordinate system on $\mathcal{E}$ based on $\mathcal{C}'$, so that A has rectangular coordinates $(0, 0)$, O has coordinates $(b, 0)$, and $\mathcal{C}'$ is given by $x^2 + y^2 = a^2$. We use rectangular and polar coordinates to show that a type-1 line in $\mathcal{P}$ is mapped to a type-2 line under the type-2 reflection determined by $\mathcal{C}'$. Because circular inversion is an involution, this is enough to show that type-2 reflections map L-lines to L-lines in $\mathcal{P}$.

Note that a diameter of $\mathcal{C}$ belongs to a line that can be described in rectangular coordinates by

$$x - b = cy,$$

for some $c \in \mathbb{R}$. Switching to polar coordinates, the line is given by $r\cos\theta - b = cr\sin\theta$. Under inversion through radius a, the line is mapped to the circle in $\mathcal{E}$ given by

$$a^2 r\cos\theta - br^2 = a^2 cr\sin\theta + br^2.$$

Switching back to rectangular we have

$$x^2 - \frac{a^2}{b}x + y^2 + \frac{a^2 c}{b}y = 0,$$

which can be written

$$\left(x-\frac{a^2}{2b}\right)^2+\left(y+\frac{a^2c}{2b}\right)^2=\frac{a^4(1+c^2)}{4b^2}.$$

The line through O is thus mapped to the circle $\mathcal{C}''$ in $\mathcal{E}$ with radius $a^2\sqrt{1+c^2}/(2b)$ and center Q (in rectangular coordinates) given by

$$Q=\left(\frac{a^2}{2b},-\frac{a^2c}{2b}\right).$$

Again invoking Exercise 5.3.9, we know that $\mathcal{C}''$ is orthogonal to $\mathcal{C}$ if and only if $|OQ|^2$ is the sum of the squares of the radii of $\mathcal{C}$ and $\mathcal{C}''$. We see then that ℓ, the L-line underlying the diameter of $\mathcal{C}$, is mapped to a type-2 line if and only if

$$|OQ|^2=1+\frac{a^4(1+c^2)}{4b^2}.$$

With an eye toward Equation (6.6), we see that

$$|OQ|^2=\left(\frac{a^2}{2b}-b\right)^2+\left(-\frac{a^2c}{2b}\right)^2=\frac{a^4}{4b^2}-a^2+b^2+\frac{a^4c^2}{4b^2}$$

$$=\frac{a^4(1+c^2)}{4b^2}+(b^2-a^2)=\frac{a^4(1+c^2)}{4b^2}+1,$$

as was to be shown. □

We can proceed now under the assumption that any L-reflection maps an L-line to an L-line.

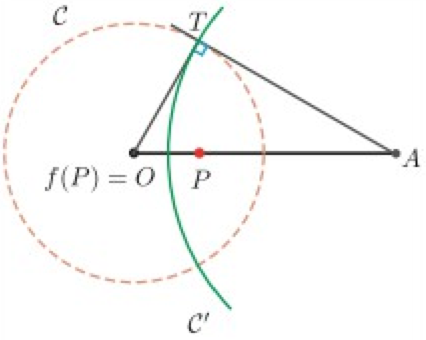

Figure 6.10: Every point can be L-reflected to O

Lemma 6.19. For every point P in $\mathcal{P}$ there is an L-reflection f with $f(P)=O$.

Proof. Given a point $P \in \mathcal{P}$ different from O, let $k = |OP|$. Since the radius of $\mathcal{C}$ is 1, $k < 1$. Let $A \in \overrightarrow{OP}$ satisfy $|OA| = 1/k$. (See Fig. 6.10.) Notice that since $0 < k < 1$, $1/k > 1$ so A is outside $\mathcal{C}$.

Form a tangent to $\mathcal{C}$ from A and say the point of tangency is T. Let $a = |AT|$. Notice that the circle $\mathcal{C}'$ with center A and radius a is indeed orthogonal to $\mathcal{C}$ so it does determine a type-2 line in $\mathcal{P}$, thus an L-reflection, f. We claim that $f(P) = O$. It suffices to show that $|Af(P)| = 1/k$.

We have $|AP||Af(P)| = a^2$. Note

$$|AP| = \frac{1}{k} - k = \frac{(1-k^2)}{k}.$$

By the Pythagorean Theorem, $|OA|^2 = 1 + a^2$ so

$$a^2 = \frac{1}{k^2} - 1 = \frac{1-k^2}{k^2} = \frac{(1-k^2)}{k}\frac{1}{k} = |AP|\frac{1}{k} = |AP||Af(P)|$$

in other words, $|Af(P)| = 1/k$, as was to be shown. □

Hilbert's Axiom III.5 says that if ΔABC and $\Delta A'B'C'$ satisfy $|AB| \cong |A'B'|$, $\angle BAC \cong \angle B'A'C'$, and $|AC| \cong |A'C'|$, then $\angle ABC \cong \angle A'B'C'$. In Hilbert's narrative, it is a short leap from Axiom III.5 to triangle congruence. With the tools in our hands, the route to the result that SAS implies L-triangle congruence is even more direct. This approach to the proof is from [18] and [23].

Theorem 6.20. SAS implies L-triangle congruence in $\mathcal{P}$.

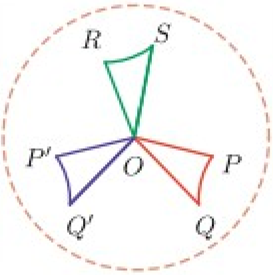

Figure 6.11: Euclidean reflection maps $\Delta OP'Q'$ to ΔOPQ. Rotation maps ΔORS to ΔOPQ

Sketch of proof. Let ΔABC and $\Delta A'B'C'$ be L-triangles in $\mathcal{P}$ with

$$L(A, B) = L(A', B'),\ L(A, C) = L(A', C'),\ \text{and } \angle BAC \cong \angle B'A'C'.$$

Let f be an L-reflection that maps A to O, the center of the Euclidean circle defining $\mathcal{P}$. Since L-reflections respect L-length, L-lines, and angle, $f(\Delta ABC) = \Delta OPQ$ is congruent to ΔABC.

Letting g be the L-reflection that maps A' to O, we get a fourth L-triangle

$$g(\Delta A'B'C') = \Delta OP'Q' \cong \Delta A'B'C'.$$

Note now that the sides OP, OQ, OP', OQ' all lie on diagonals of $\mathcal{C}$. Since $\angle POQ \cong \angle P'OQ'$, we can use either a Euclidean reflection or rotation to map $\Delta OP'Q'$ to a new L-triangle, $\Delta OP''Q''$, where P'' is on OP and Q'' is on OQ. Because

$$L(O,Q) = L(O,Q') = L(O,Q''), \text{ and } L(O,P) = L(O,P') = L(O,P''),$$

points P and P'' have to coincide, as do points Q and Q''. Since two points in $\mathcal{P}$ determine a unique L-line, the L-segments PQ and $P''Q''$ must coincide as well. Since the legs of $\angle QPO$ and $\angle Q''P''O$ coincide, the angles must be congruent as well. The same argument establishes that $\angle PQO \cong \angle P''Q''O$ so that

$$\Delta OPQ \cong \Delta OP''Q'' \cong \Delta OP'Q'.$$

Since congruence is an equivalence relation, we have $\Delta ABC \cong \Delta A'B'C'$, which proves the theorem. □

Authors who use this argument to prove SAS in $\mathcal{P}$ (see [11], besides [18] and [23], for example) usually note that it employs superposition, the method that Euclid used to argue Prop. I. 4. Remember that Euclid has been chastised through the ages for using superposition! Superposition is a valid technique if it is developed as part of the discussion of allowable transformations or *isometries* on the geometry in question. We have handled circular inversion fairly thoroughly, and appealed to intuition in our use of Euclidean reflections and rotations. In the next chapter, we meet transformations formally and in earnest.

Exercises 6.1. 1. Is the following statement true or false? Justify your answer with a proof, if it is true. If it is false, adjust the statement to make it true and supply details: "Any set of three noncollinear points in $\mathcal{P}$ is noncollinear in both the Euclidean and the hyperbolic sense, thus, by identifying a triangle with its vertices, we find that the collection of Euclidean triangles and the collection of L-triangles in $\mathcal{P}$ is the same."

2. There is a statement in the proof of Lemma 6.1 that says "P, Q and P' are noncollinear." Why is this true?

3. (a) Show that $d(x,y) = |x-y|$ is the Euclidean metric on $\mathbb{R}$.

   (b) Show that for x, y in $\mathbb{R}$, $|x+y| \le |x| + |y|$.

4. Finish the verifications that were left out of the proof of Theorem 6.6.

5. Consider points P, Q in $\mathcal{P}$ with S, T the points at infinity of the associated L-line. What happens to $L(P, Q)$ if we keep Q fixed but move P closer (in the Euclidean sense) to S? What happens if we move P closer to T? Now think of orthogonal circles that are very small at the edge of $\mathcal{D}$ and their associated L-lines in $\mathcal{P}$. What does the L-distance tell us about the type-2 lines that those circles determine? In other words, would those type-2 lines somehow seem shrunken in a hyperbolic world, as the underlying Euclidean circles are so small?

6. Show that by parametrizing the line ℓ as we did in (6.3), we get a line coordinatization that satisfies Definition 6.9.

7. Parametrize the line in $\mathbb{R}^2$ that passes through the points $(-1, 1)$ and $(2, 3)$, in three different ways, using the formula as given in (6.3), as follows. In each case, identify the point on ℓ associated with the real number 2.

    (a) Identify $(-1, 1)$ with 0 and the positive direction with $\mathbf{v} =< 3, 2 >$;

    (b) Identify $(2, 3)$ with 0 and the positive direction with $\mathbf{u} =< -3, -2 >$;

    (c) Identify $(-1, 1)$ with 0 and the positive direction with $\mathbf{u}$ as given in part (b).

8. Show that R as defined in Lemma 6.10 is a bijection in the case in which ℓ is a type-1 line.

9. Finish the proof of Lemma 6.11 for the case of a type-1 line.

10. Verify this statement, as it appears in the proof of Lemma 6.11: "Since the base on the circumference of $\mathcal{C}'$ for $\widehat{ST}$ is the major arc associated to ST, φ is obtuse."

11. Show that g' is as given in the proof of Lemma 6.13.

12. Finish the proof of Theorem 6.14 by showing that $f_2 : \ell \to \mathbb{R}_+$ is bijective and continuous. (Hint: It may be easiest to argue that (1) multiplication by a constant is a continuous bijective mapping of $\mathbb{R}$ to $\mathbb{R}$, and (2) if $h_1 : A \to B$ and $h_2 : B \to C$ are bijections, then $h_2 \circ h_1 : A \to C$ is a bijection.)

13. Show that Pasch's Axiom holds in $\mathcal{P}$.

14. Show that any mapping that leaves Euclidean distance invariant also leaves L-distance invariant. Give an example of a mapping that leaves L-distance invariant but does not leave Euclidean distance invariant.

15. Figure 6.11 depicts two different ways congruent L-triangles with a vertex at O could be oriented relative to one another. (See the proof of Theorem 6.20.) What are the other possibilities? For each possibility, identify the reflection or rotation you would use to map one of the L-triangles to ΔOPQ. For instance, reflection across the angle bisector of $\angle Q'OQ$ would

map $\Delta OP'Q'$ to ΔOPQ. What mapping would take ΔORS to $\Delta OP'Q'$? What about other configurations, for example if the L-triangles share a side?

16. Fix a type-1 line and a point P not on it in $\mathcal{P}$. Sketch the limit parallels through P. Repeat the exercise for a type-2 line in $\mathcal{P}$.

17. Describe an L-circle in $\mathcal{P}$. Are L-circles Euclidean circles as well?

Chapter 8

An Introduction to Projective Geometry

8.1 Introduction

Projective geometry has a long history going back to the late classical era with the work of Pappus. Early in the nineteenth century, Poncelet wrote the first treatise on the subject but it did not develop into one of the building blocks of modern mathematics until late in the nineteenth century. Nowadays, projective geometry is part of the everyday working tool set for mathematicians in geometry, topology, and algebra. It is also of interest in its own right.

Like affine geometry, projective geometry is a type of incidence geometry closely related to Euclidean geometry. It takes a mere three axioms to define a projective plane. Despite the seemingly spartan nature of such a configuration, a certain class of projective planes provides more than enough material to keep us occupied here.

The projective planes we study here are those that can be seen as sitting inside higher-dimensional projective spaces. Whether or not a given projective plane can be embedded naturally into projective 3-space turns on an algebraic property of the underlying coordinate system, which may be more general than a field. If the underlying coordinate system is a field, then we can model our projective plane using a vector space. Since finite-dimensional vector spaces always embed naturally into higher-dimensional vector spaces, in this setting, our projective plane embeds into projective 3-space.

This is not the first time we have seen the connection between the nature of the coordinatizing set for a line and features of the geometry itself. With a study of projective geometry, we come to a veritable precipice. Swaying above the turquoise depths of modern algebra roiling several stories below, we resist the impulse to jump, and content ourselves with a study of projective planes that arise from vector spaces over fields. (Jumpers may consult [8].)

We start by defining projective space in terms of affine space, with the addition of so-called ideal points or points at infinity. We then show that we can shed the labels and treat all points in a projective space as one class of objects, all lines as another class of objects, all planes as another, and so on.

8.2 Projective Space

Because we need it for context, we start with a study of projective 3-space, rather than a projective plane. Before adding points to $\mathbb{FA}^3$, we reprise a definition we saw in Chapter 7.

Definition 7.67. The **direction of an affine line** ℓ in $\mathbb{FA}^n$, is any vector $\mathbf{v}$ in the ambient vector space V, where, for some $\mathbf{x} \in V$, $\ell = \{\mathbf{x} + t\mathbf{v} | t \in \mathbb{F}\}$. A **direction in an affine** k**-plane** in $\mathbb{FA}^n$, is a direction for an affine line in that k-plane. For $k \in \{1, \ldots, n-1\}$ fixed, k**-planes in** $\mathbb{FA}^n$ **are parallel** provided they have the same directions and do not intersect. Two k-planes in $\mathbb{FA}^n$ are **skew** if they have different directions and do not intersect.

A pair of distinct parallel lines in $\mathbb{FA}^3$ is contained in a unique plane. (This was part of Theorem 7.68.) There is no affine plane containing a pair of skew lines.

Partition the lines in $\mathbb{FA}^3$ by direction. For instance, lines in $\mathbb{R}^3$ with direction vector $(0, 0, 1)$ are the z-axis and all lines parallel to the z-axis. (See Fig. 8.1.) These comprise one equivalence class of lines in $\mathbb{R}^3$.

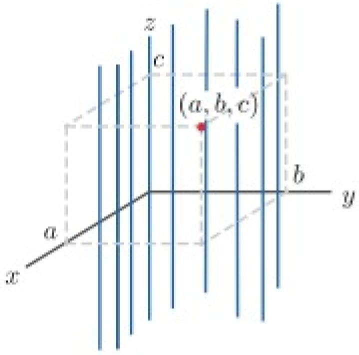

Figure 8.1: Lines parallel to the z-axis in $\mathbb{R}^3$

Add a single point, called an *ideal point* or *point at infinity*, to each line in a given equivalence class of parallel lines in $\mathbb{FA}^3$ and to each plane containing that line. The lines in each equivalence class now intersect in the unique ideal point associated to that class. Note that we add a single ideal point to $\mathbb{FA}^3$ for each different direction in $\mathbb{FA}^3$ and that this point is appended only to the lines and planes with that direction. We distinguish the points of the original affine space by calling them *ordinary points*.

Definition 8.1. The points of **projective** 3**-space over** $\mathbb{F}$, $\mathbb{FP}^3$, are the ordinary and ideal points associated to $\mathbb{FA}^3$. The **ideal plane** or **plane at infinity** is the collection of all ideal points in $\mathbb{FP}^3$. An **ordinary plane** in $\mathbb{FP}^3$ is the collection of all ordinary points associated to a plane in $\mathbb{FA}^3$ together with the ideal points associated to the directions in that affine plane. The collection of ideal points in an ordinary plane is the **ideal line** or **line at infinity** in that plane. A **projective plane** is an ordinary or ideal plane in $\mathbb{FP}^3$. An **ordinary line** is a line with ordinary points and a single ideal point. A **projective line** is an ordinary or ideal line in $\mathbb{FP}^3$. The projective points, lines, and planes in $\mathbb{FP}^3$ are its **projective objects**. Two projective objects in $\mathbb{FP}^3$ are **incident** provided the underlying sets have nonempty intersection.

An ordinary plane contains exactly one point at infinity for each direction in the underlying affine plane. It also contains exactly one line at infinity, the collection of all of its ideal points. The line at infinity for an ordinary plane α is the intersection of α with the plane at infinity.

Our first task is to establish the projective analogs to our main theorems on incidence in $\mathbb{FA}^3$, Theorem 7.68, and Theorem 7.93.

There is no concept of order in an arbitrary projective space so we will not have occasion to discuss segments in this chapter. As such, we use the notation AB for the line through the points A and B.

Theorem 8.2. (1) Two distinct points determine a unique line in $\mathbb{FP}^3$.

(2) If two lines intersect in $\mathbb{FP}^3$, their intersection is a single point.

(3) Two lines in a given plane in $\mathbb{FP}^3$ intersect.

(4) A point and a line not through the point lie in a unique plane in $\mathbb{FP}^3$.

(5) If two points are in a plane in $\mathbb{FP}^3$, the line they determine is in the plane.

(6) A line that does not lie in a plane in $\mathbb{FP}^3$ intersects the plane in one point.

(7) Two intersecting lines in $\mathbb{FP}^3$ lie in a unique plane.

(8) Three noncollinear points in $\mathbb{FP}^3$ lie in a unique plane.

(9) Two planes intersect in a unique line in $\mathbb{FP}^3$.

Proof. Let $V \cong \mathbb{F}^3$ be the ambient vector space for $\mathbb{FA}^3$.

(1) Two ordinary points in $\mathbb{FP}^3$ determine a unique affine line in $\mathbb{FA}^3$ by Theorem 7.68. The points of that affine line comprise the ordinary points on a unique ordinary line in $\mathbb{FP}^3$.

Suppose P is an ordinary point and Q_∞ an ideal point in $\mathbb{FP}^3$. P corresponds to a unique vector $\mathbf{v} \in V$, that is, a point in $\mathbb{FA}^3$, whereas Q_∞ corresponds to a direction in $\mathbb{FA}^3$ determined by a vector $\mathbf{w} \in V$. Then $\mathbf{v} + \operatorname{span}\{\mathbf{w}\}$ is a line in $\mathbb{FA}^3$, comprising the ordinary points of an ordinary line ℓ in $\mathbb{FP}^3$ that includes P and Q_∞. If there is any other line containing P and Q_∞ in $\mathbb{FP}^3$, it must be ordinary, as it contains P, and its ordinary points must coincide with $\mathbf{v} + \operatorname{span}\{\mathbf{w}\}$ because this is the unique line in $\mathbb{FA}^3$ through $\mathbf{v}$ and $\mathbf{w} - \mathbf{v}$, which means it must be ℓ.

Suppose we are given P_∞ and Q_∞, two ideal points in $\mathbb{FP}^3$. There is no ordinary line containing them both as an ordinary line contains exactly one ideal point. P_∞ and Q_∞ correspond to directions in $\mathbb{FA}^3$, say given by vectors $\mathbf{v}$, $\mathbf{w}$ in V, where $\mathbf{w} \neq c\mathbf{v}$ for any $c \in \mathbb{F}$. Then $\{\mathbf{v}, \mathbf{w}\}$ is a basis for W, a two-dimensional subspace of V. The directions in W, and all planes in $\mathbb{FA}^3$ parallel to W, are identical, so every plane in the parallel class determined by W contains P_∞, Q_∞, and the unique ideal line determined by the set of directions common to all the planes in that parallel class. That unique line at infinity is the line determined by P_∞ and Q_∞.

(2) Suppose we have two intersecting lines in $\mathbb{FP}^3$. If both are ordinary and their ordinary points form parallel lines in $\mathbb{FA}^3$, then in $\mathbb{FP}^3$ the lines intersect in a unique ideal point that represents their common direction. If both are ordinary and they intersect in a unique ordinary point, then there can be no other ordinary point in the intersection, by Theorem 7.68. Since their ordinary points form lines with different directions, they cannot have an ideal point in common in $\mathbb{FP}^3$, so in this case, the intersection is a single ordinary point. If one line is ordinary and the other is ideal, then they can share at most one ideal point representing the direction of the ordinary line. If both lines are ideal, then one arises as the directions in one parallel class of affine planes, and the other as the directions in a second parallel class of affine planes. Nonparallel planes in $\mathbb{FA}^3$ intersect in a line and the direction of that line is represented as an ideal point in $\mathbb{FP}^3$, which must be the single point of intersection of our two ideal lines.

(3) Consider lines ℓ, m in a plane α in $\mathbb{FP}^3$. Suppose α is ideal so that ℓ and m are both ideal. In this case, ℓ and m represent parallel classes of affine planes in $\mathbb{FA}^3$. Let β', γ' be affine planes, one from each of these two parallel classes. By Theorem 7.93, $\beta' \cap \gamma' = \ell'$, a single line the direction of which is represented by a unique point in $\ell \cap m$.

If α is ordinary, then at least one of the lines must be ordinary. Say it is ℓ. Let ℓ' be the affine line comprised of the ordinary points of ℓ. If m is also ordinary, let m' be the affine line comprised of the ordinary points of m. Either $\ell' \cap m'$ is a single affine point or ℓ' and m' are parallel. If $\ell' \cap m'$ is a single affine point, then the two affine lines have different directions, thus, ℓ and m have no ideal points in common so $\ell \cap m$ is a single ordinary point. If ℓ' and m' are parallel, there is a single ideal point P in α representing the direction of the two lines. In this case, $\ell \cap m = P$. If m is the line at infinity in α, then it must contain a point P associated to the direction of ℓ'. In this case $\ell \cap m = P$.

(4) Suppose we are given a point and a line not through the point. If the point and line are both ideal, they lie in the unique ideal plane by construction.

If either the line, the point, or both are ordinary, let $\mathcal{S}$ be the union of the point and the points on the line. Since affine lines contain at least two points, and since there are at least three directions in $\mathbb{FA}^3$, $\mathcal{S}$ contains at least three points. Since at least one of our objects is ordinary, $\mathcal{S}$ must contain an ordinary point, P. From the remaining points in $\mathcal{S}$, pick two more, Q, R, so that P, Q, R are noncollinear. By part (1) above, P and Q determine a unique line ℓ in $\mathbb{FP}^3$. P and R determine a second unique line m in $\mathbb{FP}^3$. By assumption, ℓ and m are distinct lines, intersecting at P. Since they contain an ordinary point, P, ℓ and m are ordinary lines so their ordinary points determine a unique affine plane, α'. That affine plane underlies a projective plane with ideal points determined by the directions in α'. Since α' is unique in $\mathbb{FA}^3$, the associated projective plane is unique in $\mathbb{FP}^3$, which proves the result.

(5) Let P and Q belong to a plane α in $\mathbb{FP}^3$. Suppose both P and Q are ideal. If α is also ideal, it contains all ideal points, so contains the unique ideal line determined by P and Q. If α is ordinary, its ordinary points comprise an affine plane, α'. Let $\mathbf{v}$ and $\mathbf{w}$ be vectors in V with the directions represented by P and Q. Then $\alpha' = \mathbf{x} + \operatorname{span}\{\mathbf{v}, \mathbf{w}\}$, for some $\mathbf{x}$ in V. The directions in $\operatorname{span}\{\mathbf{v}, \mathbf{w}\}$, which determine the ideal line determined by P and Q, are the directions in α'. It follows that α contains the ideal line determined by P and Q.

If one point is ordinary and the other ideal, then α is ordinary and the ideal point represents a direction in α', the plane in $\mathbb{FA}^3$ comprised of the ordinary points of α. Say the ordinary point is associated to some $\mathbf{v}$ in V and the ideal point is associated to $\mathbf{w}$ in V. The affine line $\ell = \mathbf{v} + \operatorname{span}\{\mathbf{w}\}$ is in α' so the associated projective line, which includes P and Q, must then be in α.

If both points are ordinary, they determine a unique affine line, ℓ', in $\mathbb{FA}^3$. The ordinary points of α comprise an affine plane that contains ℓ'. Then ℓ' is the set of ordinary points of a unique projective line determined by P and Q, and lying in α.

(6) Let α be a plane in $\mathbb{FP}^3$ and ℓ a line in $\mathbb{FP}^3$ not contained in α. The ideal plane contains all ideal lines so α and ℓ cannot both be ideal. Suppose both are ordinary. Let ℓ' be the affine line comprised of the ordinary points of ℓ. Let α' be the affine plane comprised of the ordinary points of α. We know that $\alpha' \cap \ell'$ is either empty or a single point, by Theorem 7.68. If empty, then ℓ' is parallel to lines in α' so $\alpha \cap \ell$ is the single ideal point associated to that class of parallel lines in $\mathbb{FA}^3$. If $\alpha' \cap \ell'$ contains a single point, then the direction of ℓ' is not in α'. It follows that $\alpha \cap \ell$ cannot contain an ideal point. Thus, in this case, there can be no more than the single ordinary point in $\alpha \cap \ell$.

If ℓ is ordinary and α ideal, then $\alpha \cap \ell$ is the unique ideal point associated to the parallel class of the affine line underlying ℓ. If ℓ is ideal and α ordinary, then ℓ is associated to a parallel class of planes in $\mathbb{FA}^3$ and α', the affine plane comprised of the ordinary points of α, is not in that parallel class: If it were, ℓ would be contained in α. Let β' be an affine plane in the parallel class of affine planes determined by ℓ. Since α' is not parallel to β', $\alpha' \cap \beta' = \ell''$, where ℓ'' is an affine line. Let P be the ideal point associated to the direction of ℓ''. Notice that $P \in \alpha \cap \ell$. Moreover, if β'' is another affine plane in the parallel class determined by ℓ, then $\alpha' \cap \beta''$ is a line parallel to ℓ''. It follows that $P = \alpha \cap \ell$.

(7) Let ℓ and m be intersecting lines in $\mathbb{FP}^3$, with Q the point of intersection. Let P be a point on m that is not on ℓ. By (4), P and ℓ lie in a unique plane, $\alpha \subset \mathbb{FP}^3$. Since Q is on $\ell \subset \alpha$, (5) implies that $PQ = m$ is in α as well. Now any point on m, apart from Q, together with ℓ determine α and by (4), there is no other plane containing the point and ℓ. Since this is true for all points of m, except the one that also belongs to ℓ, it follows that α is the only plane containing both ℓ and m.

(8) This also follows by (1) and (7).

(9) Suppose α and β are ordinary planes in $\mathbb{FP}^3$. Either their ordinary points comprise planes in $\mathbb{FA}^3$ that are parallel or their ordinary points comprise planes in $\mathbb{FA}^3$ that intersect in a unique affine line, ℓ'. In the former case, every direction in α is a direction in β and vice versa so the two planes intersect in their common line at infinity. In the latter case, Theorem 7.93 guarantees that ℓ' comprises all the ordinary points in the intersection $\alpha \cap \beta$. By the same theorem, the direction of ℓ' is the only direction the ordinary points of the two planes have in common so the only ideal point the two can have in common is the one associated to ℓ'. In this case, then, $\alpha \cap \beta = \ell$, the projective line associated to ℓ'.

Now suppose α is ordinary and β is ideal. By definition, the collection of ideal points in α, the intersection of α and β, is the line at infinity for α.

□

Corollary 8.3. Three distinct planes in $\mathbb{FP}^3$ that do not have a common line intersect in a unique point.

Proof. The proof is left as an exercise. □

Next is a basic theorem about counting points in $\mathbb{FP}^3$. This is the projective version of Theorem 7.70.

Theorem 8.4. (1) A line in $\mathbb{FP}^3$ has at least three points.

(2) A plane in $\mathbb{FP}^3$ has four points, no three of which are collinear.

(3) There are four noncoplanar points.

Proof. Let α_∞ be the plane at infinity in $\mathbb{FP}^3$.

(1) An ordinary line contains two ordinary points by Theorem 7.70. In $\mathbb{FP}^3$, it has an additional ideal point so the total number of points on any ordinary line is at least three.

If ℓ_∞ is an ideal line in $\mathbb{FP}^3$, then it lies in some ordinary plane, α. Let $\alpha' \subset \mathbb{FA}^3$ be the underlying affine plane and let $V \cong \mathbb{F}^3$ be the ambient vector space for $\mathbb{FA}^3$. We can use an element from $\mathrm{Aff}(V)$, if necessary, to map α' to an isomorphic copy of $\mathrm{span}\{(1,0,0),(0,1,0)\}$, which we will call the xy-plane. A direction in the xy-plane can be identified with the nonzero scalar multiples of a nonzero vector in the plane. We identify three different directions in the xy-plane, then, corresponding to the vectors $(1,0,0),(0,1,0),(1,1,0)$. Since the correspondence between α' and the xy-plane is via an isomorphism of the affine geometry, there must be lines with three different directions in α'. Those three different directions in α' are represented by three different points on ℓ_∞.

(2) In Theorem 7.70.2. we established that in any affine plane, there are four points, no three of which are collinear. It follows that in any ordinary plane in $\mathbb{FP}^3$, there are four ordinary points, no three of which are collinear.

Next we consider α_∞. Let ℓ be a line in α_∞ and say that A, B, C are three points on ℓ. Note that ℓ represents directions in some parallel class of affine planes. Let α' be an affine plane in that parallel class. By Theorem 7.70, there are four noncoplanar points in $\mathbb{FA}^3$ so we can take an affine point not in α'. Take also any point in α'. The affine line determined by these two affine points has a direction that is not in α'. That direction is realized as a point, $Q \in \alpha_\infty$, where $Q \notin \ell$.

Let $m = AQ$. Notice that $m \subset \alpha_\infty$. Take D to be any third point on m. Now we have $\{A, Q, D\} \subset m$, $\{A, B, C\} \subset \ell$, $\ell \cap m = A$, and $\ell \cup m \subset \alpha_\infty$. Consider the set $\mathcal{S} = \{B, C, Q, D\}$. Any choice of three of these points gives us two points on ℓ and a point on m not on ℓ, or two points on m, and a point on ℓ not on m. This shows that $\mathcal{S}$ is a set of four points in α_∞, no three of which are collinear.

(3) Theorem 7.70 guarantees that $\mathbb{FP}^3$ has four ordinary points which do not lie in an ordinary plane.

□

Theorems 8.2 and 8.4 establish that there is no need to distinguish between ordinary and ideal objects in $\mathbb{FP}^3$. In terms of incidences, all points are alike, all lines are alike, and all planes are alike in $\mathbb{FP}^3$.

Our construction and the attendant theorems also show that any field can be the foundation for a projective space.

Appending ideal points to affine space is one way to construct projective space. Another approach is axiomatic. Here is a set of axioms we could use to define $\mathbb{FP}^3$.

Axioms for Projective Space

Axiom PS1. Two points determine a unique line.

Axiom PS2. Three noncollinear points lie in a unique plane.

Axiom PS3. If two points lie in a plane, the line they determine lies in that plane.

Axiom PS4. Two coplanar lines intersect in a unique point.

Axiom PS5. Two planes intersect in at least two points.

Axiom PS6. A plane and a line that does not lie in the plane intersect in exactly one point.

Axiom PS7. A line contains at least three points.

Axiom PS8. A plane contains four points, no three of which are collinear.

Axiom PS9. There exist four noncoplanar points.

The primary focus of our interest is $\mathbb{FP}^2$. We could have defined a projective plane using the following set of axioms. These apply to all projective planes, not just those constructed from affine space. Among projective planes defined with this set of axioms are those that are still the subject of active research.

Axioms for Projective Plane

Axiom PP1. Two points determine a unique line.

Axiom PP2. Two lines intersect in a unique point.

Axiom PP3. There exist four points, no three of which are collinear.

An advantage to using axioms is that they highlight the *principle of duality*, an intriguing feature of projective geometry.

Definition 8.5. The **dual** of a logical statement about a projective plane is the statement we get by switching the words "point" and "line" and the phrases "lie on" and "intersect in."

Note that in Axiom PP1, "determine" means "lie on." Axiom PP2 could be rephrased, *two lines determine a unique point.* Using the word "determine" in the two different senses, we highlight the duality of the two statements.

The following are dual to the axioms for a projective plane.

Dual Axioms for a Projective Plane

Axiom PP1*. Two distinct lines intersect in a unique point.

Axiom PP2*. Two distinct points determine a unique line.

Axiom PP3*. There are four lines, no three of which are concurrent.

The dual of *collinear,* a word that refers to the relative positions of points in a set, is *concurrent*, which refers to the relative positions of lines in a set. As we progress through our study of projective geometry, we will see that various locutions regarding points and lines have natural duals that we will not necessarily discuss. The dual of a statement captures a certain idea. The exact choice of words to express that idea is variable.

Principle of Duality. Any statement about a projective plane is true if and only if its dual statement is true.

Once we show that Axioms PP1–3 are equivalent to Axioms PP1*–3* in $\mathbb{FP}^2$, we will have established the principle of duality for projective planes constructed from affine planes.

Theorem 8.6. Axioms PP1–3 are equivalent to Axioms PP1*–3* in $\mathbb{FP}^2$.

Proof. It is clear that the pair Axioms PP1, 2 is equivalent to the pair Axioms PP1*, 2*. Suppose then that Axiom PP3 is true. Let $\{A, B, C, D\}$ be four points in $\mathbb{FP}^2$, no three of which are collinear. Consider the set of lines $\mathcal{S} = \{AB, BC, CD, AD\}$. (See Fig. 8.2.) By Axiom PP3, the four lines are distinct: for instance, because A, B, C are not collinear, AB and BC are distinct lines. To see that no three of the lines are concurrent, consider BC, CD, AD. We have $BC \cap CD = C$, but by assumption, C cannot belong to AD, so BC, CD, AD cannot be concurrent. We leave it as an exercise to show that lines in the other three three-line subsets of $\mathcal{S}$ are not concurrent. This shows that Axiom PP3 implies Axiom PP3*.

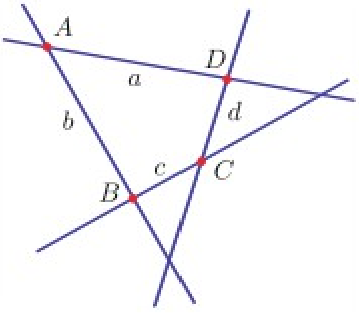

Figure 8.2: Four points, no three of which are collinear and four lines, no three of which are concurrent

Now assume Axiom PP3*. Let $\mathcal{T} = \{a, b, c, d\}$ be four lines in $\mathbb{FP}^2$, no three of which are concurrent. Since any two lines have a common point, we have four points $A = a \cap b$, $B = b \cap c$, $C = c \cap d$, $D = d \cap a$. Since the point of intersection of two lines is unique, and since no three of these lines are concurrent, the four points must be distinct. We claim that no three of the points in the set $\mathcal{U} = \{A, B, C, D\}$ are collinear. Consider $\{B, C, D\}$. If these are collinear, then $D \in c$, but that would make a, c, d concurrent as $D = a \cap d$. The other three cases follow similarly. We leave them as an exercise. □

Duality manifests in higher-dimensional projective spaces as well. Given a statement about $\mathbb{FP}^3$, we obtain its dual by switching the words "point" and "plane" and the phrases "lie on" and "intersect in." Lines are self-dual in projective 3-space. We leave it as an exercise to dualize the axioms we stated above for projective 3-space.

Relatively simple assemblages of points and lines get a good amount of attention in projective geometry and turn out to be surprisingly subtle. The following definition applies in any kind of plane or space.

Definition 8.7. The **pencil of lines through a point** P is the collection of all lines through P.

A line ℓ in $\mathbb{FP}^2$ that does not go through P intersects each line in the pencil through P exactly once. We say ℓ is a *section* of the pencil. The dual of a pencil of lines through a point in a projective plane is the collection of points on a line. It is called the *range* of points on the line.

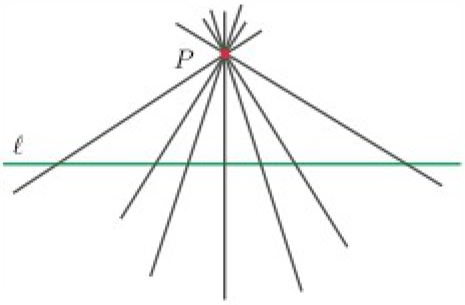

Figure 8.3: The pencil of lines through P is sectioned by ℓ

We noted in Chapter 7 that triangles form an important organizational unit in an affine plane. Triangles play a critical role in projective planes as well.

The definition of triangle does not vary much in different geometries but we repeat it here for the projective setting so that we can address the nature of its dual.

Definition 8.8. A **triangle** is a set of three noncollinear points (vertices) and the lines they determine (sides). A **trilateral** is a set of three nonconcurrent lines and the points they determine.

Triangles are **self-dual**, that is, the dual of a triangle—a trilateral—is the same collection of points and lines as the triangle itself.

Four-sided figures are not self-dual in projective geometry. We start with the four-sided analog of a triangle.

Definition 8.9. A **complete quadrangle** is a configuration in the projective plane composed of a set of four points (vertices), no three of which are collinear, together with the six lines (sides) they determine. **Opposite sides** of a complete quadrangle are two sides without a common vertex. The **diagonal points** of a complete quadrangle are the points where opposite sides intersect.

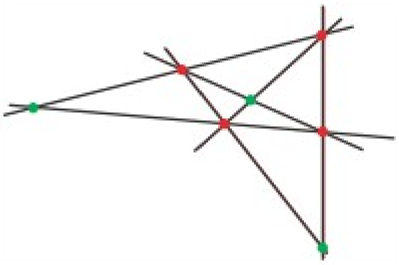

Figure 8.4: A complete quadrangle with diagonal points shown in green

Note that a complete quadrangle is an assemblage of four points and six lines. If we say "quadrangle" in projective geometry we always mean "complete quadrangle," likewise for the dual of a complete quadrangle, a *complete quadrilateral*.

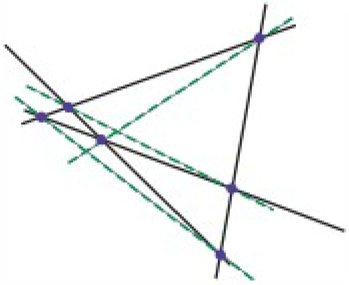

Figure 8.5: A complete quadrilateral with diagonals shown as broken green lines

Definition 8.10. A **complete quadrilateral** is a configuration in the projective plane composed of a set of four lines (sides), no three of which are concurrent, together with the six points (vertices) they determine. **Opposite vertices** of a complete quadrilateral are two vertices without a common side. The **diagonal lines** of a complete quadrilateral are lines that pass through opposite vertices.

Exercises 8.1. 1. In the proof of part (4) of Theorem 8.2, it is suggested that after choosing an ordinary point in $\mathcal{S}$, P, we could choose two more points, Q, and R, so that P, Q, R are noncollinear. Why is this true?

2. Prove Corollary 8.3.

3. In the proof of Theorem 8.4, we refer to three different directions in $\mathbb{FA}^3$ given by vectors $(1,0,0),(0,1,0),(1,1,0)$. Write down parametric and vector versions of the line through $\mathbf{0}$ and each of the three given points in $\mathbb{R}^3$. Do the same, but also write a list of the points on each line in $\mathbb{F}_2^3$, and again in $\mathbb{F}_3^3$.

4. Consider the collection of four lines referred to in the proof of Theorem 8.6, $\mathcal{S} = \{AB, BC, CD, AD\}$. The proof addresses the fact that the lines in the subset $\{BC, CD, AD\}$ are not concurrent.

   (a) Write down every other subset of $\mathcal{S}$ that contains exactly three lines.

   (b) For each subset you found in part (a), argue that the lines are not concurrent.

5. Consider the collection of four points referred to in the proof of Theorem 8.6, $\mathcal{U} = \{A, B, C, D\}$. The proof addresses the fact that the points in the subset $\{B, C, D\}$ are not collinear.

   (a) Write down every other subset of $\mathcal{U}$ that contains exactly three points.

   (b) For each subset you found in part (a), argue that the points are not collinear.

6. Dualize each of Axioms PS1-9. Remember that in projective space, points and planes are dual to one another, and lines are self-dual.

7. Write the dual of each of the following objects and statements in a projective plane.

   (a) Four points, no three of which are collinear

   (b) Two lines, and a point on neither line

   (c) The line determined by a given point and the point of intersection of two given lines

   (d) All lines in the projective plane

   (e) Distinct concurrent lines have only one common point.

   (f) Given a line and a point not on the line, distinct lines through the given point meet the given line in distinct points.

8. Write the dual for each of the following, as statements or objects in projective 3-space.
   (a) the set of points on a line
   (b) the set of points on a plane

9. Is a complete quadrangle self-dual? Explain.
10. How many sides go through a vertex of a complete quadrangle? How many sides go through a vertex of a complete quadrilateral?
11. Consider Fig. 8.6. This is a depiction of a planar geometry in which the points are represented as dots. The lines are the collections of points connected by the sides of the triangle, the cevians as shown, and what appears to be the incircle, as shown. The incidence geometry associated to the picture is called the *Fano plane*. Note that the triangle, segments, and circle are just schematic devices for capturing the incidences in the Fano plane.

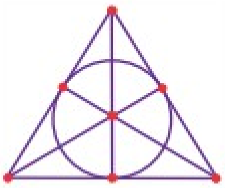

Figure 8.6: The Fano plane

   (a) Verify that the points and lines in the figure satisfy Axioms PP1–3. How many points and how many lines do we have in this plane?
   (b) Identify three different triangles in the Fano plane.
   (c) Identify a complete quadrangle in the Fano plane.
   (d) Identify a complete quadrilateral in the Fano plane.
   (e) Find the diagonal points on the complete quadrangle that you found above. Repeat the exercise with a different quadrangle. What do you notice about the diagonal points?

8.3 The Theorem of Desargues

Pappus's Theorem is often cited as the first theorem in projective geometry. Given that Pappus lived during the fourth century, and that projective geometry was not properly realized until the middle of the nineteenth century, it is clear that Pappus would not have been thinking about projective geometry per se. Pappus's Theorem has a distinctly projective flavor, though. The cleanest way to present it is in the projective plane, where intersection points of lines are guaranteed.

Desargues's Theorem is likewise often cited as the second theorem in projective geometry. Girard Desargues lived during the seventeenth century, so he is a bit closer to the development of modern projective geometry, which arose partly through the observations of Renaissance artists. Desargues was an architect, and belonged to a circle of thinkers that included the Pascals, Etienne (father) and Blaise (son), Fermat, Descartes, and Mersenne. Because his work was unorthodox—he invented his own terminology, for example—it was largely ignored except by the younger Pascal. Pascal's name is given to a result that is closely related to Pappus's Theorem. Desargues's Theorem, viewed in a certain light, is a generalization of Pappus's Theorem.

Pappus's proof of Pappus's Theorem involved heavy use of Euclidean geometry. Of course, in Pappus's time, there was no other geometry. Our approach is to use projective methods to prove Desargues's Theorem first. Deploying Desargues's Theorem after we develop projective transformations, we will find an easy proof of Pappus's Theorem.

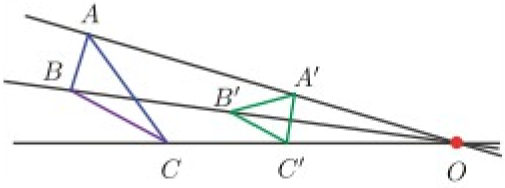

Figure 8.7: Triangles perspective from a point

Definition 8.11. Two triangles ΔABC, $\Delta A'B'C'$ are **perspective from a point** O provided AA', BB', CC' are concurrent at O. In this case, O is a **center of perspectivity**.

When triangles—or any other objects—are perspective from a point, they appear to overlap perfectly if one's eye is at the point of perspectivity. This is an essential idea in projective geometry and in art, especially Renaissance art, in which the effective illusion of space on a flat surface was an important goal.

Definition 8.12. Triangles ΔABC, $\Delta A'B'C'$ are **perspective from a line** ℓ

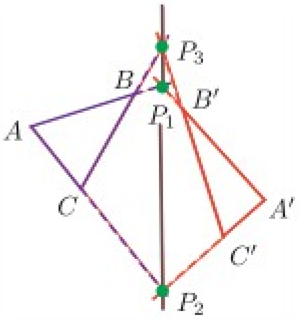

Figure 8.8: Triangles perspective from a line

provided the points $AB \cap A'B' = P_1$, $AC \cap A'C' = P_2$, and $BC \cap B'C' = P_3$ are collinear. In this case, ℓ is an **axis of perspectivity**.

Theorem 8.13 (Desargues). Two triangles are perspective from a point in $\mathbb{FP}^3$ if and only if they are perspective from a line.

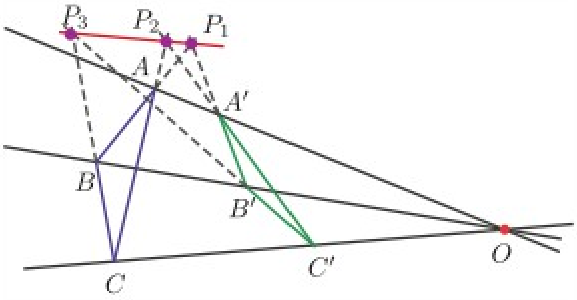

Figure 8.9: The theorem of Desargues

Proof. For the first part of the proof, we assume that the triangles lie in two different planes. Say ΔABC lies in the plane α and $\Delta A'B'C'$ lies in the plane α'.

If ΔABC and $\Delta A'B'C'$ are perspective from a point O, then since the lines AA' and BB' intersect at O, Theorem 8.2 guarantees that they determine a plane. That plane contains A, A', B, B' and O. Now the lines AB and $A'B'$ are in this plane so they intersect at a point P_1. Note that $P_1 \in \alpha \cap \alpha'$. The identical argument produces points $P_2 = AC \cap A'C'$ and $P_3 = BC \cap B'C'$, also in $\alpha \cap \alpha'$. This proves that $\alpha \cap \alpha'$ is the axis of perspectivity for the triangles.

Next suppose ΔABC and $\Delta A'B'C'$ are perspective from a line. As intersecting lines, AB and $A'B'$ lie in a plane β, again by Theorem 8.2. We then have A, B, A', B' all in β so AA' and BB' intersect in β. Similarly, AA' and CC' intersect in a plane β', and BB' and CC' intersect in a third plane β''. We must argue that the planes β, β', β'' intersect in a point, O, that is, that they do not share a line.

If the planes did share a line, that line would be $\beta \cap \beta'$, which contains AB, and at the same time, $\beta \cap \beta''$, which contains BC. As vertices of a triangle, A, B, C are noncollinear, so the line of intersection of β and β' must be different from the line of intersection of β and β''. It follows again by Theorem 8.2 that the intersection of the three planes is a single point, O. Now $AA' = \beta \cap \beta'$, $BB' = \beta \cap \beta''$, and $CC' = \beta' \cap \beta''$. The three lines AA', BB', CC' are thus concurrent at O.

Next, assume that ΔABC and $\Delta A'B'C'$ lie in a single plane, γ. The strategy for the proof in this case is to build another triangle in a different plane and then invoke the first part of the theorem.

Suppose the two triangles are perspective from a point $O \in \gamma$. Let ℓ be a line through O, not lying in γ. Choose P, P' distinct points on ℓ, both different from O. Let PAB be the plane determined by the point P and the line AB. Likewise define PAC, and PBC, each the plane containing P and one side of the triangle ΔABC.

Notice that PAB, PAC, and PBC must be distinct planes: If any two were equal, then P, A, B, and C would be coplanar, contradicting our choice of P. Moreover, $PAB \cap PAC = PA$, $PAB \cap PBC = PB$ and $PAC \cap PBC = PC$. Since the lines PA and $P'A'$ lie in the plane determined by intersecting lines AA', and PP', they must intersect in a point A''. We define points B'', C'' in a similar manner.

Next we argue that A'', B'', C'' cannot be collinear: If they were, then since $A''B''$ is in PAB, and $A''C''$ is in PAC, and $B''C''$ is in PBC, the three planes would have to intersect in a line containing P and lying in γ. This contradicts P lying outside γ. Thus, we have a new triangle, $\Delta A''B''C''$.

By construction, ΔABC and $\Delta A''B''C''$ are perspective from P, while $\Delta A'B'C'$ and $\Delta A''B''C''$ are perspective from P'. The line of perspectivity in both cases is the intersection of γ with the plane of $\Delta A''B''C$". This gives us that $A''B'' \cap AB$ and $A''B'' \cap A'B'$ fall on this line of intersection. Since $A''B''$ meets this line just once, AB and $A'B'$ intersect there as desired. The other sides of the two triangles meet on this line as well, for the same reasons. We conclude that ΔABC and $\Delta A'B'C'$ are perspective from the line $\gamma \cap \xi$, where ξ is the plane of $\Delta A''B''C''$.

We leave the last part of the proof to the reader. □

Notice that the proof of Desargues's Theorem is much easier when the triangles occupy different planes. Though it holds in Euclidean space, as long as all the intersection points exist, Desargues's Theorem is fundamentally about projective space. This business of embedding the plane in 3-space is not just a trick in the proof. The theorem is actually false in projective planes that cannot be viewed as occupying a part of projective 3-space. Projective planes for which Desargues's Theorem holds are *Desarguesian* and those for which it does not hold are *non-Desarguesian*. Non-Desarguesian planes are not defined over fields. They are not based on vector spaces or, equivalently, affine spaces.

Figure 8.10 shows the arrangement in Fig. 8.9 without specifying a particular role for any point or line. It turns out that any point in the configuration can play the role of O, the point of perspectivity. Likewise, any line can play the role of the axis of perspectivity. In the exercises, you will have a chance to explore these ideas a little bit.

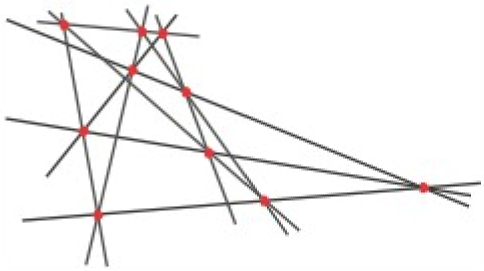

Figure 8.10: Any point can be the point of perspectivity in a Desarguesian configuration

Exercises 8.2. 1. In the proof of the second half of Desargues's Theorem, we have triangles in a single plane γ, perspective from a point O in γ. Then we let ℓ be a line not in γ, but through the point O. Why must such a line ℓ exist?

2. Make a sketch to illustrate the part of the proof of Desargues's Theorem that applies to triangles that lie in one plane.

3. Finish the proof of Desargues's Theorem.

4. Below we will learn that the Fano plane is Desarguesian. Identify two triangles perspective from a point in the Fano plane. Find the axis of perspectivity.

5. An assemblage of ten points and ten lines so that each line is incident to exactly three of the points and each point is incident to exactly three of the lines is a *Desarguesian configuration*. Verify that Fig. 8.9 depicts a Desarguesian configuration. Relabel the points in that figure so that the point of perspectivity is a point other than O. (See Fig. 8.10.) Similarly, any line can play the role of the axis of perspectivity. Relabel the points several different ways to illustrate this principle.

6. Referring to the previous exercise, does a given point of perspectivity uniquely determine the two triangles in perspective, if the choice is made in a Desarguesian configuration?

8.4 Harmonic Sequences

Desargues's Theorem is about triangles. In this section, we consider quadrangles, quadrilaterals, and associated arrangements of points and lines.

Let A, B, C, D be the vertices of a complete quadrangle, as prescribed by Definition 8.9. We designate this quadrangle simply as $ABCD$. The diagonal points of $ABCD$ are $AB \cap CD$, $AC \cap BD$, and $AD \cap BC$. If our projective plane is defined over a field of characteristic different from two, these diagonal points are noncollinear. (This is not obvious and we omit the proof. See [9], for example, where it is proved using an underlying vector space.) The triangle they determine is called the *diagonal triangle* of the quadrangle. A complete quadrilateral also has an associated diagonal triangle, which you can define using duality. (See the exercises.)

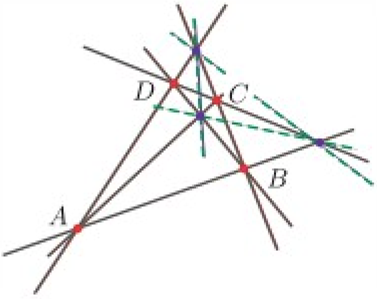

Figure 8.11: The quadrangle $ABCD$ with its diagonal points in blue and the sides of its diagonal triangle in green

Definition 8.14. A **harmonic sequence of points**, $H(P, Q; R, S)$, in a projective plane, is a set of four collinear points P, Q, R, S where P, Q are diagonal points of a quadrangle and R, S are on the sides of the quadrangle that pass through the third diagonal point. In this case, we say that S is the **harmonic conjugate** of R with respect to P and Q.

Dual to a harmonic sequence of points is a harmonic sequence of lines. When we dualize, we must remember that the dual of a quadrangle is a quadrilateral.

Definition 8.15. A **harmonic sequence of lines**, $H(p, q; r, s)$, in a projective plane, is a set of four concurrent lines p, q, r, s, where p, q are diagonal lines of a complete quadrilateral and r, s pass through the vertices of the third diagonal

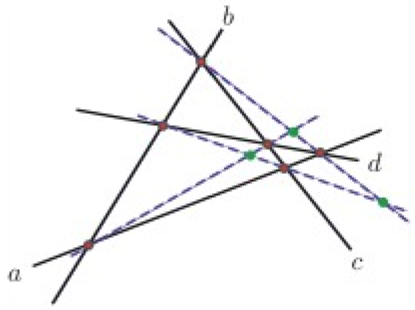

Figure 8.12: The quadrilateral *abcd* with its diagonal sides in blue, and vertices of the diagonal triangle in green

side of the quadrilateral. In this case, we say that s is the **harmonic conjugate** of r with respect to p and q.

The ordering of the points or lines in a harmonic sequence matters. While $H(P,Q;R,S)$ means $H(Q,P;S,R)$, it does not mean $H(P,R;Q,S)$, for instance.

The line determined by two of the diagonal points of a quadrangle must intersect the two sides of the third diagonal point in our projective planes. Consequently there is a harmonic sequence associated to any quadrangle. Indeed, a harmonic sequence of points is a *section* of the quadrangle: Every side of the figure intersects the line in one point.

Constructing a Harmonic Conjugate

We start our study by constructing a harmonic conjugate of a point. Our approach here closely follows [9].

Suppose P, Q, R are distinct points on a line ℓ in a projective plane. Choose C not on ℓ and $B \in QC$, B different from Q and C, as in Fig. 8.13. Form RB

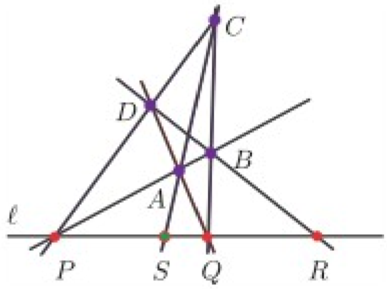

Figure 8.13: Construct the harmonic conjugate of R with respect to P and Q

and PC. Let D be their point of intersection. Next form PB and QD. Let A be their point of intersection. Form AC and let $S = AC \cap \ell$. We leave it as an exercise to verify that $ABCD$ forms a quadrangle and that S is a harmonic conjugate to R.

Our first theorem on the topic establishes that the harmonic conjugate of a point is unique.

Theorem 8.16. Given distinct points P, Q, R on a line ℓ in a projective plane, there is a unique point S on ℓ so that $H(P, Q; R, S)$.

Proof. Let P, Q, R be on ℓ in a projective plane. We have established that there is S so that $H(P, Q; R, S)$. Referring to the construction above, suppose $A'B'C'D'$ is a second quadrangle that produces a point S' so that $H(P, Q; R, S')$. We have $AC \cap \ell = S$ and $A'C' \cap \ell = S'$. Notice that $S' = S$ if and only if $AC \cap A'C'$ is on ℓ. (See Fig. 8.14.) We prove that $AC \cap A'C' \in \ell$ using Desargues's Theorem three times. First notice that ΔBCD and $\Delta B'C'D'$ are perspective from ℓ, thus, BB', CC', and DD' are concurrent. (In Fig. 8.14 they appear to be parallel, so we can think of them as projectively concurrent.) Similarly, ΔABD and $\Delta A'B'D'$ are perspective from ℓ, so AA', BB', DD' are concurrent. From there we have AA', BB', CC' concurrent so that ΔABC and $\Delta A'B'C'$ are perspective from a point, thus, $AB \cap A'B' = P$, $BC \cap B'C' = Q$, and $AC \cap A'C' = S = S'$ are collinear, as desired. □

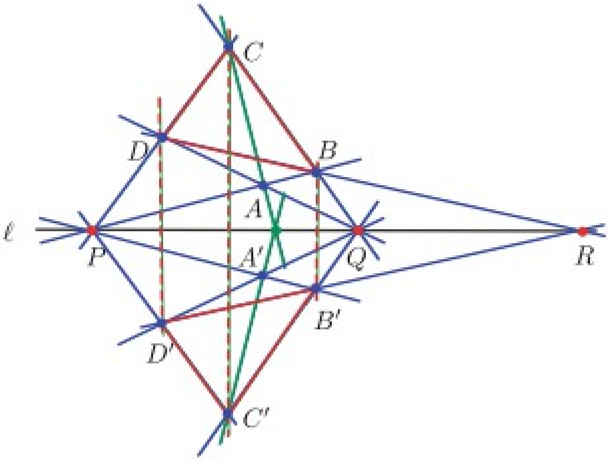

Figure 8.14: Since ΔBCD and $\Delta B'C'D'$ are perspective from ℓ, the lines BB', CC', DD' must be concurrent

The principle of duality in a projective plane allows us to make the following statement without proof.

Theorem 8.17. If p, q, r are concurrent lines in a projective plane, then among the lines in the pencil at the point of concurrency, there is a unique line s so that $H(p, q; r, s)$.

Theorem 8.18. If a line ℓ meets concurrent lines p, q, r, s in the points P, Q, R, S in a projective plane, then $H(P, Q; R, S)$ if and only if $H(p, q; r, s)$.

Proof. Suppose p, q, r, s are lines concurrent at C. Let ℓ meet lines p, q, r, s in points P, Q, R, S, respectively so that $H(P, Q; R, S)$. Using C, we can form S from P, Q, R. In the process, we construct a quadrangle $ABCD$ so that pairs of opposite sides—AB, CD; and AD, BC—intersect in P and Q, and diagonals—AC and BD—intersect PQ at R and S, respectively. We have $P = AB \cap CD$, $Q = AD \cap BC$, $R = BD \cap PQ$, and $S = AC \cap PQ$.

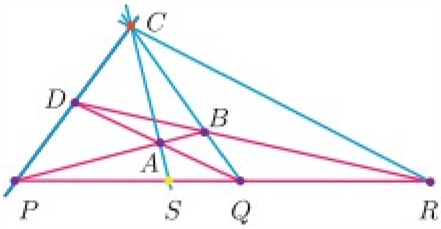

Figure 8.15: C is the point of concurrency of diagonal lines associated to the quadrilateral with pink sides

If we are to view p, q, r, s themselves so that $H(p, q; r, s)$, we need to see p, q as diagonals in a complete quadrilateral, and r, s as passing through the distinct vertices on the third diagonal side of the quadrilateral.

Consider the quadrilateral $\mathcal{Q}$ with sides $PB = PA$, $QD = QA$, $PQ = PR$, $BD = BR$, and vertices B, D, P, Q, A, R. Here $\{P, D\}$, $\{B, Q\}$, and $\{A, R\}$ are opposite vertex pairs. It follows that $PD = PC = p$ and $BQ = QC = q$ are diagonals for $\mathcal{Q}$ and that $r = RC$ and $s = AC$ satisfy $H(p, q; r, s)$.

The converse follows by duality. ☐

Exercises 8.3. 1. How many sides go through each vertex of a complete quadrangle in a projective plane? How many sides go through each diagonal point?

2. Use duality to define the diagonal triangle of a complete quadrilateral in a projective plane.

3. In Fig. 8.16 you can see Fig. 8.11 purely as a configuration. Likewise, Fig. 8.17 shows Fig. 8.12 purely as a configuration. Describe these configurations by specifying the number of points, the number of lines, and the incidences enjoyed by each point and each line. Are the two the same type of configuration? Are they dual? (See Exercise 8.2.5.)

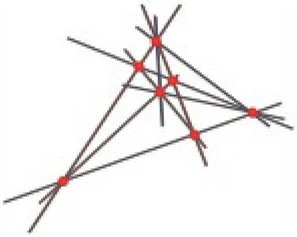

Figure 8.16: The configuration associated to a complete quadrangle and its diagonal triangle

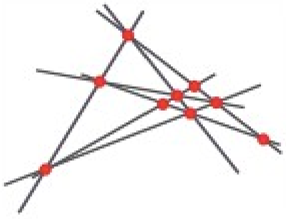

Figure 8.17: The configuration associated to a complete quadrilateral and its diagonal triangle

4. Verify that the line determined by the diagonal points of a quadrangle in a projective plane is a section of the quadrangle.

5. Verify that the construction we described as in Fig. 8.13 does in fact yield a complete quadrangle, $ABCD$, for which $H(P,Q;R,S)$.

8.5 Transformations and Pappus's Theorem

There are several different ways to approach projective geometry. We could have approached it strictly from the transformational point of view in which we identify the objects left invariant under certain transformations, declare those to be the objects of interest, and study the features of those objects that the transformations respect. This is Erlangen geometry. Our point of view is less algebraic, but from any point of view, the notions of perspectivity and projectivity are fundamental. As promised, these will lead us to Pappus's Theorem.

Our context here is a projective plane, $\mathbb{FP}^2$.

Definition 8.19. Let ℓ and ℓ' be lines in $\mathbb{FP}^2$. A **perspectivity** is a mapping from ℓ to ℓ' so that every line joining a point on ℓ to its image on ℓ' passes through a fixed point P, called the **center** of the perspectivity.

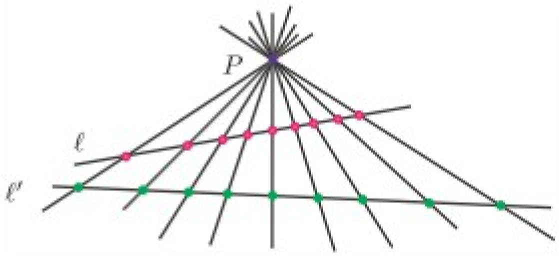

Figure 8.18: A perspectivity with center P

A perspectivity is its own inverse: In Fig. 8.18, we can view the mapping as going from ℓ to ℓ' or from ℓ' to ℓ. As long as ℓ and ℓ' are different lines, the center of a perspectivity is unique. We leave the verification of that statement as an easy exercise.

Definition 8.20. A **projectivity** or **projective transformation** is the composition of a finite number of perspectivities.

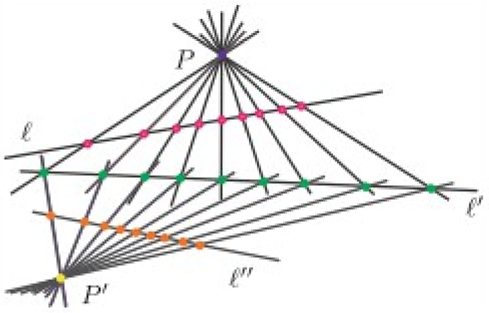

Figure 8.19: A projectivity from ℓ to ℓ'' (or from ℓ'' to ℓ) composed of two perspectivities, one through P, the second through P'

Since a perspectivity is its own inverse, a projectivity is also invertible: If $T = T_1 \cdots T_n$ is a product of perspectivities, then $T^{-1} = T_n \cdots T_1$.

If $A, B, C, \ldots$ are collinear points that are mapped to $A', B', C', \ldots$ respectively under a projectivity T, we write $T(A, B, C, \ldots) = (A', B', C', \ldots)$.

Theorem 8.21. Projectivities map harmonic sequences of points to harmonic sequences of points in a projective plane.

Proof. It is enough to argue that a single perspectivity sends a harmonic sequence of points in a projective plane to another harmonic sequence of points.

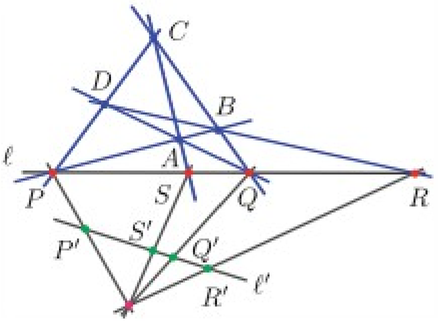

Figure 8.20: A perspectivity maps a harmonic sequence of points to a harmonic sequence of points

Suppose T is a perspectivity and $H(P,Q;R,S)$ where $\ell = PQ$. Referring to Fig. 8.20, we see this is the scenario addressed by Theorem 8.18: The line ℓ meets the concurrent lines PP', QQ', RR', SS' in the points P,Q,R,S with $H(P,Q;R,S)$ so $H(PP',QQ';RR',SS')$. By the same theorem, we also have $H(P',Q';R',S')$. □

As noted in [9], the content of the theorem suggests that there is no guarantee of the existence of a perspectivity that will map four arbitrary collinear points to another specified set of four collinear points. We can certainly map a given pair of points to any pair on another line via a perspectivity so pairs of points can be made to correspond using projective transformations, but not arbitrary quadruples. The next theorem answers the question about triplets.

Theorem 8.22 (Fundamental Theorem of Projective Geometry). Any set of three collinear points in a projective plane can be mapped to any other set of three collinear points in that plane by means of a unique projective transformation.

Sketch of proof. As in [9], we sketch the proof. First we argue for existence, then we address uniqueness. Let A,B,C and A',B',C' be arbitrary triples of collinear points in $\mathbb{FP}^2$.

Define $B'' = AB' \cap A'B$, $C'' = AC' \cap A'C$, and $A'' = AA' \cap B''C''$. If T_1 is the perspectivity through A', then $T_1(A,B,C) = (A'',B'',C'')$. Taking T_2 to be the perspectivity through A, we then have $T_2(A'',B'',C'') = (A',B',C')$. (See Fig. 8.21.) This gives us $T(A,B,C) = (A',B',C')$, where $T = T_2 \circ T_1$. The difficult part of the proof is arguing that T is unique, in other words, that knowing $T(A,B,C)$ is enough to know $X' = T(X)$ for any $X \in AB$. The approach is to argue that we can describe a given point on ℓ, or get arbitrarily close to a given point on ℓ, by means of harmonic sequences.

Theorem 8.16 implies there is unique D^* on ℓ so that $H(A,B;C,D^*)$. By Theorem 8.21, $H(A',B';C',D^{*\prime})$ where $T(D^*) = D^{*\prime}$. If $X = D^*$, we are done.

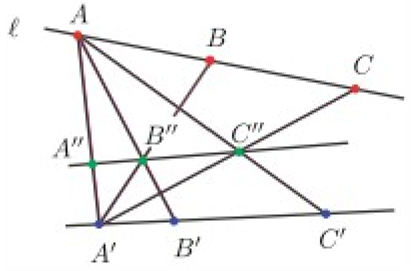

Figure 8.21: There is a projectivity relating any two sets of three collinear points

If not, repeat, noting there is unique E^* so that $H(B, C; D^*, E^*)$, and if $X \neq E^*$, there is unique F^* so that $H(C, D^*; E^*, F^*)$, etc. Depending on the nature of the underlying field—for example, whether it is $\mathbb{R}$ or $\mathbb{C}$ or finite—we either use up all the points on ℓ this way, eventually accounting for X as a member of a harmonic sequence, or we get arbitrarily close to X using harmonic sequences. Since each harmonic sequence of points is mapped to a well-defined harmonic sequence of points under T, this means $T(X)$ is determined by $T(A, B, C)$ as desired. $\square$

Corollary 8.23. Let ℓ and ℓ' be distinct lines in $\mathbb{FP}^2$. A projectivity from ℓ to ℓ' that leaves a point on ℓ fixed is a perspectivity.

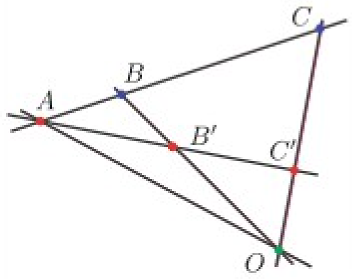

Figure 8.22: A nonidentity projectivity leaving one point fixed is a perspectivity

Proof. Let T be a projectivity with $T(A, B, C) = (A, B', C')$ for A, B, C collinear in some projective plane. Say $\ell = AB$ and $\ell' = AB'$ where $\ell \neq \ell'$. Let $O = BB' \cap CC'$. Then the perspectivity with center O is identical to T at A, B, C so by the theorem, that perspectivity must be T. $\square$

Ironically, we conclude this section with the first theorem of projective geometry, Pappus's Theorem.

Theorem 8.24 (Pappus's Theorem). Suppose A, B, C, A', B', C' are points in a projective plane so that A, B, C are collinear, and A', B', C' are collinear. Then the points $AB' \cap A'B$, $AC' \cap A'C$, $BC' \cap B'C$ are collinear.

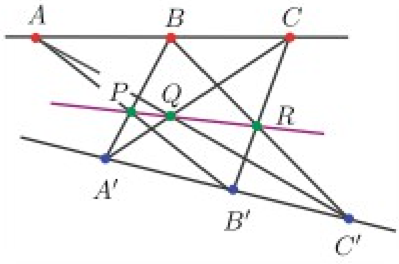

Figure 8.23: Pappus's Theorem says the green points are collinear

Proof. Let $P = AB' \cap A'B$, $Q = AC' \cap A'C$, $R = BC' \cap B'C$. We identify some additional points for the proof. Let $D = PQ \cap AC$, $E = AB' \cap A'C$, and $F = AC' \cap A'B$. Let T be the perspectivity from AB' to AC' with center A'. Then $T(A, P, E, B') = (A, F, Q, C')$. Let S be the perspectivity from AC' to PQ with center B, so that $S(A, F, Q, C') = (D, P, Q, R')$, where $R' = PQ \cap BC'$. We want to show that $R' = R$.

Composing the two perspectivities, we get the projectivity

$$(S \circ T)(A, P, E, B') = (D, P, Q, R').$$

By Corollary 8.23, $S \circ T$ is a perspectivity. Since AD and EQ meet at C, C is the center of the perspectivity and $R' = PQ \cap B'C$, implying $R' = R$, as desired. □

Exercises 8.4. 1. Show that the center of a perspectivity in a projective plane is unique.

2. Describe how to map a given pair of points in a projective plane to any pair of points on another line via a perspectivity.

3. If $T = T_1 T_2 \cdots T_n$ is a projectivity of a projective plane, with T_i a perspectivity, show that $T^{-1} = T_n \cdots T_2 T_1$.

4. Describe how to map a given pair of points in a projective plane to any other specified pair on the same line using a projectivity.

5. What is the dual of Pappus's Theorem?

6. Can you rearrange the labels A, B, C on one line and/or A', B', C' on the other line in Fig. 8.23 so that the line PQ changes? Keep the designation $P = AB' \cap A'B$, etc.

8.6 Homogeneous Coordinates

We return now to the idea that the projective planes we are studying here are those that arise from vector spaces. This time we take a slightly different point of view from the one we assumed when we first defined projective space as affine space with ideal points appended.

Let V be a three-dimensional vector space over $\mathbb{F}$ so $V \cong \mathbb{F}^3$. We use V itself to realize a projective plane over $\mathbb{F}$. In the process, we get an introduction to homogeneous coordinates. Again, remember that this cannot be done for every projective plane, just the ones based on fields. Note further that to realize a projective plane—a two-dimensional setting—we use a three-dimensional vector space.

A one-dimensional subspace of V is the span of any nonzero vector in V. In $\mathbb{R}^3$, a one-dimensional subspace looks like a line through the origin. In $\mathbb{F}_2^3$, it looks like a set of discrete points but we still refer to it as a line through the origin. **Projective points** in this model are lines through the origin in V. **Projective lines** in this model are two-dimensional subspaces of V, that is, the planes through the origin. **Incidence** is nonempty intersection. Before anything else, we establish that this model satisfies the axioms for a projective plane.

Theorem 8.25. The projective points and lines associated to $V \cong \mathbb{R}^3$ satisfy the axioms for a projective plane.

Proof. Axiom PP1 says two projective points determine a unique projective line. In our model, let $P = \operatorname{span}\{\mathbf{v}\}$ and $Q = \operatorname{span}\{\mathbf{w}\}$ be our two projective points. Here $\{\mathbf{v}, \mathbf{w}\}$ is a linearly independent set in V. P and Q determine the projective line $\ell = \operatorname{span}\{\mathbf{v}, \mathbf{w}\}$. Since the plane in V that contains $\mathbf{v}$ and $\mathbf{w}$ is unique, so is ℓ. This proves Axiom PP1.

Next, consider two projective lines $\ell = \operatorname{span}\{\mathbf{v}, \mathbf{w}\}$, and $m = \operatorname{span}\{\mathbf{u}, \mathbf{x}\}$, each modeled on a two-dimensional subspace of V. Since $\dim V = 3$, $\{\mathbf{v}, \mathbf{w}, \mathbf{u}, \mathbf{x}\}$ is linearly dependent. We assume ℓ and m are distinct, implying that

$$\dim \operatorname{span}\{\mathbf{v}, \mathbf{w}, \mathbf{u}, \mathbf{x}\} = 3.$$

There is thus a one-dimensional subspace common to $\operatorname{span}\{\mathbf{v}, \mathbf{w}\}$ and $\operatorname{span}\{\mathbf{u}, \mathbf{x}\}$. This one-dimensional subspace of V, a line through the origin, models a unique projective point, P, the point of intersection of ℓ and m. This shows that Axiom PP2 holds.

Next, let $P_1 = \operatorname{span}\{(1,0,0)\}$, $P_2 = \operatorname{span}\{(0,1,0)\}$, $P_3 = \operatorname{span}\{(0,0,1)\}$, and $P_4 = \operatorname{span}\{(1,1,1)\}$. Take any pair of these, for example P_1, P_2. These determine a unique projective line $\ell = \operatorname{span}\{(1,0,0),(0,1,0)\}$. Notice that neither P_3 nor P_4 lies on $\ell = \{(a, b, 0) | \, a, b \in \mathbb{R}\}$. The other two cases are easy to check, allowing us to conclude that our model contains four points, no three of which of are collinear. This verifies Axiom PP3. $\square$

Next we coordinatize our model.

Define $\sim$ on nonzero $\mathbf{v}, \mathbf{w} \in \mathbb{F}^3$ by $\mathbf{v} \sim \mathbf{w}$ provided $\mathbf{v} = c\mathbf{w}$ for some $c \in \mathbb{F}$. We leave it as an exercise to check that $\sim$ is an equivalence relation on $\mathbb{F}^3 \setminus \mathbf{0}$.

Designate the equivalence class containing $\mathbf{v} = (a, b, c) \neq \mathbf{0}$ by $[\mathbf{v}] = [a, b, c]$. Each equivalence class corresponds to a unique projective point in our model. Each point in the model now has coordinates $[a, b, c]$, where not all a, b, c are zero.

Definition 8.26. The **homogeneous coordinates** for a point $P \in \mathbb{FP}^2$ determined by the span of a nonzero vector $\mathbf{v} = (a, b, c) \in \mathbb{F}^3$ is the equivalence class $[a, b, c] = \{t(a, b, c) \,|\, t \neq 0\}$.

If P is a projective point with $P = [a, b, c]$, at least one of the numbers a, b, c must be nonzero. There is thus always a representative of P that has one coordinate equal to 1.

It is instructive to reconcile this model of $\mathbb{FP}^2$ with the first model we had, where we appended ideal points to $\mathbb{FA}^2$. Because our experience is mostly with $\mathbb{R}^3$, we can use that to flesh out the connection between the two. This is purely for the convenience of familiarity. Nothing we say here depends on properties of $\mathbb{R}$ as the field of scalars.

Consider the pencil of lines through $\mathbf{0}$ in $\mathbb{R}^3$. This pencil corresponds to the set of projective points in our model. An arbitrary line in the pencil has the form $\ell = \operatorname{span}\{(a, b, c)\}$, where $(a, b, c) \neq (0, 0, 0)$. If $c \neq 0$, $1/c$ is defined in $\mathbb{R}$ and we have the point $(a/c, b/c, 1)$ on ℓ. In other words, ℓ intersects the plane $z = 1$ at $(a/c, b/c, 1)$. In the usual coordinate system for $\mathbb{R}^3$, the plane $z = 1$ is one unit above, and parallel to, the xy-plane.

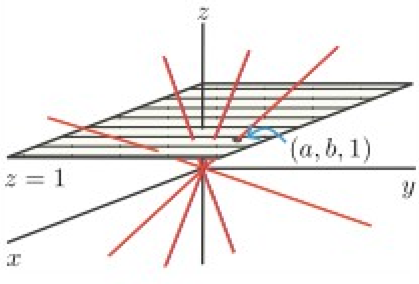

Figure 8.24: In the lines-through-the-origin model of $\mathbb{RP}^2$, the lines with homogeneous coordinates $[a, b, 1]$ correspond to affine points, and those with homogeneous coordinates $[a, b, 0]$ correspond to points at infinity

Any line ℓ in the pencil that does not intersect the plane $z = 1$ must be the span of a vector with the form $(a, b, 0)$. In other words, ℓ lies in the xy-plane. We thus have two kinds of lines in the pencil: those that intersect the plane $z = 1$, and those that lie in the xy-plane.

The projective points associated to the lines that intersect the plane $z = 1$ have homogeneous coordinates $[a, b, 1]$. The projective points associated to the lines in the xy-plane have homogeneous coordinates $[a, b, 0]$. Since $z = 1$ is a copy of $\mathbb{RA}^2$, we can identify the projective points having homogeneous coordinates $[a, b, 1]$ with the points of $\mathbb{RA}^2$, that is, the ordinary points of $\mathbb{RP}^2$. We then identify the projective points having homogeneous coordinates $[a, b, 0]$ with the ideal points appended to $\mathbb{RA}^2$.

There is yet another related model for $\mathbb{RP}^2$. Think about the pencil of lines through $\mathbf{0}$ in $\mathbb{R}^3$, this time in its relationship to the unit sphere in $\mathbb{R}^3$, also called the **unit 2-sphere**:

$$S^2 = \{(x, y, z) \in \mathbb{R}^3 \mid x^2 + y^2 + z^2 = 1\}.$$

Each line intersects the surface of S^2 in exactly two Euclidean points. Those two points are called **antipodal points** on S^2. A pair of antipodal points on S^2 determines the single projective point that the line represents. In this S^2-based model of $\mathbb{RP}^2$, projective lines are based on the great circles on the sphere—that is, circles centered at $\mathbf{0}$. A projective line, then, is the set of antipodal point pairs on a great circle on S^2. Since any plane through $\mathbf{0}$ in $\mathbb{R}^3$ intersects S^2 in a great circle, and any great circle on S^2 determines a plane through $\mathbf{0}$, we have a neat correspondence between the elements in one model and the elements in the other model.

Antipodal point pairs on S^2 give us a good model for thinking about the physical nature of $\mathbb{RP}^2$, that is, what it would be like to live in $\mathbb{RP}^2$. Consider

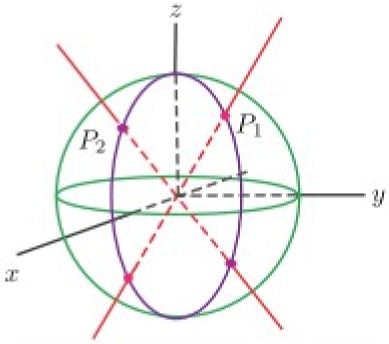

Figure 8.25: In the S^2-based model for $\mathbb{RP}^2$, a projective point is realized as an antipodal point pair on the sphere. A projective line is realized as the antipodal point pairs on a great circle.

a point P on S^2 and say P' is its antipodal point. If we move along any great circle through P, we must eventually arrive at P'. In $\mathbb{RP}^2$, then, if move along a line through a point, we meet back up again with that point. This suggests that if light travels in a line, then in a projective plane, observers who could see far enough would actually be looking at the backs of their own heads.

Finally, we employ homogeneous coordinates to do a calculation in $\mathbb{RP}^2$.

Example 8.27. Let $P = [1, 0, 0]$, $Q = [0, 1, 0]$, and $R = [1, 1, 0]$ in $\mathbb{RP}^2$. Notice that P, Q, R are collinear: This follows because the two-dimensional vector subspace of $\mathbb{R}^2$, $\alpha = \text{span}\{(1, 0, 0), (0, 1, 0)\}$ contains the one-dimensional subspace of $\mathbb{R}^2$, $\ell = \text{span}\{(1, 1, 0)\}$. We would like to find the harmonic conjugate of R with respect to P and Q.

Referring to the construction we carried out in Section 8.4, we choose a projective line through Q, different from PQ, and take two points on that line, different from Q. Let the projective line be modeled by the Euclidean plane

$$\beta = \text{span}\{(0, 1, 0), (0, 0, 1)\} = \{(0, a, b) |\ a, b, \in \mathbb{R}\}.$$

The projective points $B = [0, 1, 1]$ and $C = [0, 2, 1]$ are on that line and different from Q.

Let $D = PC \cap RB$. The projective line PC is determined by the Euclidean plane $\{(a, 2b, b) |\ a, b \in \mathbb{R}\}$. RB is determined by $\{(a, a + b, b) |\ a, b \in \mathbb{R}\}$. It follows that $D = [1, 2, 1]$. The projective line PB is represented by the Euclidean plane $\{(a, b, b) |\ a, b \in \mathbb{R}\}$, while QD is represented by $\{(a, b, a) |\ a, b \in \mathbb{R}\}$. The projective point $A = PB \cap QD$ is then $[1, 1, 1]$. We have AC represented by $\{(a, a + 2b, a + b) |\ a, b \in \mathbb{R}\}$ and PQ represented by $\{(a, b, 0) |\ a, b \in \mathbb{R}\}$. It follows that $S = AC \cap PQ$, the harmonic conjugate of R with respect to P and Q, is $[1, -1, 0]$.

Exercises 8.5.

1. Show that $\sim$ defined on $\mathbb{F}^3 \setminus \mathbf{0}$ by $\mathbf{v} \sim \mathbf{w}$ provided $\mathbf{v} = c\mathbf{w}$ for some $c \in \mathbb{F}$ is an equivalence relation.

2. If $V = \mathbb{R}^3$, the lines $\ell_1 = \text{span}\{(1, 0, 0)\}$ and $\ell_2 = \text{span}\{(0, 1, 0)\}$ determine what plane? What is the plane determined by lines ℓ_1 and $\ell_3 = \text{span}\{(0, 0, 1)\}$? What about the plane determined by lines ℓ_2 and ℓ_3? What is the plane determined by ℓ_1 and $\ell_4 = \text{span}\{(1, 1, 1)\}$? Describe it. How is it oriented in V?

3. Let $\alpha = \text{span}\{\mathbf{v}, \mathbf{w}\}$, and $\beta = \text{span}\{\mathbf{u}, \mathbf{x}\}$ be distinct planes in V where $\dim V = 3$. Detail the argument that $\{\mathbf{v}, \mathbf{w}, \mathbf{u}, \mathbf{x}\}$ is linearly dependent, thus that there is one-dimensional subspace in common to α and β. Use a dependence relation to describe the line of intersection of α and β.

4. Finish the proof of Theorem 8.25.

5. In Example 8.27, we note that if $C = [0, 2, 1]$ and $P = [1, 0, 0]$, then the projective line PC is determined by the Euclidean plane $\{(a, 2b, b) |\ a, b \in \mathbb{R}\}$. Verify that this is correct. Do the same for the rest of the Euclidean

planes in that example and verify that the intersection points, given in homogeneous coordinates, are correct. Note in particular the Euclidean plane underlying the projective line QD. Why can we say that plane contains any Euclidean point of the form (a, b, a)?

6. Rework Example 8.27 using different points B and C.
7. Rework Example 8.27 over $\mathbb{F}_2$ and again over $\mathbb{F}_3$.
8. Show that the Fano plane is a model for $\mathbb{F}_2\mathbb{P}^2$.
9. Use homogeneous coordinates to count the number of points in $\mathbb{F}_3\mathbb{P}^2$.

The Geometry of Submanifolds

Werner Ballmann

© Springer Basel 2018
W. Ballmann, *Introduction to Geometry and Topology*, Compact Textbooks in Mathematics,
https://doi.org/10.1007/978-3-0348-0983-2_4

In this chapter we will discuss the geometry of submanifolds of Euclidean spaces. We assume that the reader is familiar with the fundamentals of Euclidean geometry, that is, the geometry of $\mathbb{R}^m$ equipped with the Euclidean scalar product and the associated metric $d(p,q) = \|p-q\|$. A motion of $\mathbb{R}^m$ is a map $B\colon \mathbb{R}^m \longrightarrow \mathbb{R}^m$ of the form $B(x) = Sx + t$ for $S \in \mathrm{O}(m)$ and $t \in \mathbb{R}^m$. As a warm-up exercise, show that a map $\mathbb{R}^m \longrightarrow \mathbb{R}^m$ preserves distances if and only if it is a motion.

The geometry of submanifolds consists of two parts: interior and exterior geometry. Interior geometry relates to measurements within the submanifold, exterior geometry to the form of the submanifold relative to the surrounding Euclidean space. We will first briefly discuss these two aspects for curves in Euclidean spaces, for which interior geometry naturally consists only of measuring the lengths of curve segments. Afterwards, we will consider the interior geometry of submanifolds, then their exterior geometry, and conclude by proving the Theorema Egregium of Gauß.[1]

We are interested in *geometric properties and invariants* of submanifolds $M \subseteq \mathbb{R}^n$. These should not depend on the coordinates of M, and should not change if M is replaced by $B(M)$, where B is a motion of $\mathbb{R}^n$. The lengths of curves are examples of such invariants, but there are less obvious, deeper, properties and invariants.

Throughout, we identify the tangent space $T_x\mathbb{R}^n$ with $\mathbb{R}^n$ as in Example 2.2.3.1, and the tangent spaces of submanifolds $M \subseteq \mathbb{R}^n$ with linear subspaces of $\mathbb{R}^n$ as in Proposition 2.3.2.2. Compare with Example 2.2.3.2. More generally, we consider immersions $f\colon M \longrightarrow \mathbb{R}^n$ instead of submanifolds.

With the above identification of the tangent spaces, a *vector field along* f is, in this chapter, a map $X\colon M \longrightarrow \mathbb{R}^n$. We then imagine $X(p)$ as a vector with basepoint $f(p)$. We call such an f *tangential*, if $X(p) \in \operatorname{im} f_{*p}$ for all $p \in M$, that is, when there is a vector field Y on M with $X = df \circ Y$. For a smooth map φ from M to a vector space V, we also commonly write $X\varphi$ instead of $d\varphi \circ X$. Compare with (2.19).

---

[1] Johann Carl Friedrich Gauß (1777–1855).

4.1 Curves

We begin our investigations with curves in Euclidean spaces. If $c\colon I \longrightarrow \mathbb{R}^n$ is a smooth curve, we typically interpret the parameter $t \in I$ as time, and therefore call $\|\dot{c}\|$ the *speed* of c. We call c *regular*, if $\dot{c}(t) \neq 0$ for all $t \in I$. If c is regular, then the *field of directions* of c,

$$e\colon I \longrightarrow \mathbb{R}^3, \quad e(t) := \dot{c}(t)/\|\dot{c}(t)\|, \tag{4.1}$$

is a smooth vector field along c with constant norm 1. We will sometimes also refer to e as the *direction field* of c.

Example 4.1.1

As curves $c\colon \mathbb{R} \longrightarrow \mathbb{R}^2$,

1. $c(t) = (t, t^3)$ is regular,
2. $c(t) = (t^2, t^3)$ is not regular at $t = 0$ and its image has a crease at $(0, 0)$,
3. $c(t) = (t^3, t^3)$ is not regular at $t = 0$, although its image, a line, looks regular.

■

If $c\colon I \longrightarrow \mathbb{R}^n$ is a smooth curve and $\varphi\colon J \longrightarrow I$ is a diffeomorphism, then $\bar{c} = c \circ \varphi$ is regular if and only if c is regular. We refer to such a φ as a *change of parameters* and $\bar{c}$ as a *reparameterization* of c. More generally, we call $c \circ \varphi$ a *monotone reparameterization* of c, if $\varphi\colon [\alpha, \beta] \longrightarrow [a, b]$ is monotone, surjective, and smooth.

4.1.1 Length and Energy

Geometry in Euclidean spaces is based on length measurements. Let $c\colon [a, b] \longrightarrow \mathbb{R}^n$ be a smooth curve. Then

$$L(c) := \int_a^b \|\dot{c}(t)\|\, dt \quad \text{and} \quad E(c) = \frac{1}{2} \int_a^b \|\dot{c}(t)\|^2\, dt \tag{4.2}$$

are respectively called the *length* and *energy* of c. It follows from the Cauchy-Schwarz inequality[2] that

$$L^2(c) = \Big(\int_a^b 1 \cdot \|\dot{c}\| \Big)^2 \leq \Big(\int_a^b 1^2 \Big) \Big(\int_a^b \|\dot{c}\|^2 \Big) = 2(b - a) E(c), \tag{4.3}$$

and equality holds if and only if c has constant speed, that is, when the function $\|\dot{c}\|$ is constant. Clearly, the length and energy of curves are invariant under motions: If B is a motion of $\mathbb{R}^n$, then $L(B \circ c) = L(c)$ and $E(B \circ c) = E(c)$. The lengths of curves are, moreover, independent of the parameterization of the curve, see Exercise 4.6.1.1. Length is therefore a geometric invariant of curves in the sense described above.

---

[2] Hermann Amandus Schwarz (1843–1921).

We say that a smooth curve $c\colon I \longrightarrow \mathbb{R}^n$ is *parameterized by arc length*, if c has constant speed $\|\dot{c}(t)\| = 1$. Then c is regular, and the lengths of segments of c correspond to the lengths of the parameter intervals.

Proposition 4.1.2 *If $c\colon I \longrightarrow \mathbb{R}$ is a regular curve and $t_0 \in I$, there is a change of parameters $\varphi\colon J \longrightarrow I$ with $0 \in J$ such that $\varphi(0) = t_0$ and $c \circ \varphi$ is parameterized by arc length.*

Proof

Define $\psi\colon I \longrightarrow \mathbb{R}$ via $\psi(t) := \int_{t_0}^{t} \|\dot{c}\|$. Since c is regular, ψ is smooth with $\dot{\psi}(t) = \|\dot{c}(t)\| \neq 0$. Therefore ψ is a diffeomorphism on an interval $J \subseteq \mathbb{R}$ with $\psi(t_0) = 0$. The inverse map $\varphi\colon J \longrightarrow I$ is then the desired change of parameters. □

We now discuss a few elementary facts about length and energy. The arguments are chosen so that they may be used again in later extensions of these claims.

Proposition 4.1.3 *For $x, y \in \mathbb{R}^n$ and all smooth curves $c\colon [a, b] \longrightarrow \mathbb{R}^n$ from x to y, $L(c) \geq d(x, y)$. Equality holds if and only if c is a monotone reparameterization of the line $ty + (1 - t)x$, $0 \leq t \leq 1$, from x to y.*

Proof

We assume $x \neq y$ and set $v := (y - x)/\|y - x\|$, the unit vector pointing from x to y. Let $h : \mathbb{R}^n \longrightarrow \mathbb{R}$, $h(z) := \langle v, z\rangle$, be the height function associated to v. Then $\operatorname{grad} h = v$, and therefore

$$\begin{aligned} L(c) = \int_a^b \|\dot{c}\| \geq \int_a^b \langle v, \dot{c}\rangle = \int_a^b \langle \operatorname{grad} h, \dot{c}\rangle \\ = h(c(b)) - h(c(a)) = h(y) - h(x) = \|y - x\| = d(x, y). \end{aligned}$$

Equality implies that $\langle v, \dot{c}\rangle = \|\dot{c}\|$. □

Corollary 4.1.4 *For $x, y \in \mathbb{R}^n$,*

$$d(x, y) = \min\{L(c) \mid c \text{ is a smooth curve from } x \text{ to } y\},$$

and the minimum is realized precisely by the monotone reparameterizations of the line segment $ty + (1 - t)x$, $0 \leq t \leq 1$, from x to y. □

Energy possesses better analytic properties than length, it is *not* invariant under change of parameters, but rather prefers curves of constant speed:

Proposition 4.1.5 *Let $x, y \in \mathbb{R}^n$ and*

$$c_0\colon [a, b] \longrightarrow \mathbb{R}^n, \quad c_0(t) = \frac{1}{b - a}\big((t - a)y + (b - t)x\big),$$

be the line segment from x to y. Then for all smooth curves $c\colon [a,b] \longrightarrow \mathbb{R}^n$ from x to y, $E(c) \geq E(c_0)$, and equality implies $c = c_0$.

Proof

We assume $x \neq y$. With terminology as in Proposition 4.1.3 we then obtain

$$\begin{aligned}
2E(c) &= \int_a^b \|\dot{c}\|^2 \geq \int_a^b \langle v, \dot{c}\rangle^2 \\
&\geq \frac{1}{b-a}\Big(\int_a^b \langle v, \dot{c}\rangle\Big)^2 \\
&= \frac{1}{b-a}\big(h(y) - h(x)\big)^2 = 2E(c_0).
\end{aligned}$$

Equality implies that $\langle v, \dot{c}\rangle$ is constant and $\dot{c} = \langle v, \dot{c}\rangle v$. □

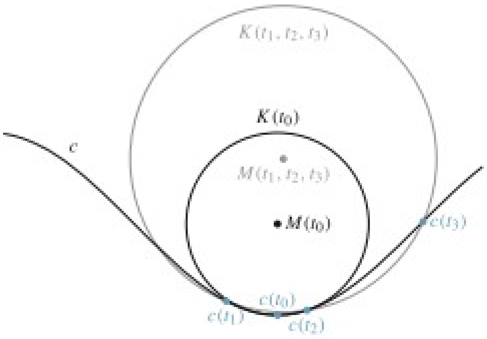
4.1.2 Curvature

While the derivative of a curve at a point is the best approximation of the curve by a line, we are now interested in approximations of second order. To this end, let $c\colon I \longrightarrow \mathbb{R}^n$ be a smooth curve and t_0 be a point in the interior of I such that $\dot{c}(t_0)$ and $\ddot{c}(t_0)$ are linearly independent.

Proposition 4.1.6 *For $t_1 < t_2 < t_3$ in I close enough to t_0, $c(t_1)$, $c(t_2)$ and $c(t_3)$ are not collinear. Moreover, for $t_1, t_2, t_3 \longrightarrow t_0$, the unique circle $K(t_1, t_2, t_3)$ through $c(t_1)$, $c(t_2)$, and $c(t_3)$ converges to a limit circle $K(t_0)$; see Fig. 4.1. This limit circle passes through $c(t_0)$, is tangent to c at $c(t_0)$, and lies in the affine plane $E(t_0)$ through $c(t_0)$ spanned by $\dot{c}(t_0)$ and $\ddot{c}(t_0)$. Its center $M = M(t_0) \in E(t_0)$ is determined by the following system of linear equations:*

$$\begin{aligned}
\langle M - c(t_0), \dot{c}(t_0)\rangle &= 0, \\
\langle M - c(t_0), \ddot{c}(t_0)\rangle &= \|\dot{c}(t_0)\|^2.
\end{aligned}$$

Fig. 4.1 Circles approximating a curve



Proof

The first claim follows easily from the second-order Taylor approximation[3] to c at t_0. We now denote by $M(t_1, t_2, t_3)$ the center of the circle $K(t_1, t_2, t_3)$. Then the function

$$f = f(t) := \|c(t) - M(t_1, t_2, t_3)\|^2$$

takes the same value at the points t_1, t_2, and t_3, namely, the square of the radius of $K(t_1, t_2, t_3)$. Its first derivative

$$2\langle c(t) - M(t_1, t_2, t_3), \dot{c}(t)\rangle$$

therefore has zeros at points $s_1 \in (t_1, t_2)$ and $s_2 \in (t_2, t_3)$, and so its second derivative

$$2\langle c(t) - M(t_1, t_2, t_3), \ddot{c}(t)\rangle + 2\|\dot{c}(t)\|^2$$

has a zero at a point $r \in (s_1, s_2)$. □

Definition 4.1.7

For c and t_0 as above, we call $E(t_0)$ the *osculating plane* and $K(t_0)$ the *osculating circle* of c at t_0. We call $M(t_0)$ the *center of curvature*, $R(t_0) = \|M - c(t_0)\|$ the *radius of curvature*, and $\kappa(t_0) = 1/R(t_0)$ the *curvature* of c at t_0.

In light of the first equation in Proposition 4.1.6, the second equation says that $R(t_0)$ times the norm of the component of $\ddot{c}(t_0)$ perpendicular to $\dot{c}(t_0)$ is equal to $\|\dot{c}(t_0)\|^2$. In other words,

$$\kappa(t_0) = \frac{\|\ddot{c}(t_0) - \langle e(t_0), \ddot{c}(t_0)\rangle e(t_0)\|}{\|\dot{c}(t_0)\|^2}, \tag{4.4}$$

where $e = \dot{c}/\|\dot{c}\|$ denotes the field of directions of c as in (4.1). We thereby obtain a second definition of the curvature $\kappa(t_0)$ of c at t_0, consistent with the first, that also applies when $\ddot{c}(t_0)$ is linearly dependent on $\dot{c}(t_0)$.

If c is parameterized by arc length, then $\langle \dot{c}, \dot{c}\rangle/2$ is by definition constant, and therefore has derivative $\langle \dot{c}, \ddot{c}\rangle = 0$. Then $\ddot{c}(t)$ is perpendicular to $\dot{c}(t)$ for all $t \in I$ and consequently

$$\kappa(t_0) = \|\ddot{c}(t_0)\|. \tag{4.5}$$

In Exercises 4.6.2 and 4.6.3 we will check that the curvature of curves is a geometric invariant, which adequately replicates our conception of curvature.

---

[3] Brook Taylor (1685–1731).

4.1.3 Plane Curves

We call curves $c\colon I \longrightarrow \mathbb{R}^2$ *plane curves*. If $c\colon I \longrightarrow \mathbb{R}^2$ is a regular plane curve, then there is exactly one vector field n along c perpendicular to the field of directions $e = \dot{c}/\|\dot{c}\|$ of c such that $(e(t), n(t))$ is a positively oriented basis of $\mathbb{R}^2$ for all $t \in I$, namely

$$n = (-e^2, e^1)$$

with $e = (e^1, e^2)$; see Fig. 4.2. We call $n = n(t)$ the *principal normal (vector) field* of c. This allows us to give a sign to the curvature of regular plane curves,

$$\kappa_o(t) := \frac{\langle n(t), \ddot{c}(t)\rangle}{\|\dot{c}(t)\|^2}. \tag{4.6}$$

We call κ_o the *oriented curvature* of c. We can rewrite the formula (4.6) as

$$\kappa_o(t) = \frac{\det(\dot{c}(t), \ddot{c}(t))}{\|\dot{c}(t)\|^3}. \tag{4.7}$$

If c is parameterized by arc length, we obtain

$$\kappa_o(t) = \langle n(t), \ddot{c}(t)\rangle = \det(\dot{c}(t), \ddot{c}(t)). \tag{4.8}$$

It is clear that, for the curvature defined in the preceding section, $\kappa = |\kappa_o|$.

Fig. 4.2 The vector fields e and n

Proposition 4.1.8 *For the field of directions e and the principal normal field n of a regular plane curve $c\colon I \longrightarrow \mathbb{R}^2$,*

$$\dot{e} = \|\dot{c}\|\kappa_o n \quad \textit{and} \quad \dot{n} = -\|\dot{c}\|\kappa_o e.$$

Proof
Since the functions $\langle e, e\rangle$ and $\langle n, n\rangle$ are constant, their derivatives vanish, so $\langle e, \dot{e}\rangle = \langle n, \dot{n}\rangle = 0$. Therefore $\dot{e}$ is a multiple of n and $\dot{n}$ is a multiple of e. Now $\|\dot{c}\|e = \dot{c}$, and therefore $\|\dot{c}\|\langle n, \dot{e}\rangle = \langle n, \ddot{c}\rangle = \|\dot{c}\|^2\kappa_o$. This proves the first equation. The function $\langle n, e\rangle$ is also constant, so $\langle \dot{n}, e\rangle = -\langle n, \dot{e}\rangle$. The second equation follows. □

With the aid of the differential equations from Proposition 4.1.8, we obtain further interpretations of the curvature: Let $c\colon I \longrightarrow \mathbb{R}^2$ be a regular plane curve, and $v \in \mathbb{R}^2$

be a fixed unit vector. Let $\alpha = \alpha(t) \in \mathbb{R}/2\pi\mathbb{Z}$ be the oriented angle from v to $e(t)$, that is $\cos\alpha = \langle v, e\rangle$ and $\sin\alpha = -\langle v, n\rangle$. With Proposition 4.1.8, it follows that

$$\dot\alpha \sin\alpha = -\langle v, \dot e\rangle = \|\dot c\|\kappa_o \sin\alpha,$$
$$\dot\alpha \cos\alpha = -\langle v, \dot n\rangle = \|\dot c\|\kappa_o \cos\alpha.$$

Therefore, we have

$$\dot\alpha = \|\dot c\|\,\kappa_o. \tag{4.9}$$

If $I = \mathbb{R}$ and c is periodic with period $\omega > 0$, then $e(\omega) = e(0)$, so $\alpha(\omega) = \alpha(0)$ modulo $2\pi\mathbb{Z}$ and therefore

$$\frac{1}{2\pi}\int_0^\omega \kappa_0(t)\|\dot c(t)\|\,dt = k \in \mathbb{Z}. \tag{4.10}$$

The number k is called the *winding number* of c (with respect to the given period ω). The winding number counts the number of times e circles the origin during one period. The *Winding Number Theorem* states that the winding number is ±1 if c is a Jordan curve, that is, the curve does not repeat points except when forced to by the period. See, for example, section 2.2 in [Kl].

A further interpretation of the curvature refers to the change in the length of c when we pass to parallel curves. To this end, let $I = [a, b]$ and

$$c_s \colon [a, b] \longrightarrow \mathbb{R}^2, \quad c_s(t) := c(t) + sn(t), \quad s \in \mathbb{R}, \tag{4.11}$$

be the family of *curves parallel to* $c = c_0$. Then by Proposition 4.1.8,

$$\dot c_s = \dot c - s\|\dot c\|\kappa_o e = (1 - s\kappa_o)\dot c.$$

Therefore the derivative δL of the length $L(c_s)$ as a function of s at $s = 0$ is given by

$$\delta L = -\int_a^b \kappa_o(t)\|\dot c(t)\|\,dt. \tag{4.12}$$

We can therefore interpret the oriented curvature as a measure of the change in length of a plane curve in the normal direction.

For a given speed and a given curvature, the equations from Proposition 4.1.8 are a linear system of ordinary differential equations for the fields e and n. In preparation for the next proposition, we write these equations in matrix form,

$$\dot F = FS \tag{4.13}$$

with

$$F := \begin{pmatrix} e^1 & n^1 \\ e^2 & n^2 \end{pmatrix} \quad \text{and} \quad S := \|\dot c\| \cdot \begin{pmatrix} 0 & -\kappa_o \\ \kappa_o & 0 \end{pmatrix}. \tag{4.14}$$

Here, the coefficients of F and S are functions of $t \in I$, and differentiating F means differentiating the coefficients of F. The important point in (4.13) is the skew-symmetry of S.

Proposition 4.1.9 *Let $T: I \longrightarrow (0, \infty)$ and $\kappa_o: I \longrightarrow \mathbb{R}$ be smooth functions. Then:*

1. *(Existence) For $t_0 \in I$ and $x_0, e_0 \in \mathbb{R}^2$ with $\|e_0\| = 1$, there is a regular plane curve $c: I \longrightarrow \mathbb{R}^2$ with $c(t_0) = x_0$ and $e(t_0) = e_0$ such that T is the speed of c and κ_o is the oriented curvature of c.*
2. *(Uniqueness) For every two regular plane curves $c_1, c_2: I \longrightarrow \mathbb{R}^2$ with speed T and oriented curvature κ_o, there is precisely one orientation-preserving motion B of $\mathbb{R}^2$ with $c_2 = B \circ c_1$.*

Proof

Let $F: I \longrightarrow \mathbb{R}^{2\times 2}$ be a solution of the linear ordinary differential equation (4.13) with $\|\dot{c}\|$ replaced by T and with $F(t_0) \in \mathrm{SO}(2)$. By the skew-symmetry of S,

$$\frac{d}{dt}(FF^*) = \dot{F}F^* + F\dot{F}^* = FSF^* + FS^*F^* = FSF^* - FSF^* = 0.$$

It therefore follows that $F(t)$ is in $\mathrm{O}(2)$ for all $t \in I$. However, F is a smooth function of t, and therefore so is $\det F$. Since $\det F(t) = \pm 1$ for all $t \in I$ and $\det F(t_0) = 1$, we must have $\det F(t) = 1$ for all $t \in I$. From this it follows that $F(t)$ is in $\mathrm{SO}(2)$ for all $t \in I$. We now choose the particular solution $F: I \longrightarrow \mathbb{R}^{2\times 2}$ with

$$F(t_0) = \begin{pmatrix} e_0^1 & -e_0^2 \\ e_0^2 & e_0^1 \end{pmatrix} \in \mathrm{SO}(2).$$

By what we have just proved, $F(t)$ is in $\mathrm{SO}(2)$ for all $t \in I$. Moreover, the first column e and the second column n of F satisfy the differential equations from Proposition 4.1.8 (with $\|\dot{c}\|$ replaced by T). Since $F(t) \in \mathrm{SO}(2)$, we then have that $(e(t), n(t))$ is a positively oriented basis of $\mathbb{R}^2$ for all $t \in I$. Therefore,

$$c = c(t) := x_0 + \int_{t_0}^{t} T \cdot e$$

is a smooth plane curve with field of directions e, principal normal field n, speed T, and oriented curvature κ_o. Claim 1 of the proposition follows from this.

Now let $c_1, c_2: I \longrightarrow \mathbb{R}^2$ be curves with speed T and oriented curvature κ_o. Let $B = Ax + a$ be the unique, orientation-preserving motion of $\mathbb{R}^2$ with

$$A(c_1(t_0)) + a = c_2(t_0), \quad A(e_1(t_0)) = e_2(t_0), \quad A(n_1(t_0)) = n_2(t_0),$$

where e_1, e_2, n_1 and n_2 denote the fields of directions and principal normal fields associated to c_1 and c_2. Then $B \circ c_1$ is a curve parameterized by arc length with direction field $A \circ e_1$, principal normal field $A \circ n_1$, and oriented curvature κ_o. Therefore, $A \circ e_1$ and $A \circ n_1$ are solutions to the equations of Proposition 4.1.8 with the same initial conditions as e_2 and n_2. It therefore follows that $A \circ e_1 = e_2$ and $A \circ n_1 = n_2$. Finally, since $A(c_1(t_0)) + a = c_2(t_0)$, it follows that $c_2 = B \circ c_1$. □

Remark 4.1.10 The Lie algebra of SO(2) (the tangent space at the identity matrix) consists of the skew-symmetric (2×2)-matrices, compare with Example 2.3.8.3. The matrix $S = S(t)$ in (4.13) is skew-symmetric, so $\mathrm{SO}(2) \ni B \mapsto BS(t)$ is a left-invariant vector field on SO(2) for all $t \in I$; see also Exercise 2.7.14.1. The solutions of the corresponding differential equations on SO(2) therefore lie in SO(2). The first part of the above proof shows this with elementary methods.

Corollary 4.1.11 *A regular plane curve moves counter-clockwise around a circle of radius $R > 0$ if and only if its oriented curvature is constant with value $1/R$.*

4.1.4 Space Curves

We now move to the next case, $n = 3$, that of *space curves*, i.e. curves in $\mathbb{R}^3$. Let $c\colon I \longrightarrow \mathbb{R}^3$ be a smooth space curve, such that $\dot{c}(t)$ and $\ddot{c}(t)$ are linearly independent for all $t \in I$. Then c is regular, and, in addition to the field of directions $e = \dot{c}/\|\dot{c}\|$, we obtain a second vector field along c,

$$n := \frac{\ddot{c} - \langle e, \ddot{c}\rangle e}{\|\ddot{c} - \langle e, \ddot{c}\rangle e\|}, \tag{4.15}$$

the *principal normal field* along c. Together with the *binormal field*

$$b = e \times n, \tag{4.16}$$

where × denotes the cross product, we obtain the *Frenet frame* $e, n, b\colon I \longrightarrow \mathbb{R}^3$ of c. The triple $(e(t), n(t), b(t))$ is a positively oriented orthonormal basis of $\mathbb{R}^3$ for all $t \in I$. The corresponding differential equations are called the *Frenet-Serret formulas*[4]:

$$\dot{e} = \|\dot{c}\|\kappa\, n, \quad \dot{n} = -\|\dot{c}\|\kappa\, e + \|\dot{c}\|\tau\, b, \quad \dot{b} = -\|\dot{c}\|\tau\, n. \tag{4.17}$$

Here, $\tau = \tau(t) := \langle \dot{n}(t), b(t)\rangle = -\langle n(t), \dot{b}(t)\rangle$ is called the *torsion* of c.

As in the case of plane curves, it is instructive and helpful to write the Frenet-Serret formulas in matrix form,

$$\dot{F} = FS \tag{4.18}$$

with

$$F := \begin{pmatrix} e^1 & n^1 & b^1 \\ e^2 & n^2 & b^2 \\ e^3 & n^3 & b^3 \end{pmatrix} \quad \text{and} \quad S := \|\dot{c}\| \cdot \begin{pmatrix} 0 & -\kappa & 0 \\ \kappa & 0 & -\tau \\ 0 & \tau & 0 \end{pmatrix}. \tag{4.19}$$

The skew-symmetry of S is again important. Using it, we obtain a theorem about space curves analogous to Proposition 4.1.9:

---

[4] Jean Frédéric Frenet (1816–1900), Joseph Alfred Serret (1819–1885).

Proposition 4.1.12 *Let* $T, \kappa : I \longrightarrow (0, \infty)$ *and* $\tau : I \longrightarrow \mathbb{R}$ *be smooth functions.*

1. *(Existence) For* $t_0 \in I$ *and* $x_0, e_0, n_0 \in \mathbb{R}^3$ *with* (e_0, n_0) *orthonormal, there is a regular space curve* $c : I \longrightarrow \mathbb{R}^3$ *with* $c(t_0) = x_0$, $e(t_0) = e_0$ *and* $n(t_0) = n_0$, *such that* T *is the speed of* c, κ *the curvature, and* τ *the torsion.*
2. *(Uniqueness) For every two regular space curves* $c_1, c_2 : I \longrightarrow \mathbb{R}^3$ *with speed* T, *curvature* κ, *and torsion* τ, *there is exactly one orientation-preserving motion* B *of* $\mathbb{R}^3$ *with* $c_2 = B \circ c_1$.

Proof

The proof is, *mutatis mutandis*, identical to the proof of Theorem 4.1.9: In some places, the numeral 2 is replaced by 3; the matrices F and S are now (3×3)-matrices as in (4.19), and the initial conditions read

$$F(t_0) := (e_0, n_0, e_0 \times n_0) \in \mathrm{SO}(3).$$

We leave reworking the details as an exercise. □

4.1.5 Parallelism from a New Perspective

We can only define the Frenet frame along a space curve c if $\dot{c}$ and $\ddot{c}$ are pointwise linearly independent. Moreover, the differential equations (4.17) of Frenet and Serret involve third derivatives of c. An analogous theory in arbitrary dimensions, in particular for curves in $\mathbb{R}^n$ with $n \geq 4$, involves the first n derivatives of the curve and requires that the first $n - 1$ thereof are pointwise linearly independent. Compare, for example, with sections 1.2 and 1.3 in [Kl]. This is rather a lot to ask when n is large.

To arrive at a new canonical class of vector fields along c, we bring another idea into play, that of curve-dependent parallelism. This is a central notion in modern differential geometry, that we first encounter here in a simple situation. To this end, let $c : I \longrightarrow \mathbb{R}^n$ be a regular curve.

Definition 4.1.13

We call a vector field $X : I \longrightarrow \mathbb{R}^n$ along c a *normal field*, if X is perpendicular to c, i.e., if $\langle \dot{c}(t), X(t) \rangle = 0$ for all $t \in I$. For a normal field X along c, we call the component of $\dot{X}$ normal to c the *covariant derivative* of X along c, written as $\nabla X/dt$ or X':

$$\frac{\nabla X}{dt} = X' := \dot{X} - \langle e, \dot{X} \rangle e.$$

We call a normal field X along c *parallel* if $X' = 0$.

If X is a normal field along c, then the function $\langle e, X\rangle$ vanishes identically, and therefore so does its derivative. We thereby obtain

$$\langle e, \dot{X}\rangle = -\langle \dot{e}, X\rangle. \tag{4.20}$$

The component $\langle e(t), \dot{X}(t)\rangle e(t)$ of $\dot{X}(t)$ tangent to c therefore only depends on the value of X at t. It moreover follows that, for given $t \in I$ and $v \in \mathbb{R}^n$ perpendicular to $e(t)$, the derivative of a normal field X along c with $X(t) = v$ has norm at least $|\langle \dot{e}(t), v\rangle|$, with equality holding if and only if $\dot{X}(t)$ is tangent to c. Parallel normal fields are, in this sense, the most parsimonious normal fields.

Proposition 4.1.14 *Let X and Y be normal fields along c. Then the following hold:*

1. *(Linearity) For $\alpha, \beta \in \mathbb{R}$, $(\alpha X + \beta Y)' = \alpha X' + \beta Y'$.*
2. *(Product rule) The function $\langle X, Y\rangle$ has derivative $\langle X', Y\rangle + \langle X, Y'\rangle$.*

Proof

Equation (1) is clear. To prove (2), we compute

$$\frac{d}{dt}\langle X, Y\rangle = \langle \dot{X}, Y\rangle + \langle X, \dot{Y}\rangle = \langle X', Y\rangle + \langle X, Y'\rangle,$$

where we use $\langle e, X\rangle = \langle e, Y\rangle = 0$ for the equality on the right. □

Corollary 4.1.15 *For parallel normal fields X and Y along c, the following hold:*

1. *Linear combinations $\alpha X + \beta Y$ are themselves parallel along c.*
2. *The function $\langle X, Y\rangle$ is constant.* □

Proposition 4.1.16 *For $t_0 \in I$ and $X_0 \in \mathbb{R}^n$ perpendicular to $\dot{c}(t_0)$, there is precisely one parallel normal field X along c with $X(t_0) = X_0$.*

Proof

By Definition 4.1.13 and (4.20), parallel normal fields X along c satisfy the linear ordinary differential equation

$$\dot{X} = -\frac{\langle \ddot{c}, X\rangle}{\|\dot{c}\|^2}\dot{c}. \tag{4.21}$$

Conversely, let $X : I \longrightarrow \mathbb{R}^n$ be the solution of (4.21) with $X(t_0) = X_0$. Scalar multiplication of the left- and right-hand sides of (4.21) by $\dot{c}$ shows that $\langle \dot{c}, X\rangle$ has vanishing derivative, and therefore is constant. Since $\langle \dot{c}(t_0), X(t_0)\rangle = 0$, we conclude from this that X is a normal field along c. In summation, then, it follows that a vector field X along c is a parallel normal field along c if and only if it is a solution of (4.21) and $X(t)$ is perpendicular to $\dot{c}(t)$ for some $t \in I$. □

Corollary 4.1.17 *Let $c \colon I \longrightarrow \mathbb{R}^n$ be a regular curve. For $t_0 \in I$ and orthonormal vectors $x_2, \ldots, x_n \in \mathbb{R}^n$ perpendicular to $\dot{c}(t_0)$, let $X_2, \ldots, X_n$ be the parallel normal fields along*

c with $X_i(t_0) = x_i$ for all $2 \le i \le n$. Then $(e(t), X_2(t), \dots, X_n(t))$ is an orthonormal basis of $\mathbb{R}^n$ for all $t \in I$. □

A parallel normal field along c does not generally consist of vectors that are parallel in the usual sense—if that were the case, the normal field would be constant. To determine the parallel normal fields along c, one must solve the differential equation (4.21).

Example 4.1.18

Let c be a space curve such that $\dot{c}$ and $\ddot{c}$ are pointwise linearly independent. The Frenet frame $(e, n, b = e \times n)$ is then easy to determine. Determining the parallel normal fields is more difficult. We can express the normal fields as linear combinations $X = \alpha n + \beta b$ with real functions α and β. With the aid of (4.17), the condition that X be parallel then translates to the differential equations

$$\dot{\alpha} = \|\dot{c}\|\tau\beta \quad \text{and} \quad \dot{\beta} = -\|\dot{c}\|\tau\alpha$$

for the coefficients. If the speed and torsion of c are constant, then this system of equations is easy to solve: If α solves the differential equation $\ddot{\alpha} + \|\dot{c}\|\tau\alpha = 0$, then the pair α and $\beta := \dot{\alpha}/\|\dot{c}\|\tau$ solves the system of differential equations above. ■

Proposition 4.1.19 *For smooth functions $T\colon I \longrightarrow (0, \infty)$ and $\kappa_2, \dots, \kappa_n\colon I \longrightarrow \mathbb{R}$, the following hold:*

1. *(Existence) For $t_0 \in I$ and $x_0, \dots, x_n \in \mathbb{R}^n$ with $(x_1, \dots, x_n)$ orthonormal, there exist a regular curve $c\colon I \longrightarrow \mathbb{R}^n$ with speed T and parallel normal fields $X_2, \dots, X_n$ along c with $c(t_0) = x_0$, $e(t_0) = x_1$, $X_i(t_0) = x_i$, and $\langle \dot{e}, X_i \rangle = \kappa_i T$ for all $2 \le i \le n$.*
2. *(Uniqueness) For every two regular curves $c_1, c_2\colon I \longrightarrow \mathbb{R}^n$ with speed T and parallel and pointwise orthonormal normal fields $X_2, \dots, X_n$ along c_1 and $Y_2, \dots, Y_n$ along c_2 with $\langle \dot{e}_1, X_i \rangle = \kappa_i T$ and $\langle \dot{e}_2, Y_i \rangle = \kappa_i T$, there is exactly one motion $B = Ax + a$ of $\mathbb{R}^n$ with $c_2 = B \circ c_1$ and $Y_i = A \circ X_i$ for all $2 \le i \le n$.*

Proof

We once again write the differential equations for e and $X_2, \dots, X_n$ in matrix form,

$$\dot{F} = FS \tag{4.22}$$

with

$$F := \begin{pmatrix} e^1 & X_2^1 & \dots & X_n^1 \\ \vdots & \vdots & & \vdots \\ e^n & X_2^n & \dots & X_n^n \end{pmatrix} \quad \text{and} \quad S := T \cdot \begin{pmatrix} 0 & -\kappa_2 & \dots & -\kappa_n \\ \kappa_2 & 0 & \dots & 0 \\ \vdots & \vdots & & \vdots \\ \kappa_n & 0 & \dots & 0 \end{pmatrix}. \tag{4.23}$$

The skew-symmetry of S is again important. The rest proceeds as before. □

Compare the matrices S from (4.19) and (4.23) and the corresponding systems of differential equations (4.18) and (4.22). This "small change" to the matrix S has a large effect, namely that we now have canonical normal fields along regular curves in Euclidean spaces regardless of the dimension of the space. Moreover, the differential equation (4.23) only involves second derivatives of c (and first derivatives of the X_i). We will end with this insight, and not delve any deeper, as we only introduced the concepts of covariant derivatives and parallelism along curves to give motivation for analogous concepts in our later discussions.

4.2 Interior Geometry

After our introductory remarks about curves, we now consider the general case of submanifolds in the Euclidean space $\mathbb{R}^n$. There are two ways these may be specified: firstly via equations, that is as level sets of mappings, or via embeddings or immersions $M \longrightarrow \mathbb{R}^n$. The second case includes the first, since we can think of a submanifold $M \subseteq \mathbb{R}^n$ with inclusion $i\colon M \longrightarrow \mathbb{R}^n$ as an embedding. Nevertheless, it is often worthwhile to give results separately for the first case, as their formulations are usually simpler and easier to grasp.

The interior geometry of submanifolds deals with measurements of geometric objects which are contained in the submanifold. The measuring stick is provided by the ambient space $\mathbb{R}^n$, namely, the Euclidean scalar product. In every other respect, however, the surrounding space is ignored, in some sense because the inhabitants of the submanifold are incapable of perceiving the space outside the submanifold.[5] In the preceding discussion of curves, their lengths are measurements belonging to their interior geometry, but their curvature is not.

In the following, we denote by M a manifold of dimension m, and by $f\colon M \longrightarrow \mathbb{R}^n$ an immersion. For $p \in M$, we call the linear subspaces

$$T_p f := \operatorname{im} df(p) \quad \text{and} \quad N_p f := [\operatorname{im} df(p)]^{\perp} \tag{4.24}$$

of $\mathbb{R}^n$ the *tangent space* and *normal space* to f at p. We denote by

$$\pi_p^T : \mathbb{R}^n \longrightarrow \mathbb{R}^n \quad \text{and} \quad \pi_p^N : \mathbb{R}^n \longrightarrow \mathbb{R}^n \tag{4.25}$$

the orthogonal projections from $\mathbb{R}^n$ to $T_p f$ and $N_p f$. If $M \subseteq \mathbb{R}^n$ is a submanifold with inclusion f, then $T_p f = T_p M$ under the usual identification of $T_p M$ as in Proposition 2.3.2. Therefore, we then write $T_p M$ and $N_p M$ instead of $T_p f$ and $N_p f$.

Example 4.2.1

1) For a regular curve $c\colon I \longrightarrow \mathbb{R}^n$, $T_t c = \mathbb{R} \cdot \dot{c}(t) = \mathbb{R} \cdot e(t)$. For regular plane curves c, $N_t c = \mathbb{R} \cdot n(t)$, for regular space curves c, $N_t c$ is the span of the principal normal $n(t)$ and the binormal $b(t)$.

---

[5] This perceptual difficulty is one of the topics of the novella *Flatland*, written by Edwin Abbott Abbott (1838–1926) and published in 1884.

Compare the matrices S from (4.19) and (4.23) and the corresponding systems of differential equations (4.18) and (4.22). This "small change" to the matrix S has a large effect, namely that we now have canonical normal fields along regular curves in Euclidean spaces regardless of the dimension of the space. Moreover, the differential equation (4.23) only involves second derivatives of c (and first derivatives of the X_i). We will end with this insight, and not delve any deeper, as we only introduced the concepts of covariant derivatives and parallelism along curves to give motivation for analogous concepts in our later discussions.

4.2 Interior Geometry

After our introductory remarks about curves, we now consider the general case of submanifolds in the Euclidean space $\mathbb{R}^n$. There are two ways these may be specified: firstly via equations, that is as level sets of mappings, or via embeddings or immersions $M \longrightarrow \mathbb{R}^n$. The second case includes the first, since we can think of a submanifold $M \subseteq \mathbb{R}^n$ with inclusion $i\colon M \longrightarrow \mathbb{R}^n$ as an embedding. Nevertheless, it is often worthwhile to give results separately for the first case, as their formulations are usually simpler and easier to grasp.

The interior geometry of submanifolds deals with measurements of geometric objects which are contained in the submanifold. The measuring stick is provided by the ambient space $\mathbb{R}^n$, namely, the Euclidean scalar product. In every other respect, however, the surrounding space is ignored, in some sense because the inhabitants of the submanifold are incapable of perceiving the space outside the submanifold.[5] In the preceding discussion of curves, their lengths are measurements belonging to their interior geometry, but their curvature is not.

In the following, we denote by M a manifold of dimension m, and by $f\colon M \longrightarrow \mathbb{R}^n$ an immersion. For $p \in M$, we call the linear subspaces

$$T_p f := \operatorname{im} df(p) \quad \text{and} \quad N_p f := [\operatorname{im} df(p)]^{\perp} \tag{4.24}$$

of $\mathbb{R}^n$ the *tangent space* and *normal space* to f at p. We denote by

$$\pi_p^T : \mathbb{R}^n \longrightarrow \mathbb{R}^n \quad \text{and} \quad \pi_p^N : \mathbb{R}^n \longrightarrow \mathbb{R}^n \tag{4.25}$$

the orthogonal projections from $\mathbb{R}^n$ to $T_p f$ and $N_p f$. If $M \subseteq \mathbb{R}^n$ is a submanifold with inclusion f, then $T_p f = T_p M$ under the usual identification of $T_p M$ as in Proposition 2.3.2. Therefore, we then write $T_p M$ and $N_p M$ instead of $T_p f$ and $N_p f$.

Example 4.2.1

1) For a regular curve $c\colon I \longrightarrow \mathbb{R}^n$, $T_t c = \mathbb{R} \cdot \dot{c}(t) = \mathbb{R} \cdot e(t)$. For regular plane curves c, $N_t c = \mathbb{R} \cdot n(t)$, for regular space curves c, $N_t c$ is the span of the principal normal $n(t)$ and the binormal $b(t)$.

---

[5] This perceptual difficulty is one of the topics of the novella *Flatland*, written by Edwin Abbott Abbott (1838–1926) and published in 1884.

2) The sphere $S_r^m = \{x \in \mathbb{R}^{m+1} \mid \|x\|^2 = r^2\}$ of radius $r > 0$ is a submanifold of $\mathbb{R}^{m+1}$ with $T_x S^m = \{y \in \mathbb{R}^{m+1} \mid \langle x, y\rangle = 0\}$ and $N_x M = \mathbb{R} \cdot x$ for all $x \in S_r^m$.

■

Let $X\colon M \longrightarrow \mathbb{R}^n$ be a vector field along f. Then for $p \in M$, we call

$$X^T(p) := \pi_p^T(X(p)) \quad \text{and} \quad X^N(p) = \pi_p^N(X(p)) \tag{4.26}$$

the *tangential* and *normal components* of X at p. We also write

$$X^T = \pi^T \circ X \quad \text{und} \quad X^N = \pi^N \circ X. \tag{4.27}$$

4.2.1 The First Fundamental Form

Measurements in M only depend on the restriction of the Euclidean scalar product of the ambient space $\mathbb{R}^n$ to the tangent spaces $T_p f$. The first fundamental form gets to the heart of this fact.

Definition 4.2.2

For p in M, we call the scalar product g_p on T_pM,

$$g_p(v, w) := \langle df(p)(v), df(p)(w)\rangle, \quad v, w \in T_pM,$$

the *first fundamental form* of f at p. We call the family of scalar products $g = (g_p)_{p\in M}$ the *first fundamental form* of f.

Instead of $g_p(v, w)$, we sometimes write $\langle v, w\rangle_p$ or $\langle v, w\rangle$, and similarly for the corresponding norms. These notations are particularly useful for submanifolds $M \subseteq \mathbb{R}^n$, as f is then the inclusion and $df(p)$ is the usual identification of T_pM with a linear subspace of $\mathbb{R}^n$.

We next clarify the regularity of the first fundamental form's dependence on the point p. To this end, let (U, x) be a chart on M. For all $p \in U$, the coordinate fields $\partial/\partial x^1(p), \ldots, \partial/\partial x^m(p)$ then form a basis T_pM. Since $df(p)(\partial/\partial x^i(p)) = (\partial f/\partial x^i)(p)$, the coefficients of the fundamental matrix of the first fundamental form with respect to this basis are given by

$$g_{ij}(p) := \Big\langle \frac{\partial}{\partial x^i}(p), \frac{\partial}{\partial x^j}(p)\Big\rangle_p = \Big\langle \frac{\partial f}{\partial x^i}(p), \frac{\partial f}{\partial x^j}(p)\Big\rangle. \tag{4.28}$$

Now the partial derivatives $\partial f/\partial x^i\colon U \longrightarrow \mathbb{R}^n$ are smooth, and therefore so are the functions $g_{ij}\colon U \longrightarrow \mathbb{R}$. Since the g_p are scalar products, the matrix of the g_{ij} is pointwise symmetric and positive definite.

Example 4.2.3

1) If $c : I \longrightarrow \mathbb{R}^n$ is a regular curve, then $g_{tt} = \|\dot{c}\|^2$.[6]
2) *Surfaces of revolution:* Let $c = (r, h) = (r(t), h(t))$, $t \in I$, be a regular curve in the (x, z)-plane with $r > 0$. We call c the *profile curve* of the *surface of revolution*

$$f : I \times \mathbb{R} \longrightarrow \mathbb{R}^3, \quad f(t, \varphi) := (r(t)\cos(\varphi), r(t)\sin(\varphi), h(t)).$$

A concrete example from this class is the torus considered in Exercise 2.7.8.1.
Based on the corresponding terms from geography, we call the curves $\varphi = \text{const}$ *meridians* or *longitudes*, and the curves $t = \text{const}$ *latitudes* of f. The partial derivatives of f are

$$\frac{\partial f}{\partial t} = (\dot{r}\cos(\varphi), \dot{r}\sin(\varphi), \dot{h}), \quad \frac{\partial f}{\partial \varphi} = (-r\sin(\varphi), r\cos(\varphi), 0).$$

Now $\partial f/\partial t$ and $\partial f/\partial \varphi$ are pointwise $\neq 0$ and perpendicular to one another, and are consequently pointwise linearly independent. Therefore, f is an immersion. For all $p \in M$, the vectors $(\partial f/\partial t)(p)$ and $(\partial f/\partial \varphi)(p)$ form a basis of $T_p f$, and their cross product is the generator of the line $N_p f$. The coefficients of the fundamental matrix of the first fundamental form are

$$g_{tt} = \langle \frac{\partial f}{\partial t}, \frac{\partial f}{\partial t} \rangle = \|\dot{c}\|^2, \quad g_{t\varphi} = g_{\varphi t} = \langle \frac{\partial f}{\partial t}, \frac{\partial f}{\partial \varphi} \rangle = 0, \quad g_{\varphi\varphi} = \langle \frac{\partial f}{\partial \varphi}, \frac{\partial f}{\partial \varphi} \rangle = r^2.$$

Therefore, the fundamental matrix

$$\begin{pmatrix} \|\dot{c}\|^2 & 0 \\ 0 & r^2 \end{pmatrix}$$

of the first fundamental form is diagonal. If c is parameterized by arc length, that is, has speed 1, then $g_{tt} = \|\dot{c}\|^2 = 1$.
3) *Generalized helicoids:* Let $a \neq 0$ be a constant and $c = c(t) = (x(t), y(t))$, $t \in I$, be a regular curve in the (x, y)-plane. We call c the *profile curve* of the *generalized helicoid*

$$f(t, \varphi) = (x(t)\cos\varphi - y(t)\sin\varphi, x(t)\sin\varphi + y(t)\cos\varphi, a\varphi).$$

A concrete example in this class is the *helicoid*, where $f(t, \varphi) = (t\cos\varphi, t\sin\varphi, a\varphi)$.
The partial derivatives of f are

$$\frac{\partial f}{\partial t} = (\dot{x}\cos\varphi - \dot{y}\sin\varphi, \dot{x}\sin\varphi + \dot{y}\cos\varphi, 0),$$
$$\frac{\partial f}{\partial \varphi} = (-x\sin\varphi - y\cos\varphi, x\cos\varphi - y\sin\varphi, a).$$

---

[6] Here and in other examples we use the variable names as indices.

These are pointwise linearly independent, since $\partial f/\partial t \neq 0$ and $a \neq 0$. The coefficients of the fundamental matrix of the first fundamental form are therefore

$$g_{tt} = \|\dot{c}\|^2, \quad g_{t\varphi} = g_{\varphi t} = x\dot{y} - \dot{x}y, \quad g_{\varphi\varphi} = \|c\|^2 + a^2.$$

These do not depend on the parameter φ.

4) *Ruled surfaces:* Let $c : I \longrightarrow \mathbb{R}^3$ be a regular space curve and $X : I \longrightarrow \mathbb{R}^3$ be a smooth vector field along c, such that $\dot{c}(t)$ and $X(t)$ are linearly independent for all $t \in I$. The associated *ruled surface* is then

$$f(s, t) = c(t) + sX(t).$$

A concrete example is the helicoid as above with $f(s, t) = (s \cos t, s \sin t, at)$.
Each line $t =$ const is called a *generator*, and each curve $s =$ const a *directrix* of f. The partial derivatives of f are

$$\frac{\partial f}{\partial s} = X \quad \text{and} \quad \frac{\partial f}{\partial t} = \dot{c} + s\dot{X}.$$

Therefore, there is a neighborhood U of $\{s = 0\}$ in $\mathbb{R} \times I$, such that f is an immersion on U. The coefficients of the first fundamental form are

$$g_{ss} = \|X\|^2, \quad g_{st} = g_{ts} = \langle X, \dot{c} + s\dot{X}\rangle, \quad g_{tt} = \langle \dot{c} + s\dot{X}, \dot{c} + s\dot{X}\rangle.$$

5) *Graphs:* Let $W \subset \mathbb{R}^m$ be open and $h : W \longrightarrow \mathbb{R}$ be smooth. Then $f : W \longrightarrow \mathbb{R}^{m+1}$, $f(x) := (x, h(x))$, is an embedding with $\partial f/\partial x^j = (e_j, \partial h/\partial x^j)$, where e_j denotes the j-th standard basis vector of $\mathbb{R}^m$. For each $p \in M$, the tangent space $T_p f$ is the span of the $(\partial f/\partial x^j)(p)$. The coefficients of the first fundamental form with respect to this basis are

$$g_{ij} = \left\langle \frac{\partial f}{\partial x^i}, \frac{\partial f}{\partial x^j} \right\rangle = \delta_{ij} + \frac{\partial h}{\partial x^i}\frac{\partial h}{\partial x^j}.$$

In the case $m = 2$ the normal spaces to f are generated by the $(\partial f/\partial x^1) \times (\partial f/\partial x^2)$.

■

Now let (U, x) again be a chart on M, and let X and Y be vector fields on U. We write X and Y as linear combinations

$$X = \xi^i \frac{\partial}{\partial x^i} \quad \text{and} \quad Y = \eta^i \frac{\partial}{\partial x^i}$$

of the coordinate vector fields. At every $p \in U$, then

$$\langle X(p), Y(p)\rangle = \langle \xi^i(p) \frac{\partial}{\partial x^i}(p), \eta^j(p) \frac{\partial}{\partial x^j}(p)\rangle = g_{ij}(p)\xi^i(p)\eta^j(p). \tag{4.29}$$

For ease of notation, we omit the p, and write (4.29) as an equality of functions,

$$\langle X, Y\rangle = g_{ij}\xi^i\eta^j. \tag{4.30}$$

Since the g_{ij} are smooth, we conclude that the function $\langle X, Y\rangle$ is smooth if X and Y are smooth. We also write

$$g = g_{ij}dx^i dx^j, \tag{4.31}$$

since $dx^i(X) = \xi^i$ and

$$dx^i dx^j(X, Y) := dx^i(X)dx^j(Y) = \xi^i\eta^j. \tag{4.32}$$

We will often need the inverse of the fundamental matrix (g_{ij}). In light of the Einstein summation convention, it is convenient to denote its coefficients by g^{ij}. Then, by definition,

$$g^{ij}g_{jk} = g_{kj}g^{ji} = \delta^i_k. \tag{4.33}$$

The formulas for the inverse matrix from linear algebra show that the g^{ij} are also smooth.

Lemma 4.2.4 *Let $p \in M$ and (U, x) be a chart on M around p. Let $w \in \mathbb{R}^n$ be a vector and $w = w^T + w^N$ be the decomposition of w into tangential and normal components with respect to the decomposition $\mathbb{R}^n = T_p f \oplus N_p f$ as in (4.24). Then there is exactly one tangent vector $v \in T_pM$ with $w^T = df(p)(v)$:*

$$v = \xi^j \frac{\partial}{\partial x^j}(p) \quad \textit{and} \quad w^T = \xi^j \frac{\partial f}{\partial x^j}(p) \quad \textit{with} \quad \xi^j = \langle w, \frac{\partial f}{\partial x^i}(p)\rangle g^{ij}(p).$$

In particular, the tangential and normal components of a smooth vector field along f are smooth.

Proof

The first claim is clear, since $df(p)$ is injective. Now write $w^T = \xi^j(\partial f/\partial x^j)(p)$. Then

$$\langle w, \frac{\partial f}{\partial x^i}(p)\rangle = \langle w^T, \frac{\partial f}{\partial x^i}(p)\rangle = \xi^k\langle\frac{\partial f}{\partial x^k}(p), \frac{\partial f}{\partial x^i}(p)\rangle = \xi^k g_{ki}(p).$$

From this it follows that

$$\xi^j = \xi^k g_{ki}(p)g^{ij}(p) = \langle w, \frac{\partial f}{\partial x^i}(p)\rangle g^{ij}(p). \qquad \square$$

Remark 4.2.5 In the case of a submanifold $M \subseteq \mathbb{R}^n$, the correspondence between the tangential component w^T of w and tangent vector v of M can be seen as the usual identification of the tangent spaces of M with linear subspaces of $\mathbb{R}^n$, and is, in this sense, trivial.

;. 5 86 $ * 3 *

4.2.2 The Internal Distance

The first fundamental form is defined so that, for all $p \in M$, $df(p)\colon T_pM \longrightarrow \mathbb{R}^n$ preserves norms. We define the length and energy of a piecewise smooth curve $c\colon [a,b] \longrightarrow M$ as before,

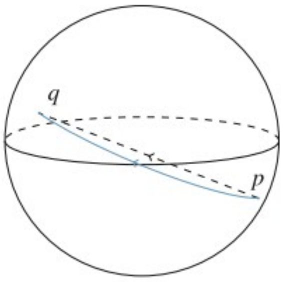
$$L(c) = \int_a^b \|\dot{c}(t)\|\,dt \quad \text{and} \quad E(c) = \frac{1}{2}\int_a^b \|\dot{c}(t)\|^2 dt. \tag{4.34}$$

Since $d(f \circ c)/dt = df \circ \dot{c}$, we then have $L(c) = L(f \circ c)$ and $E(c) = E(f \circ c)$.

In Corollary 4.1.4 we saw that the distance between points in Euclidean spaces is realized by the lengths of curves. By analogy, we arrive at the *internal metric* or *internal distance* d on M,

$$d(p,q) = \inf L(c), \qquad p, q \in M, \tag{4.35}$$

where the infimum is taken over all piecewise smooth curves c in M running from p to q. The external metric $\|f(p) - f(q)\|$, $p, q \in M$, therefore satisfies $\|f(p) - f(q)\| \leq d(p,q)$ (and is only a true metric if f is injective). The external metric usually requires the use of measurements outside of M (resp. the image of f), as the shortest curves between points in $\mathbb{R}^n$ are lines, which are not typically contained in M (resp. the image of f). See ◘ Fig. 4.3.



◘ **Fig. 4.3** The internal distance and the Euclidean distance between points on the unit sphere

Remark 4.2.6 We allow d to take the value ∞: $d(p,q) = \infty$ if and only if p and q lie in different connected components of M.

Proposition 4.2.7 *The internal metric on M is a metric on M, and it induces the topology of M.*

Proof

Let $p \in M$ and $x\colon U \longrightarrow U'$ be a chart on M around p with $x(p) = 0$. Choose $\varepsilon > 0$ such that the open Euclidean ball B' of radius ε around 0 is contained in U' and such that, for all $q \in x^{-1}(B')$ and $\xi \in \mathbb{R}^m$,

$$\varepsilon^2 \delta_{ij}\xi^i\xi^j \leq g_{ij}(q)\xi^i\xi^j \leq \varepsilon^{-2}\delta_{ij}\xi^i\xi^j.$$

Now, M is a Hausdorff space. Therefore, every continuous path from p to a point q outside of $B = x^{-1}(B')$ must first run through B to $x^{-1}(\partial B')$. Such a path segment has length $\geq \varepsilon^2$. It therefore follows $d(p, q) > 0$.

For the length of a piecewise smooth curve c in B,

$$\varepsilon L(c) \leq L_E(x \circ c) \leq L(c)/\varepsilon,$$

where $L_E(x \circ c)$ denotes the Euclidean distance of $x \circ c$. This estimate carries over to the distance from p to $q \in B$,

$$\varepsilon d(p, q) \leq \|x(p) - x(q)\| \leq d(p, q)/\varepsilon.$$

It therefore follows that $d(p, q) > 0$ whenever $p \neq q$. Since d is symmetric and satisfies the triangle inequality, it is a metric on M. The claim about the topology follows directly from our estimate of distances in B. □

Remark 4.2.8 Since, in general, f need not be injective, we advise caution in the above proof of the positivity of $d(p, q) > 0$.

Example 4.2.9

We use the argument from the proof of Proposition 4.1.3 to show that the internal distance $d(x, y)$ on the sphere S^m of radius 1 in $\mathbb{R}^{m+1}$ is given by the angle $\angle(x, y)$.

For a given $x \in S^m$, we choose $\varphi = \varphi(y) = \angle(x, y)$ as a replacement for the height function h in the proof of Proposition 4.1.3. Now we can write points $y \in S^m \setminus \{\pm x\}$ uniquely as

$$y = \cos(\varphi)x + \sin(\varphi)z$$

with $z = z(y)$ in the equator of x, that is $\langle x, z\rangle = 0$, $\langle z, z\rangle = 1$, and $\varphi = \varphi(y) \in (0, \pi)$. The function $\varphi \colon S^m \setminus \{\pm x\} \longrightarrow (0, \pi)$ is smooth, with gradient (see Exercise 4.6.11)

$$(\operatorname{grad} \varphi)(\cos(\varphi)x + \sin(\varphi)z) = -\sin(\varphi)x + \cos(\varphi)z.$$

We now show that $d(x, y) \geq \varphi(y)$. It suffices to show that every piecewise smooth curve $c : [a, b] \longrightarrow S^m$ with $c(a) = x$ has length $L(c) \geq \varphi(c(b))$. To this end, we can assume that $a = \sup\{t \in [a, b] \mid c(t) = x\}$ and $b = \inf\{t \in [a, b] \mid \varphi(c(t)) = \varphi(c(b))\}$. For all $t \in (a, b)$, then, $c(t)$ lies in $S^m \setminus \{\pm x\}$. Since $\|\operatorname{grad} \varphi\| = 1$, we obtain

$$L(c) = \int_a^b \|\dot c(t)\|\, dt \geq \int_a^b \langle \operatorname{grad} \varphi(c(t)), \dot c(t)\rangle\, dt = \varphi(y).$$

On the other hand, the great circle

$$c\colon [0, 1] \longrightarrow S^m, \quad c(t) = \cos(t\varphi(y))x + \sin(t\varphi(y))z(y)$$

is smooth, with length $\varphi(y) = \angle(x, y)$. The claim that $d(x, y) = \angle(x, y)$ follows. It also follows that the shortest curves connecting two points are monotone reparameterizations of arcs along great circles. ■

4.2.3 Variations and Geodesics

We now address the question of which conditions a piecewise smooth curve $c\colon [a, b] \longrightarrow M$ must satisfy if it is the shortest curve between its endpoints $p = c(a)$ and $q = c(b)$. We consider the length L as a functional on the space of piecewise smooth curves from p to q.[7] The shortest curves are then those for which L attains a minimum, and so will be critical points of L. To make this notion of critical points of L precise, one considers families of piecewise smooth curves, or so-called *variations*, such that L is differentiable along these families. We have already encountered variations in a special case. Compare (4.11) and (4.12).

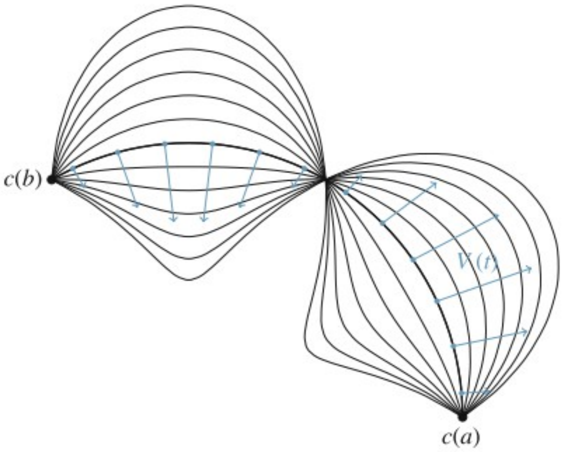
Definition 4.2.10

A *variation* of c is a map

$$h\colon (-\varepsilon, \varepsilon) \times [a, b] \longrightarrow M \quad \text{with} \quad h(0, t) = c(t),$$

such that there is a subdivision $a = t_0 < t_1 < \cdots < t_k = b$ of $[a, b]$ such that the restriction of h to $(-\varepsilon, \varepsilon) \times [t_{i-1}, t_i]$ is smooth for all $1 \leq i \leq k$.
The variation consists of the piecewise smooth curves $c_s := h(s, .)$. We call the piecewise smooth vector field $V = V(t) = (\partial_s h)(0, t)$ along c the *variation field* of h. Instead of h, we sometimes write (c_s). We call a variation $h = (c_s)$ of $c = c_0$ *proper*, if $c_s(a) = c(a)$ and $c_s(b) = c(b)$ for all $s \in (-\varepsilon, \varepsilon)$. See ◘ Fig. 4.4.

◘ **Fig. 4.4** A proper variation



---

[7] Since the domain of L is a space of functions, one does not simply call L a function, but rather uses the hifalutin term *functional*, which does not, however, have a deeper meaning.

Let $c\colon [a,b] \longrightarrow M$ be a piecewise smooth curve. As in the smooth case, we call c *regular* if $\dot{c}(t) \neq 0$ for all $t \in [a,b]$. Now let c be regular and let $h = (c_s)$ be a variation of $c = c_0$. Then the c_s are also regular if we only consider sufficiently small s. By definition of the first fundamental form,

$$\|\dot{c}_s(t)\| = \|\partial_t(f \circ h)(s,t)\|.$$

With a subdivision as in Definition 4.2.10 it therefore follows that $\|\dot{c}_s(t)\|$ is smooth on the rectangles $(-\varepsilon,\varepsilon) \times [t_{i-1},t_i]$, $1 \leq i \leq k$. From this it follows that the lengths $L(c_s)$ depend smoothly on s.

Definition 4.2.11

Let $c\colon [a,b] \longrightarrow M$ be regular and let $h = (c_s)$ be a variation of $c = c_0$. Then we call the derivative δL of $L(c_s)$ by s at $s = 0$ the *the first variation of arc length* of (c_s).

Proposition 4.2.12 *Let $c\colon [a,b] \longrightarrow M$ be piecewise smooth with constant speed $T \neq 0$. Then for a variation $h = (c_s)$ of $c = c_0$ with variation field V,*

$$\begin{aligned}
\delta L &= \frac{1}{T}\left[\sum_{i=1}^{k} \big\langle V, \dot{c}\big\rangle\Big|_{t_{i-1}}^{t_i} - \int_a^b \Big\langle df \circ V, \frac{d^2(f \circ c)}{dt^2}\Big\rangle\, dt\right] \\
&= \frac{1}{T}\left[\big\langle V, \dot{c}\big\rangle\Big|_a^b + \sum_{i=1}^{k-1} \big\langle V(t_i), \Delta_i\big\rangle - \int_a^b \Big\langle df \circ V, \frac{d^2(f \circ c)}{dt^2}\Big\rangle\, dt\right]
\end{aligned}$$

with $\Delta_i := \dot{c}(t_i-) - \dot{c}(t_i+)$, $1 \leq i \leq k-1$.

Proof

We may assume that $\dot{c}_s(t) \neq 0$ for all s and t. Then $\|\dot{c}_s(t)\|$ is smooth on the rectangles $(-\varepsilon,\varepsilon) \times [t_{i-1},t_i]$ as in Definition 4.2.10. Therefore,

$$\begin{aligned}
\frac{d(L(c_s))}{ds} &= \frac{d}{ds}\Big(\int_a^b \|\dot{c}_s(t)\|\, dt\Big) \\
&= \int_a^b \frac{d}{ds}\sqrt{\langle \partial_t(f \circ h), \partial_t(f \circ h)\rangle}\, dt.
\end{aligned}$$

With the requirement that $\|\dot{c}(t)\| = T = \text{const}$, we thereby obtain

$$\begin{aligned}
\delta L &= \frac{1}{T}\int_a^b \big\langle \partial_s\partial_t(f \circ h), \partial_t(f \circ h)\big\rangle(0,t)\, dt \\
&= \frac{1}{T}\int_a^b \big\langle \partial_t\partial_s(f \circ h), \partial_t(f \circ h)\big\rangle(0,t)\, dt
\end{aligned}$$

$$= \frac{1}{T}\int_a^b \partial_t\big\langle \partial_s(f\circ h), \partial_t(f\circ h)\big\rangle(0,t)\,dt - \frac{1}{T}\int_a^b \big\langle \partial_s(f\circ h), \partial_t^2(f\circ h)\big\rangle(0,t)\,dt$$

$$= \frac{1}{T}\sum_{i=1}^{k}\big\langle \partial_s(f\circ h), \partial_t(f\circ h)\big\rangle(0,t)\Big|_{t_{i-1}}^{t_i} - \frac{1}{T}\int_a^b \big\langle \partial_s(f\circ h), \partial_t^2(f\circ h)\big\rangle(0,t)\,dt.$$

However, at $s = 0$, by definition,

$$\partial_s(f\circ h) = df\circ V, \quad \partial_t(f\circ h) = df\circ\dot{c} \quad \text{and} \quad \partial_t^2(f\circ h) = \frac{d^2(f\circ c)}{dt^2}. \qquad \square$$

We now come to a result of Johann Bernoulli[8] from 1698 (unpublished), one of the first results ever in differential geometry; compare with [HT, pp. 117].

Proposition 4.2.13 *A piecewise smooth curve $c\colon [a,b] \longrightarrow M$ has constant speed T and first variation of arc length $\delta L = 0$ for every proper variation of c if and only if c is smooth and the tangential component of the second derivative of the second derivative of $f\circ c$ vanishes.*

Proof

We first assume that c is smooth and the tangential component of the second derivative of $f\circ c$ vanishes. By the definition of the first fundamental form

$$\frac{d}{dt}\langle\dot{c},\dot{c}\rangle = \frac{d}{dt}\Big\langle\frac{d(f\circ c)}{dt}, \frac{d(f\circ c)}{dt}\Big\rangle = 2\Big\langle\frac{d(f\circ c)}{dt}, \frac{d^2(f\circ c)}{dt^2}\Big\rangle = 0,$$

since $d(f\circ c)/dt$ is tangent to f. Therefore c has constant speed T.

We may now further assume that c is not constant, that is that $T > 0$. Let $h = (c_s)$ be a proper variation of $c = c_0$ with variation field V.

Since h is proper and c is smooth, it follows that $V(a) = 0$, $V(b) = 0$, and $\Delta_i = 0$, $1 \le i \le k-1$. Therefore, the first terms in the formula for δL vanish. The integrand of the integral now vanishes pointwise, since $df\circ V$ is tangential and $d^2(f\circ c)/dt^2$ is normal to f. Therefore $\delta L = 0$.

In the opposite direction, we can assume that c is not constant. Then let $a = t_0 < t_1 < \cdots < t_k = b$ be a subdivision, such that c is smooth on the intervals $[t_{i-1}, t_i]$. We first show, that the tangential component of the second derivative of $f\circ c$ vanishes on the intervals $[t_{i-1}, t_i]$. Since, by Lemma 4.2.4, the tangential component is smooth on these intervals, it suffices to show that it vanishes on the open intervals (t_{i-1}, t_i). Assume that this is not the case for some $t' \in (t_{i-1}, t_i)$. Then there is a vector $v \in T_{c(t')}M$ with

$$\Big\langle df(c(t'))(v), \frac{d^2(f\circ c)}{dt^2}(t')\Big\rangle > 0.$$

---

[8] Johann Bernoulli (1667–1748). He, of course, only discussed curves on surfaces in $\mathbb{R}^3$, but this amounts to much the same thing in proofs.

Now let (U, x) be a chart on M around $c(t')$, and let $\xi \in \mathbb{R}^m$ be the principal part of v with respect to x. Then

$$v = \xi^i \frac{\partial}{\partial x^i}\Big|_{c(t')} \quad \text{and} \quad df(c(t')) \cdot v = \xi^i \frac{\partial f}{\partial x^i}(c(t')).$$

Since the derivatives of f and c are continuous, there is an $\varepsilon > 0$ with $(t' - \varepsilon, t' + \varepsilon) \subseteq (t_{i-1}, t_i)$, such that $c((t' - \varepsilon, t' + \varepsilon)) \subseteq U$ and

$$\Big\langle \xi^i \frac{\partial f}{\partial x^i}(c(t)), \frac{d^2(f \circ c)}{dt^2}(t) \Big\rangle > 0$$

for all $t \in (t' - \varepsilon, t' + \varepsilon)$. Now let $\varphi : \mathbb{R} \longrightarrow \mathbb{R}$ be a bump function with

$$0 \le \varphi \le 1, \quad \operatorname{supp} \varphi \subseteq (t' - \varepsilon, t' + \varepsilon), \quad \text{and} \quad \varphi(t') = 1.$$

Set

$$h(s, t) = \begin{cases} x^{-1}\big(x(c(t)) + s\,\varphi(t)\,\xi\big) & \text{for } t \in (t' - \varepsilon, t' + \varepsilon), \\ c(t) & \text{otherwise}. \end{cases}$$

Then h is a proper variation of c. The variation field V of h satisfies

$$df(c(t))(V(t)) = \varphi(t)\,\xi^i \frac{\partial f}{\partial x^i}(c(t))$$

for all $t \in (t' - \varepsilon, t' + \varepsilon)$, and $V(t) = 0$ otherwise. However, the choice of v or ξ respectively implies $\delta L \neq 0$, which is a contradiction. Therefore, the tangential component of the second derivative of $f \circ c$ vanishes on the intervals $[t_{i-1}, t_i]$.

We next show that c is continuously differentiable, that is, that $\dot{c}(t_i-) = \dot{c}(t_i+)$ for all $0 < i < k$. To find a contradiction, we assume that $\Delta_i = \dot{c}(t_i-) - \dot{c}(t_i+) \neq 0$ for some i. We again choose a chart (U, x) on M, this time about $c(t_i)$, and a bump function φ as above, but now with support in $(t_i - \varepsilon, t_i + \varepsilon) \subseteq (t_{i-1}, t_{i+1})$ and with $\varphi(t_i) = 1$, such that $c((t_i - \varepsilon, t_i + \varepsilon)) \subseteq U$, and define a proper variation h of c as above, where ξ^i are the coefficients of Δ_i with respect to x. Since the tangential derivatives of $f \circ c$ are normal to f, it follows that $\delta L = \langle V(t_i), \Delta_i \rangle = \|\Delta_i\|^2 \neq 0$, a contradiction. So c is continuously differentiable.

It now only remains to show that c is smooth. For this, we refer to the discussion below: By the choice of t_i, c is already smooth on the intervals $[t_{i-1}, t_i]$. Now let $0 < i < k$ and (U, x) be a chart around $c(t_i)$. Let $\varepsilon > 0$ be chosen so that $c((t_i - \varepsilon, t_i + \varepsilon))$ is contained in U. Since the tangential component of the second derivative of $f \circ c$ vanishes on the intervals $(t_i - \varepsilon, t_i]$ and $[t_i, t_i + \varepsilon)$, the $c^j := x^j \circ c$ satisfy the second-order ordinary differential equations (4.40) on these intervals. Now, the values and the derivatives of the $c^j|_{(t_i - \varepsilon, t_i]}$ and $c^j|_{[t_i, t_i + \varepsilon)}$ agree at $t = t_i$, since c is continuously differentiable. Thus the c^j solve the equations in (4.40) on $(t_i - \varepsilon, t_i + \varepsilon)$. Since the coefficients Γ_{ij}^k of the equation are smooth, the c^j are smooth on these intervals. Therefore, c is smooth on $(t_i - \varepsilon, t_i + \varepsilon)$ and therefore on $[a, b]$. □

Definition 4.2.14

We call a smooth curve $c\colon I \longrightarrow M$ a *geodesic*, if the tangential component of the second derivative of $f \circ c$ vanishes,

$$\left[\frac{d^2(f \circ c)}{dt^2}\right]^T = 0.$$

Example 4.2.15

Let $p, q \in M$. Suppose there is a curve $c_0\colon [a, b] \longrightarrow M$ such that $f \circ c_0$ is the constant-speed line segment in $\mathbb{R}^n$ from $f(p)$ to $f(q)$. Then c_0 is smooth and has constant speed $\|f(q) - f(p)\|/|b - a|$. The second derivative $f \circ c_0$ vanishes, so c_0 is a geodesic.

$f \circ c_0$ is the shortest among all the piecewise smooth curves in $\mathbb{R}^n$ from $f(p)$ to $f(q)$, and therefore, *a fortiori*, is the shortest among all curves of the form $f \circ c$. Thus, c_0 is a shortest curve connecting p to q in M. The first variation of arc length of every proper variation of c_0 must therefore vanish, so we again see that c_0 is a geodesic.

For the ruled surfaces of Example 4.2.3.4, the generators $t = \text{const}$ are lines in $\mathbb{R}^3$ and therefore are geodesics in the surface. ■

4.2.4 Covariant Derivative and Geodesics

The definitions of the length of piecewise smooth curves in M and of the geodesics as critical points of the length functional only involve the first fundamental form on M (resp. f). We therefore seek a formula for geodesics that only requires the first fundamental form. It is even advisable to aim higher. Let $X\colon I \longrightarrow TM$ be a smooth *vector field along* c, , i.e., $X(t) \in T_{c(t)}M$ for all $t \in I$. Then $Xf = df \circ X$ is a smooth tangent vector field along $f \circ c$. In general, $d(Xf)/dt$ is no longer tangent to f. The tangential part of $d(Xf)/dt$ is our focus. See also Lemma 4.2.4.

Definition 4.2.16

We call the unique vector field $X'\colon I \longrightarrow TM$ along c with

$$df \circ X' = [d(Xf)/dt]^T$$

the *covariant derivative* of X, and we sometimes write $\nabla X/dt$ instead of X'. We call X *parallel* (along c) if $X' = 0$.

Geodesics are therefore, by Definition 4.2.14, characterized by the condition that the covariant derivative $\nabla\dot{c}/dt$ vanishes, or, in other words, that $\dot{c}$ is parallel along c.

Remark 4.2.17

1) To the best of my knowledge, we have Levi-Civita[9] to thank for the insight that the orthogonal projection onto the tangential component as in Definition 4.2.16 leads to a sensible kind of derivative: the covariant derivative.
2) For a vector field X along a curve c in M, X' is once again a vector field along c, while the usual derivative $\dot{X}$ of X takes values in TTM. The second derivative $\ddot{X}$ then has values in $TTTM$, and so forth. In contrast, higher covariant derivatives of X always remain vector fields along c.
3) We have already encountered the strategy of considering orthogonal projections of usual derivatives in our discussion of the normal fields of curves; see Definition 4.1.13 and the discussion which follows it.

We now discuss the computation of covariant derivatives in terms of local coordinates. Let (U, x) be a chart on M and $c\colon I \longrightarrow U$ a smooth curve. Let $X\colon I \longrightarrow M$ be a smooth vector field along c. Then

$$X = \xi^i \frac{\partial}{\partial x^i} \quad \text{and} \quad Xf = df \circ X = \xi^i \frac{\partial f}{\partial x^i} \quad \text{with} \quad \xi^j = \left\langle X, \frac{\partial}{\partial x^i}\right\rangle g^{ij},$$

where these equations are to be read as equations along c. With $c^i := x^i \circ c$ and since $f \circ c = (f \circ x^{-1}) \circ (x \circ c)$, we therefore obtain

$$\frac{d(Xf)}{dt} = \frac{d}{dt}\big(\xi^i \frac{\partial f}{\partial x^i}\big) = \dot{\xi}^i \frac{\partial f}{\partial x^i} + \dot{c}^j \xi^i \frac{\partial^2 f}{\partial x^j \partial x^i}. \tag{4.36}$$

Since the partial derivatives $\partial f/\partial x^i$ are tangent to f, the first term is already tangent to f. The second term is a linear combination of the second partial derivatives of f with respect to x, and is not, in general, tangent to f. The tangential components of the second partial derivatives are, however, pointwise linear combinations of the first partial derivatives, which are bases of their respective tangent spaces $T_p f$,

$$\left[\frac{\partial^2 f}{\partial x^i \partial x^j}\right]^T =: \Gamma_{ij}^k \frac{\partial f}{\partial x^k}. \tag{4.37}$$

The coefficients $\Gamma_{ij}^k : U \longrightarrow \mathbb{R}$ are called *Christoffel symbols*.[10] Using Definition 4.2.16 and (4.36), we can now compute the covariant derivative of X to be

$$\frac{\nabla X}{dt} = X' = \big(\dot{\xi}^k + \Gamma_{ij}^k \dot{c}^i \xi^j\big) \frac{\partial}{\partial x^k}, \tag{4.38}$$

---

[9] Tullio Levi-Civita (1873–1941).

[10] Elwin Bruno Christoffel (1829–1900).

where Γ_{ij}^k, strictly speaking, should be read as $\Gamma_{ij}^k \circ c$. By Lemma 4.2.4, or by Proposition 4.2.23 below, the Christoffel symbols are smooth. Therefore, the covariant derivative of X is also smooth. Since the second derivatives $\partial^2 f/\partial x^i \partial x^j$ are symmetric in i and j, the Christoffel symbols are symmetric in their two lower indices, $\Gamma_{ij}^k = \Gamma_{ji}^k$.

Proposition 4.2.18 *Let X and Y be smooth vector fields along c. Then the following hold:*

1. *(Linearity) For $\alpha, \beta \in \mathbb{R}$, $(\alpha X + \beta Y)' = \alpha X' + \beta Y'$.*
2. *(Product rule 1) For smooth $\varphi \colon I \longrightarrow \mathbb{R}$, $(\varphi X)' = \dot{\varphi} X + \varphi X'$.*
3. *(Product rule 2) The function $\langle X, Y \rangle$ has derivative $\langle X', Y \rangle + \langle X, Y' \rangle$.*

Proof

Claims 1 and 2 follow immediately from Definition 4.2.16 or from (4.38). By the definition of the first fundamental form $\langle X, Y \rangle = \langle Xf, Yf \rangle$, and therefore

$$\begin{aligned} d\langle X, Y \rangle/dt &= d\langle Xf, Yf \rangle/dt = \langle d(Xf)/dt, Yf \rangle + \langle Xf, d(Yf)/dt \rangle \\ &= \langle df \circ X', df \circ Y \rangle + \langle df \circ X, df \circ Y' \rangle = \langle X', Y \rangle + \langle X, Y' \rangle. \end{aligned}$$

In passing from the first line to the second, we have used that, in the first term, the normal part of $d(Xf)/dt$ is by definition perpendicular to f and therefore is perpendicular to $Yf = df \circ Y$. We reason analogously for the second term. □

Corollary 4.2.19 *For parallel vector fields X and Y along c the following hold:*

1. *Linear combinations $\alpha X + \beta Y$ are themselves parallel along c.*
2. *The function $\langle X, Y \rangle$ is constant.* □

Let $W \subseteq \mathbb{R}^2 = \{(s, t) \mid s, t \in \mathbb{R}\}$ be an open subset, and let $\varphi : W \longrightarrow M$ be smooth. Then the partial derivatives $\partial\varphi/\partial s$ and $\partial\varphi/\partial t$ are vector fields along the s- and t-coordinate lines. We can therefore consider their covariant derivatives along these curves.

Proposition 4.2.20 *Let W be an open subset of the (s, t)-plane and let $\varphi : W \longrightarrow M$ be smooth. Then*

$$\frac{\nabla}{\partial s}\frac{\partial\varphi}{\partial t} = \frac{\nabla}{\partial t}\frac{\partial\varphi}{\partial s}.$$

Proof

By definition,

$$\frac{\nabla}{\partial s}\frac{\partial\varphi}{\partial t} = \left[\frac{\partial^2\varphi}{\partial s \partial t}\right]^T = \left[\frac{\partial^2\varphi}{\partial t \partial s}\right]^T = \frac{\nabla}{\partial t}\frac{\partial\varphi}{\partial s}.$$

□

With respect to local coordinates x and using (4.38), a vector field X along a smooth curve c is parallel, in the sense of Definition 4.2.16, if the coefficients ξ^i of X with respect to x solve the first-order ordinary differential equation

$$\dot{\xi}^k + \Gamma_{ij}^k \dot{c}^i \xi^j = 0. \tag{4.39}$$

The equation is linear in the ξ^i, so maximal solutions are defined on the entire domain of definition of the differential equation.

Corollary 4.2.21 *Let $c : I \longrightarrow M$ be a smooth curve and $t_0 \in I$. Then the following hold:*

1. *For $v \in T_{c(t_0)}M$ there is precisely one parallel vector field X along c with $X(t_0) = v$.*
2. *For a basis $(v_1, \ldots, v_m)$ of $T_{c(t_0)}M$ and parallel vector fields X_i along c with $X_i(t_0) = v_i$, $(X_1(t), \ldots, X_m(t))$ is a basis of $T_{c(t)}M$ for all $t \in I$. Furthermore, $\langle X_i(t), X_j(t)\rangle = \langle v_i, v_j\rangle$.* □

By definition, geodesics are smooth curves c with $\nabla \dot{c}/dt = 0$. Therefore, by (4.39), they are characterized as solutions to the second-order differential equation

$$\ddot{c}^k + \Gamma_{ij}^k \dot{c}^i \dot{c}^j = 0. \tag{4.40}$$

In contrast to (4.39), however, this equation is not linear in its solutions. Nonetheless, we can extract some important consequences from the fact that geodesics are solutions to an ordinary differential equation:

Corollary 4.2.22

1. *If $c_1 \colon I_1 \longrightarrow M$ and $c_2 \colon I_2 \longrightarrow M$ are geodesics with $I_1 \cap I_2 \neq \emptyset$ and $c_1|_{I_1 \cap I_2} = c_2|_{I_1 \cap I_2}$, then the concatenation $c \colon I_1 \cup I_2 \longrightarrow M$ of c_1 and c_2 is also a geodesic.*
2. *If c is a geodesic, so is $\tilde{c} = \tilde{c}(t) = c(at + b)$ for all $a, b \in \mathbb{R}$.*
3. *For $t \in \mathbb{R}$, $p \in M$, and $v \in T_pM$ there is precisely one maximal geodesic $c \colon I \longrightarrow M$ with $c(t) = p$ and $\dot{c}(t) = v$.* □

By *maximal*, we mean that the domain of every other geodesic with the given initial conditions is contained in I. In particular, I is open, since in local coordinates geodesics are solutions of the differential equation (4.40).

Proposition 4.2.23 *The Christoffel symbols associated to a chart x on M can be calculated from the coefficients of the first fundamental form in x. More explicitly,*

$$\Gamma_{ij}^l = \frac{1}{2} g^{kl} \Big(\frac{\partial g_{jk}}{\partial x^i} + \frac{\partial g_{ik}}{\partial x^j} - \frac{\partial g_{ij}}{\partial x^k} \Big).$$

Proof

We have

$$\frac{\partial g_{ij}}{\partial x^k} = \frac{\partial}{\partial x^k} \Big\langle \frac{\partial f}{\partial x^i}, \frac{\partial f}{\partial x^j} \Big\rangle = \Big\langle \frac{\partial^2 f}{\partial x^k \partial x^i}, \frac{\partial f}{\partial x^j} \Big\rangle + \Big\langle \frac{\partial f}{\partial x^i}, \frac{\partial^2 f}{\partial x^k \partial x^j} \Big\rangle.$$

Now $\partial f/\partial x^j$ and $\partial f/\partial x^i$ are tangent to f, so, on the right-hand side, only the tangential components of the second partial derivatives of f contribute. With (4.37), we then obtain

$$\frac{\partial g_{ij}}{\partial x^k} = \Big\langle \Gamma^l_{ki}\frac{\partial f}{\partial x^l}, \frac{\partial f}{\partial x^j}\Big\rangle + \Big\langle \frac{\partial f}{\partial x^i}, \Gamma^l_{kj}\frac{\partial f}{\partial x^l}\Big\rangle = \Gamma^l_{ki}g_{lj} + \Gamma^l_{kj}g_{il},$$

and similarly for $\partial g_{jk}/\partial x^i$ and $\partial g_{ik}/\partial x^j$. With the aid of the symmetry of the lower indices of the Christoffel symbols, we therefore obtain

$$\frac{\partial g_{jk}}{\partial x^i} + \frac{\partial g_{ik}}{\partial x^j} - \frac{\partial g_{ij}}{\partial x^k} = 2\,\Gamma^l_{ij}g_{lk}.$$

Finally, therefore

$$\begin{aligned} 2\,\Gamma^l_{ij} &= 2\,\Gamma^\mu_{ij}\,\delta^l_\mu = 2\,\Gamma^\mu_{ij}(g_{\mu k}g^{kl}) \\ &= 2\left(\Gamma^\mu_{ij}g_{\mu k}\right)g^{kl} = g^{kl}\Big(\frac{\partial g_{jk}}{\partial x^i} + \frac{\partial g_{ik}}{\partial x^j} - \frac{\partial g_{ij}}{\partial x^k}\Big). \qquad \square \end{aligned}$$

We see that the Christoffel symbols can be explicitly computed from the coefficients of the first fundamental form and their derivatives. Therefore, the Christoffel symbols are quantities belonging to interior geometry! With (4.39) and (4.40), geodesics and parallel vector fields are therefore also explicitly characterized as objects from interior geometry.

4.3 Exterior Geometry

The tangent space $T_p f$ approximates the image of f around p to first order, but does not describe, how that image bends in the ambient space. As in the case of curves, we therefore consider approximations of second order.

For $p \in M$, we consider the orthogonal decomposition $\mathbb{R}^n = T_p f \oplus N_p f$ with the corresponding projections π^T_p and π^N_p. Compare with (4.24) and (4.26). Then for the smooth map

$$x\colon M \longrightarrow T_p f, \quad x(q) = \pi^T_p(f(q) - f(p)), \tag{4.41}$$

we have $x(p) = 0$, and, since π^T_p is linear, $dx(p) = \pi^T_p \circ df(p) = df(p)$. Therefore $dx(p) : T_pM \longrightarrow T_p f$ is an isomorphism. The Inverse Function Theorem thus implies that there are open neighborhoods U of p in M and U' of 0 in $T_p f$, such that $x\colon U \longrightarrow U'$ is a diffeomorphism with $x(p) = 0$ and $dx(p) = df(p)$. Up to the choice of an isomorphism $T_p f \simeq \mathbb{R}^m$, (U, x) is thus the chart on M about p which best fits the region of M around p in the ambient space $\mathbb{R}^n$.

Proposition 4.3.1 (Local Normal Form) *Let* $h = \pi^N_p \circ (f - f(p)) \circ x^{-1} : U' \longrightarrow N_p f$ *be the* $N_p f$ *component of* $(f - f(p)) \circ x^{-1}$. *Then* $h(0) = 0$, $dh(0) = 0$, *and*

$$(f \circ x^{-1})(u) = f(p) + u + h(u) \quad \textit{for all } u \in U'.$$

Now $\partial f/\partial x^j$ and $\partial f/\partial x^i$ are tangent to f, so, on the right-hand side, only the tangential components of the second partial derivatives of f contribute. With (4.37), we then obtain

$$\frac{\partial g_{ij}}{\partial x^k} = \left\langle \Gamma^l_{ki}\frac{\partial f}{\partial x^l}, \frac{\partial f}{\partial x^j}\right\rangle + \left\langle \frac{\partial f}{\partial x^i}, \Gamma^l_{kj}\frac{\partial f}{\partial x^l}\right\rangle = \Gamma^l_{ki}g_{lj} + \Gamma^l_{kj}g_{il},$$

and similarly for $\partial g_{jk}/\partial x^i$ and $\partial g_{ik}/\partial x^j$. With the aid of the symmetry of the lower indices of the Christoffel symbols, we therefore obtain

$$\frac{\partial g_{jk}}{\partial x^i} + \frac{\partial g_{ik}}{\partial x^j} - \frac{\partial g_{ij}}{\partial x^k} = 2\,\Gamma^l_{ij}g_{lk}.$$

Finally, therefore

$$\begin{aligned} 2\,\Gamma^l_{ij} &= 2\,\Gamma^\mu_{ij}\,\delta^l_\mu = 2\,\Gamma^\mu_{ij}\,(g_{\mu k}g^{kl}) \\ &= 2\left(\Gamma^\mu_{ij}g_{\mu k}\right)g^{kl} = g^{kl}\left(\frac{\partial g_{jk}}{\partial x^i} + \frac{\partial g_{ik}}{\partial x^j} - \frac{\partial g_{ij}}{\partial x^k}\right). \end{aligned} \qquad \square$$

We see that the Christoffel symbols can be explicitly computed from the coefficients of the first fundamental form and their derivatives. Therefore, the Christoffel symbols are quantities belonging to interior geometry! With (4.39) and (4.40), geodesics and parallel vector fields are therefore also explicitly characterized as objects from interior geometry.

4.3 Exterior Geometry

The tangent space $T_p f$ approximates the image of f around p to first order, but does not describe, how that image bends in the ambient space. As in the case of curves, we therefore consider approximations of second order.

For $p \in M$, we consider the orthogonal decomposition $\mathbb{R}^n = T_p f \oplus N_p f$ with the corresponding projections π^T_p and π^N_p. Compare with (4.24) and (4.26). Then for the smooth map

$$x\colon M \longrightarrow T_p f, \quad x(q) = \pi^T_p(f(q) - f(p)), \tag{4.41}$$

we have $x(p) = 0$, and, since π^T_p is linear, $dx(p) = \pi^T_p \circ df(p) = df(p)$. Therefore $dx(p) : T_p M \longrightarrow T_p f$ is an isomorphism. The Inverse Function Theorem thus implies that there are open neighborhoods U of p in M and U' of 0 in $T_p f$, such that $x\colon U \longrightarrow U'$ is a diffeomorphism with $x(p) = 0$ and $dx(p) = df(p)$. Up to the choice of an isomorphism $T_p f \simeq \mathbb{R}^m$, (U, x) is thus the chart on M about p which best fits the region of M around p in the ambient space $\mathbb{R}^n$.

Proposition 4.3.1 (Local Normal Form) *Let $h = \pi^N_p \circ (f - f(p)) \circ x^{-1} : U' \longrightarrow N_p f$ be the $N_p f$ component of $(f - f(p)) \circ x^{-1}$. Then $h(0) = 0$, $dh(0) = 0$, and*

$$(f \circ x^{-1})(u) = f(p) + u + h(u) \quad \textit{for all } u \in U'.$$

Proof

Since $x^{-1}(0) = p$, $h(0) = 0$. Furthermore,

$$dh(0) = \pi_p^N \circ df(p) \circ dx^{-1}(0).$$

Now $\operatorname{im} df(p) = T_p f$, so $\pi_p^N \circ df(p) = 0$. The rest is clear. □

By Proposition 4.3.1, the Taylor expansion of h around 0 is given by

$$h(u) = \frac{1}{2} H_p(u, u) + \text{terms of third or higher order in } u, \tag{4.42}$$

where $H_p := D^2 h|_0$. Up to translation by $f(p)$ and terms of third or higher order in u,

$$Q_p = \{u + v \in \mathbb{R}^n \mid u \in T_p f,\ v = H_p(u, u)/2 \in N_p f\} \tag{4.43}$$

therefore describes the image of f around p. We call Q_p the *osculating paraboloid* to f at p. The osculating paraboloid to f at p is an m-dimensional submanifold of $\mathbb{R}^n$ and describes $f - f(p)$ about p to second order.

With the chart (U, x) on M around p as above, we now let $c\colon I \longrightarrow U$ be a smooth curve with $c(t_0) = p$ for some $t_0 \in I$. Then, by Proposition 4.3.1,

$$f \circ c = (f \circ x^{-1}) \circ (x \circ c) = f(p) + x \circ c + h \circ (x \circ c).$$

It therefore follows from (4.42) that

$$\begin{aligned}
\frac{d^2(f \circ c)}{dt^2}(t_0) &= \frac{d^2(x \circ c + h \circ (x \circ c))}{dt^2}(t_0) \\
&= \frac{d^2(x \circ c)}{dt^2}(t_0) + H_p\big(dx(p)(\dot{c}(t_0)), dx(p)(\dot{c}(t_0))\big) \\
&= \frac{d^2(x \circ c)}{dt^2}(t_0) + H_p\big(df(p)(\dot{c}(t_0)), df(p)(\dot{c}(t_0))\big).
\end{aligned}$$

The first term on the right is tangent to f at p, the second is normal. Therefore, the right-hand side is an orthogonal decomposition of the second derivative of $f \circ c$ at $t = t_0$. In this section, the second, normal, term is our focus.

Definition 4.3.2

We call the symmetric bilinear form

$$S_p : T_p M \times T_p M \longrightarrow N_p f, \quad S_p(v, w) := H_p(df(p)(v), df(p)(w)),$$

the *second fundamental form* of f at p.

We can summarize the computations above in the following equation:

$$\frac{d^2(f \circ c)}{dt^2} = df \circ \frac{\nabla \dot c}{dt} + S(\dot c, \dot c), \tag{4.44}$$

where $\nabla \dot c/dt$ denotes the covariant derivative of $\dot c$, see Definition 4.2.16. The reference points have been omitted in (4.44) for ease of reading. The first term is tangent to f, the second is normal. By (4.44), we can determine the second fundamental form S of f by polarization, without computing the special charts x or the local normal form of f as in Proposition 4.3.1.

Remark 4.3.3 In Definition 4.3.2 and (4.44) we again encounter the natural identification $df(p)\colon T_pM \longrightarrow T_p f$. In the case of a submanifold, this is the usual identification of T_pM with a subspace of $\mathbb{R}^n$ and will therefore be omitted from our notation. For submanifolds, the above formulas simplify to

$$S_p = H_p \quad \text{and} \quad \ddot c = \frac{\nabla \dot c}{dt} + S(\dot c, \dot c), \tag{4.45}$$

where $\nabla \dot c/dt$ is the tangential part of $\ddot c$, and $S(\dot c, \dot c)$ is the normal part.

Example 4.3.4

1) Let $M = I$ be an open interval and $c\colon I \longrightarrow \mathbb{R}^n$ be a regular curve, that is, an immersion. Then for $t \in I$, $T_t c = \mathbb{R}\cdot e(t)$ with $e(t) = \dot c(t)/\|\dot c(t)\|$ as in (4.1). The second fundamental form associates to $\partial/\partial t$ the normal component of $\ddot c$ (at the corresponding point), that is, $S(\partial/\partial t, \partial/\partial t) = \ddot c - \langle \ddot c, e\rangle e$. The length of these vectors is $\kappa \cdot \|\dot c\|^2$. Compare with (4.4).
2) Let $M = S^m_r \subseteq \mathbb{R}^{m+1}$ be the sphere with center 0 and radius r (and f be the inclusion). For $x \in S^m_r$, let $U = \{y \in S^m_r \mid \langle x, y\rangle > 0\}$. Then the orthogonal projection π^T_x : $U \longrightarrow T_x S^m_r = \{u \in \mathbb{R}^{m+1} \mid \langle x, u\rangle = 0\}$ is a diffeomorphism onto its image U' and is therefore a chart on S^m_r around x. Up to conflicts in the notation, it corresponds to the charts in (4.41) and Proposition 4.3.1, there denoted by x. As in Proposition 4.3.1 (for the case $f =$ inclusion), we can now write U as the graph of the map

$$h\colon U' \longrightarrow \mathbb{R}\,x = N_x S^m_r, \quad h(u) = \left(\sqrt{r^2 - \|u\|^2} - r\right)\frac{x}{r}.$$

Therefore, the second fundamental form of $M = S^m_r$ at x is given by

$$S_x(v, w) = -\frac{\langle v, w\rangle}{r^2} \cdot x.$$

With (4.44), we can determine $S_x(v, v)$ for a unit vector $v \in T_x S^n_r$ by determining the normal portion of the second derivative of a smooth curve c through x with derivative $\dot c(0) = v$. Here, the curve $c = c(t) = \cos(t)x + r\sin(t)v$ recommends itself, since $\ddot c = -c$ is normal to the sphere at all points, and therefore c is a geodesic. It thereby follows that $S_x(rv, rv) = -x$. Polarization then leads to the formula for S_x which we obtained in a different way above.

■

Proposition 4.3.5 *For smooth vector fields X, Y on M,*

$$S(X, Y) = [XYf]^N.$$

Proof

Let $p \in M$ with the chart x around p as in (4.41) and the map h as in Proposition 4.3.1. Since $dh(0) = 0$, it then follows that

$$\begin{aligned}[XYf]^N(p) &= [X(df \circ Y)]^N(p) = X(d(h \circ x) \circ Y)(p) \\ &= D^2h(0)\big(df(p)(X(p)), df(p)(Y(p))\big) = S_p(X(p), Y(p)).\end{aligned}$$ □

By (4.44), we already knew that we need not determine the special chart x as in (4.41) and h as in Proposition 4.3.1 to compute the second fundamental form. Proposition 4.3.5 provides another argument for this fact.

Now let $x : U \longrightarrow U'$ be an arbitrary chart on M. It then follows from Proposition 4.3.5 that the (vector-valued) entries in the fundamental matrix of the second fundamental form with respect to x are given by

$$h_{ij} := S\Big(\frac{\partial}{\partial x^i}, \frac{\partial}{\partial x^j}\Big) = \left[\frac{\partial^2 f}{\partial x^i \partial x^j}\right]^N. \tag{4.46}$$

In conclusion, by (4.37) and (4.46), the tangential component of the second derivative of f determines the Christoffel symbols, and the normal component determines the coefficients of the second fundamental form.

4.3.1 Hypersurfaces

The classical case of submanifolds of Euclidean spaces are surfaces in $\mathbb{R}^3$. Since the discussion is essentially the same, we consider hypersurfaces $M \subseteq \mathbb{R}^{m+1}$ or immersions $f : M \longrightarrow \mathbb{R}^{m+1}$. Then, for all $p \in M$, $\dim N_p f = 1$. In particular, $N_p f$ contains precisely two unit vectors. For a given $p \in M$, let $n = n_p$ be one of these. Then we can write the second fundamental form S_p as

$$S_p(v, w) = S_p^n(v, w)\, n_p \quad \text{with} \quad S_p^n(v, w) := \langle S_p(v, w), n_p \rangle. \tag{4.47}$$

We call S_p^n the *second fundamental form of f at p with respect to n_p*. If x is a chart on M about p, then we obtain, by (4.46),

$$h_{ij}^n(p) := S_p^n\Big(\frac{\partial}{\partial x^i}(p), \frac{\partial}{\partial x^j}(p)\Big) = \Big\langle \frac{\partial^2 f}{\partial x^i \partial x^j}(p), n_p \Big\rangle \tag{4.48}$$

for the coefficients of the fundamental matrix of the second fundamental form. The sign of $h_{ij}^n(p)$ depends on the choice of the vector $n = n_p$.

The *Weingarten map*[11] is the self-adjoint endomorphism $L_p\colon T_pM \longrightarrow T_pM$ corresponding to the second fundamental form, which is characterized by

$$\langle L_p v, w\rangle = S_p^n(v, w) \quad \text{for all } v, w \in T_pM. \tag{4.49}$$

We know from linear algebra that the characteristic values and directions of a symmetric bilinear form on a Euclidean vector space correspond precisely to the eigenvalues and eigenvectors of the associated self-adjoint endomorphism of the vector space. Correspondingly, the characteristic values and directions of the second fundamental form are the eigenvalues and eigenvectors of the Weingarten map.

Definition 4.3.6

The characteristic values of the second fundamental form S_p^n are called the *principal curvatures* and the corresponding direction in T_pM *principal directions* of M or f at p. Regular curves $c\colon I \longrightarrow M$, such that $\dot{c}(t)$ is a principal direction for all $t \in I$ are called *lines of curvature*.

The principal directions do not depend on the choice of n_p, and only the signs of the principal curvatures do.

We now describe three classical results for surfaces in $\mathbb{R}^3$ connected with the correspondence between symmetric bilinear forms and self-adjoint endomorphisms:

1. The *Theorem of Rodrigues*[12] (1816) states that the minimum and the maximum of the function $S_p(v, v)$, where v runs through the unit vectors in T_pM, are attained at eigenvectors of L_p.
2. Let $E \subseteq \mathbb{R}^{m+1}$ be an affine plane through $f(p)$ tangent to n_p and a unit vector $u \in T_pf$. Furthermore, let $x : U \longrightarrow U'$ be the chart in (4.41). For a smooth curve $c\colon I \longrightarrow U$ through p, the image of $\sigma := f \circ c$ is contained in E if and only if $x \circ c$ lies in $\mathbb{R}\cdot u$. If this holds and $\dot{\sigma}(0)$ is a positive multiple of u, then we call σ a *normal section* of M (resp. f) through p in the direction u. See ◘ Fig. 4.5. With h as in Proposition 4.3.1, for example,

$$\sigma_u = \sigma_u(t) = (f \circ x^{-1})(tu) = f(p) + tu + h(tu) \tag{4.50}$$

is one such normal section. Since normal sections in the direction u only differ in their parameterizations locally around $t = 0$, their oriented curvatures (at least at $t = 0$), in the plane E oriented by (u, n_p), are independent of the choice of normal section and therefore define a function of the unit vector u, written as $\kappa_o(u)$. *Euler's Theorem* states that κ_o (as a function of u) is either constant or attains its maximum and minimum in directions perpendicular to one another. To see this, write $u =$

[11] Julius Weingarten (1836–1910).

[12] Benjamin Olinde Rodrigues (1794–1851).

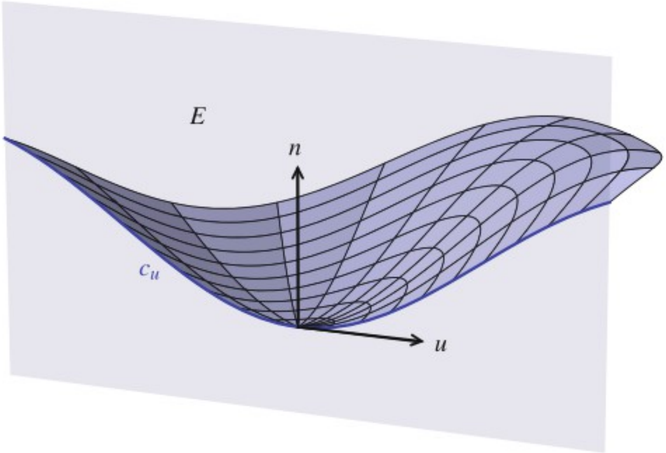

Fig. 4.5 A normal section

$df(p)(v)$ with $v \in T_pM$. With σ_u as above, we then have $\langle \dot{\sigma}_u(0), \ddot{\sigma}_u(0) \rangle = 0$ and therefore

$$\kappa_o(u) = \langle \ddot{\sigma}_u(0), n_p \rangle = S^n_p(v, v). \tag{4.51}$$

Therefore the maximum and minimum of κ_o correspond precisely to the extreme values of $S^n_p(v, v)$, where v runs through the unit vectors in T_pM. These will be attained in directions perpendicular to one another if the function $S^n_p = S^n_p(v, v)$ is not constant.

1) *Meusnier's Theorem*[13] (1776) complements Euler's Theorem: Let $v \in T_pM$ be a unit vector with $S^n_p(v, v) \neq 0$ and $c\colon I \longrightarrow M$ a smooth curve with $c(0) = p$ and $\dot{c}(0) = v$. Then for $\sigma := f \circ c$, $u := \dot{\sigma}(0) = df(p)(v)$ and $\ddot{\sigma}(0)$ are linearly independent. Let σ_u be a normal section of f through p in the direction u. Meusnier's Theorem now says that the orthogonal projection of the center of curvature M_u of σ_u at $t = 0$ onto the affine plane E through $f(p)$, spanned by $u = \dot{\sigma}(0)$ and $\ddot{\sigma}(0)$, is the center of curvature of σ at $t = 0$. Since $\dot{\sigma}(0)$ has norm 1, the curvature of σ at $t = 0$ is, by (4.4), given by $\|\ddot{\sigma}(0) - \langle \dot{\sigma}(0), \ddot{\sigma}(0) \rangle \dot{\sigma}(0)\|$. Therefore, Meusnier's Theorem follows from (4.44) and (4.51), since

$$\|\ddot{\sigma}(0) - \langle \dot{\sigma}(0), \ddot{\sigma}(0) \rangle \dot{\sigma}(0)\| \cos\theta = |\langle \ddot{\sigma}(0), n_p \rangle| = |S^n_p(v, v)|,$$

where $\theta \in [0, \pi/2)$ denotes the angle between E and N_pf. In particular, it follows from Meusnier's Theorem, that the osculating circles of all such $\sigma = f \circ c$ with

---

[13] Jean Baptiste Marie Charles Meusnier de la Place (1754–1793).

$\dot{c}(0) = v$ form a sphere with center M_u and radius $1/|S^n_p(v, v)|$, the so-called *Meusnier sphere*.

At every $p \in M$, we have a choice of two unit vectors $\pm n_p$. Naturally, it is disadvantageous to choose n_p separately for each point.

Definition 4.3.7

For an open subset $W \subseteq M$ a smooth map $n : W \longrightarrow S^m \subseteq \mathbb{R}^{m+1}$ is called a *Gauß map* on M (resp. f), if $n_p = n(p) \in N_p f$ for all $p \in W$.

Example 4.3.8

If $m = 2$ and (U, x) is a chart on M, then

$$\tilde{n} := \frac{\partial f}{\partial x^1} \times \frac{\partial f}{\partial x^2} \tag{4.52}$$

is perpendicular to f, and therefore $n := \tilde{n}/\|\tilde{n}\|$ is a Gauß map on U. For the case $m > 2$ there is an analogous formula. (Exercise: check the latter.) ■

Remark 4.3.9 We call a connected hypersurface $M \subseteq \mathbb{R}^{m+1}$ *two-sided* if there is a global Gauß map $n : M \longrightarrow S^m$, otherwise we call M one-sided. Two-sidedness and one-sidedness are equivalent to the orientability and non-orientability of M respectively. Compare with ► Sect. 3.6. The Möbius strip is one-sided.

In the following, let $n\colon M \longrightarrow S^m$ be a Gauß map on f. For vector fields X and Y on M, we then have $\langle Yf, n\rangle = 0$, and therefore

$$0 = X\langle n, Yf\rangle = \langle n, XYf\rangle + \langle Xn, Yf\rangle.$$

By Proposition 4.3.5, $\langle XYf, n\rangle = S^n(X, Y)$. It therefore follows that

$$S^n(X, Y) = \langle n, XYf\rangle = -\langle Xn, Yf\rangle = -\langle df \circ Y, dn \circ X\rangle. \tag{4.53}$$

The second fundamental form thus agrees with the bilinear form $-\langle df, dn\rangle$, also written as $-df \cdot dn$. Now, for every $p \in M$, $T_p f$ is the orthogonal complement to $n(p) \in S^m$, so $T_p f = T_{n(p)} S^m$. Therefore the ranges of $df(p)$ and $dn(p)$ agree. Since $df(p)\colon T_p M \longrightarrow T_p f$ is by definition of the first fundamental form an orthogonal transformation, we can reformulate (4.53) as follows:

$$dn = -df \circ L, \tag{4.54}$$

where L denotes the Weingarten map. If, in particular, $M \subseteq \mathbb{R}^{m+1}$ and f is the inclusion, then $L = -dn$.

For a chart (U, x) on M, we write $L(\partial/\partial x^i) = a_i^l\,\partial/\partial x^l$ with as yet undetermined coefficients a_i^l. Since

$$h_{ij}^n = S^n\Big(\frac{\partial}{\partial x^i}, \frac{\partial}{\partial x^j}\Big) = \Big\langle L\Big(\frac{\partial}{\partial x^i}\Big), \frac{\partial}{\partial x^j}\Big\rangle = a_i^l g_{lj}$$

it follows that $a_i^k = a_i^l g_{lj} g^{jk} = h_{ij}^n g^{jk}$. Therefore, we finally obtain

$$L\Big(\frac{\partial}{\partial x^i}\Big) = h_{ij}^n g^{jk} \frac{\partial}{\partial x^k}. \tag{4.55}$$

In other words, with respect to the basis $\partial/\partial x^i$, L is represented by the matrix with entries $h_{ij}^n g^{jk}$.

Up to sign, the elementary symmetric functions in the characteristic values of the second fundamental form correspond to the coefficients of the characteristic polynomial of the Weingarten map, and therefore, by (4.55), to the coefficients of the characteristic polynomial of the matrix $(h_{ij}^n g^{jk})$.

Definition 4.3.10

The determinant $K := \det L$ is called the *Gauß-Kronecker curvature*[14] of M (resp. f). The arithmetic mean $H := \operatorname{tr} L/m$ is called the *mean curvature* of M (resp. f).

If $\kappa_1, \ldots, \kappa_m$ denote the characteristic values of the second fundamental form S_p^n, that is, the eigenvalues of the Weingarten map L_p, then

$$K(p) = \kappa_1 \cdots \kappa_m \quad \text{and} \quad H(p) = (\kappa_1 + \cdots + \kappa_m)/m. \tag{4.56}$$

The sign of H always depends on the choice of n_p, the sign of K does so only when m is odd.

We ought not neglect the important classical case:

Definition 4.3.11

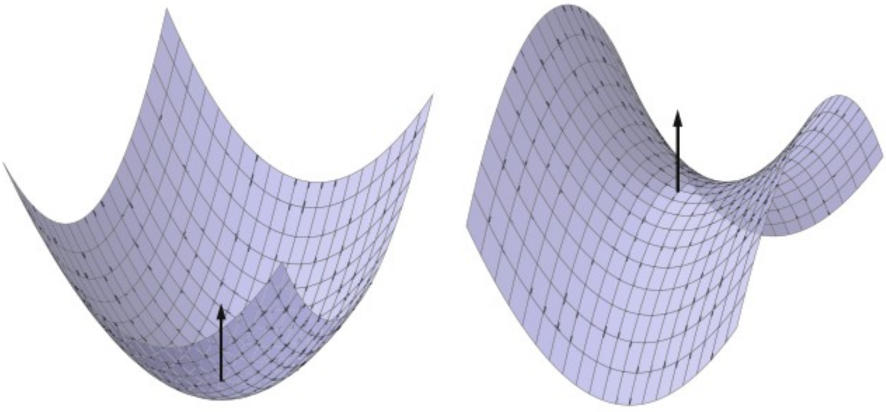
If M is a surface, that is, $m = 2$, then

$$K := \det L = \det(h_{ij}^n)/\det(g_{ij})$$

is called the *Gaußian curvature* of M (resp. f). See ▪ Fig. 4.6.

---

[14] Leopold Kronecker (1823–1891).



$K > 0$ $K < 0$

Fig. 4.6 Positive and negative Gaußian curvature

Example 4.3.12

1) For the *surface of revolution* $f = f(t, \varphi)$ as in Example 4.2.3.2, we have

$$\tilde{n} = (-\dot{h}\cos(\varphi), -\dot{h}\sin(\varphi), \dot{r})$$

in the sense of Example 4.3.8, and $n = \tilde{n}/\|\tilde{n}\|$ is the associated Gauß map of f. The coefficients of the second fundamental form of f, as in (4.48), are

$$h^n_{tt} = \frac{\dot{r}\ddot{h} - \ddot{r}\dot{h}}{\sqrt{\dot{r}^2 + \dot{h}^2}}, \quad h^n_{t\varphi} = h^n_{\varphi t} = 0, \quad h^n_{\varphi\varphi} = \frac{r\dot{h}}{\sqrt{\dot{r}^2 + \dot{h}^2}}.$$

Since the first and second fundamental forms are both in diagonal form, meridians and lines of latitude are lines of curvature. The corresponding principal curvatures are

$$\kappa_t = \frac{\dot{r}\ddot{h} - \ddot{r}\dot{h}}{(\dot{r}^2 + \dot{h}^2)^{3/2}} \quad \text{and} \quad \kappa_\varphi = \frac{\dot{h}}{r\sqrt{\dot{r}^2 + \dot{h}^2}}.$$

If the profile curve is parameterized by arc length, then the Gaußian curvature is $K = -\ddot{r}/r$.

2) For the *generalized helicoid* $f = f(t, \varphi)$ as in Example 4.2.3.3,

$$\tilde{n} = (a\dot{x}\sin\varphi + a\dot{y}\cos\varphi, -a\dot{x}\cos\varphi + a\dot{y}\sin\varphi, x\dot{x} + y\dot{y})$$

in the sense of Example 4.3.8, and $n = \tilde{n}/\|\tilde{n}\|$ is the associated Gauß map of f. Therefore,

$$h^n_{tt} = a\frac{\dot{y}\ddot{x} - \dot{x}\ddot{y}}{\|\tilde{n}\|}, \quad h^n_{t\varphi} = h^n_{\varphi t} = -a\frac{\dot{x}^2 + \dot{y}^2}{\|\tilde{n}\|}, \quad h^n_{\varphi\varphi} = a\frac{\dot{x}y - x\dot{y}}{\|\tilde{n}\|}$$

with $\|\tilde{n}\|^2 = a^2(\dot{x}^2 + \dot{y}^2) + (x\dot{x} + y\dot{y})^2$. The formula for the Gaußian curvature is somewhat long, and so will not be written out here.

3) For the *ruled surface* $f = f(s, t)$ as in Example 4.2.3.4, $\tilde{n} = X \times (\dot{c} + s\dot{X})$ in the sense of Example 4.3.8, and $n = \tilde{n}/\|\tilde{n}\|$ is the associated Gauß map of f. Therefore,

$$h^n_{ss} = 0, \quad h^n_{st} = h^n_{ts} = \frac{\langle \dot{X}, X \times \dot{c}\rangle}{\|\tilde{n}\|}, \quad \text{and} \quad h^n_{tt} = \frac{\langle \ddot{c} + s\ddot{X}, X \times (\dot{c} + s\dot{X})\rangle}{\|\tilde{n}\|}.$$

Since $h^n_{ss} = 0$, the Gaußian curvature K is non-positive.

■

Definition 4.3.13

A point $p \in M$ is called an *umbilic point*, if the function $S^n_p(v, v)$ is constant, where v runs through the unit vectors in T_pM.

Clearly, $p \in M$ is an umbilic point if and only if the Weingarten map L_p is a multiple of the identity or, equivalently by (4.54), if $dn(p)$ is a multiple of $df(p)$.

Proposition 4.3.14 *If M is connected, $m \geq 2$, and all points in M are umbilic, then the image of f is contained in an affine hyperplane or a sphere.*

Proof

Since all points in M are umbilic, there is, by (4.54), a smooth function λ on M with $dn = \lambda\, df$. Now let (U, x) be a chart on M with U connected. Then $\partial n/\partial x^i = \lambda\, \partial f/\partial x^i$, and therefore

$$\frac{\partial\lambda}{\partial x^i}\frac{\partial f}{\partial x^j} + \lambda\frac{\partial^2 f}{\partial x^i \partial x^j} = \frac{\partial^2 n}{\partial x^i \partial x^j} = \frac{\partial^2 n}{\partial x^j \partial x^i} = \frac{\partial\lambda}{\partial x^j}\frac{\partial f}{\partial x^i} + \lambda\frac{\partial^2 f}{\partial x^j \partial x^i}.$$

Since the second terms on the left and right are equal, the first terms are as well. For $i \neq j$, however, $\partial f/\partial x^i$ and $\partial f/\partial x^j$ are linearly independent. Since $m \geq 2$, it therefore follows that the partial derivatives of λ vanish, so λ is constant on U.

For $\lambda = 0$ it follows that n is constant on U. Then the image of U under f is contained in an affine hyperplane of $\mathbb{R}^{m+1}$. For $\lambda \neq 0$ it follows that $f - n/\lambda = x_0 =$ constant on U. Since $\|n\| = 1$, we therefore obtain that $\|f - x_0\| = 1/|\lambda|$ on U. This shows the claim in the case $M = U$. But M is connected, so the claim follows. □

Affine planes in $\mathbb{R}^3$ and cylinders over regular plane curves are surfaces in space with vanishing Gaußian curvature. With an appropriate parameterization, one can (clearly) even ensure that their first fundamental forms have constant coefficients δ_{ij}. Consequently, the first fundamental form by no means determines the external appearance of a surface in space. Generalized helicoids provide an interesting example of this.

Example 4.3.15

Let $f = f(t,\varphi)$ be a generalized helicoid as in Example 4.2.3.3. We will show that—up to a t-dependent shift in the φ-parameter (that is, a diffeomorphism of the parameter domain)—there is a surface of revolution with the same first fundamental form. We first consider surfaces of the form

$$\tilde{f}(t,\varphi) = f(t, \varphi + \alpha(t)).$$

The partial derivatives of $\tilde{f}$ are

$$\begin{aligned}\frac{\partial \tilde{f}}{\partial t}(t,\varphi) &= \frac{\partial f}{\partial t}(t, \varphi + \alpha) + \frac{\partial f}{\partial \varphi}(t, \varphi + \alpha)\,\dot{\alpha},\\ \frac{\partial \tilde{f}}{\partial \varphi}(t,\varphi) &= \frac{\partial f}{\partial \varphi}(t, \varphi + \alpha).\end{aligned}$$

With x, y, and a as in Example 4.2.3.3, the coefficients of the first fundamental form of $\tilde{f}$ can be computed to be

$$\begin{aligned}\tilde{g}_{tt} &= \dot{x}^2 + \dot{y}^2 + 2(x\dot{y} - \dot{x}y)\,\dot{\alpha} + (x^2 + y^2 + a^2)\,\dot{\alpha}^2,\\ \tilde{g}_{t\varphi} = \tilde{g}_{\varphi t} &= x\dot{y} - \dot{x}y + (x^2 + y^2 + a^2)\,\dot{\alpha},\\ \tilde{g}_{\varphi\varphi} &= x^2 + y^2 + a^2.\end{aligned}$$

Now the first fundamental form of $\tilde{f}$ ought to also be that of a surface of revolution. Therefore, we must have $\tilde{g}_{t\varphi} = \tilde{g}_{\varphi t} = 0$ and $\tilde{g}_{\varphi\varphi} = r^2$, where the profile curve of the surface of revolution as in Example 4.2.3.2 is given by radius r and height h. So we must have

$$\dot{\alpha} = \frac{\dot{x}y - x\dot{y}}{r^2} \quad \text{with} \quad r = \sqrt{x^2 + y^2 + a^2}$$

and

$$\frac{(x\dot{x} + y\dot{y})^2}{r^2} + \dot{h}^2 = \dot{r}^2 + \dot{h}^2 = \tilde{g}_{tt} = \dot{x}^2 + \dot{y}^2 - \frac{(x\dot{y} - \dot{x}y)^2}{r^2}.$$

It therefore follows that

$$\dot{h} = \pm\frac{a}{r}\sqrt{\dot{x}^2 + \dot{y}^2}, \quad \text{so} \quad h = \pm\int \frac{a}{r}\sqrt{\dot{x}^2 + \dot{y}^2}.$$

We are free to choose the sign and constant of integration of h. Geometrically, these choices correspond to a reflection or a translation in the z-direction respectively. The constant of integration of α can also be chosen freely.

We can also assume that the profile curve of f is parameterized by arc length. Then

$$h = \pm\int \frac{a}{r}\,dt.$$

;. :5:6 +* *3 $ @. .

For the helicoid $f = (t\cos\varphi, t\sin\varphi, 1)$, we obtain (with appropriate choices)

$$r(t) = \sqrt{t^2+1} \quad \text{and} \quad h(t) = \operatorname{arcsinh} t.$$

So the corresponding surface of revolution, $t = \sinh h$ and $r = \cosh h$, is a catenoid. ■

4.4 Gauß Equations and the Theorema Egregium

We now return to the covariant derivative.

Definition 4.4.1

For $Y \in \mathcal{V}(M)$, the *covariant derivative* of Y in the direction $v \in T_pM$ is the unique tangent vector $\nabla_v Y \in T_pM$ with

$$df \circ \nabla_v Y = [v(Yf)]^T = [d(Yf)(v)]^T.$$

For $X \in \mathcal{V}(M)$, the covariant derivative of Y in the direction of X is correspondingly given by $(\nabla_X Y)(p) := \nabla_{X(p)} Y = [(XYf)(p)]^T$.

Let $p \in M$ and (U, x) be a chart on M about p. Let $v = \xi^i\,\partial/\partial x^i(p)$ and $Y = \eta^i\,\partial/\partial x^i$ be a smooth vector field on U. Then $Yf = \eta^i\,\partial f/\partial x^i$ and so

$$v(Yf) = v(\eta^i)\frac{\partial f}{\partial x^i}(p) + \xi^i\eta^j(p)\frac{\partial^2 f}{\partial x^i \partial x^j}(p).$$

By the definition of the Christoffel symbols, therefore,

$$\nabla_v Y = \left(v(\eta^k) + \Gamma^k_{ij}(p)\xi^i\eta^j(p)\right)\frac{\partial}{\partial x^k}(p), \tag{4.57}$$

see (4.37). If X is a smooth vector field on U with $X = \xi^i\,\partial/\partial x^i$, then correspondingly

$$\nabla_X Y = \left(X\eta^k + \Gamma^k_{ij}\xi^i\eta^j\right)\frac{\partial}{\partial x^k}. \tag{4.58}$$

We see that $\nabla_X Y$ is again a smooth vector field.

Corollary 4.4.2

1. *If Y is a smooth vector field on M and $c\colon I \longrightarrow M$ is a smooth curve with $\dot c(t_0) =: v \in T_pM$, then $Y \circ c$ is a smooth vector field along c with $(Y \circ c)'(t_0) = \nabla_v Y$.*
2. *If X and Y are smooth vector fields on M, then*

$$XYf = [XYf]^T + [XYf]^N = df \circ \nabla_X Y + S(X, Y). \tag{4.59}$$

Proof

The first claim follows directly from (4.38) and (4.57), the second from Proposition 4.3.5 and Definition 4.4.1. □

With (4.58), we see that the covariant derivative $\nabla_X Y$ with respect to a chart corresponds to the usual derivative of the coefficients of Y in the direction of X up to a correction term of order 0. Furthermore, Proposition 4.2.23 shows us that the covariant derivative belongs to the interior geometry of M.

Proposition 4.4.3 *For the map* $\nabla\colon \mathcal{V}(M)\times\mathcal{V}(M)\longrightarrow\mathcal{V}(M)$, $(X, Y)\mapsto \nabla_X Y$, *the following hold:*

1. ∇ *is bilinear, that is,* $\mathbb{R}$*-linear in both* X *and* Y.
2. *For all* $\varphi \in \mathcal{F}(M)$, $\nabla_{\varphi X} Y = \varphi\nabla_X Y$ *and* $\nabla_X(\varphi Y) = X(\varphi)Y + \varphi\nabla_X Y$.
3. ∇ *is* symmetric*:* $\nabla_X Y - \nabla_Y X = [X, Y]$.
4. ∇ *is* metric *(product rule):* $X\langle Y, Z\rangle = \langle\nabla_X Y, Z\rangle + \langle Y, \nabla_X Z\rangle$.

Proof

The first two assertions follow from (4.58). By the symmetry of the second fundamental form and (4.59),

$$\begin{aligned} df\circ[X, Y] &= [X, Y]f = XYf - YXf \\ &= df\circ\nabla_X Y - df\circ\nabla_Y X = df\circ(\nabla_X Y - \nabla_Y X). \end{aligned}$$

Assertion 3 follows. The product rule follows from Proposition 4.2.18.3 together with Corollary 4.4.2.1. □

A map $\nabla\colon \mathcal{V}(M)\times\mathcal{V}(M)\longrightarrow\mathcal{V}(M)$ that satisfies the first two conditions of Proposition 4.4.3 is called a *connection* or sometimes a *covariant derivative* on M. The special connection from Definition 4.4.1 is called the *Levi-Civita connection* of M (resp. f). It is distinguished among all connections on M by the last two conditions in Proposition 4.4.3.

We next discuss the *Riemann curvature tensor*,[15]

$$R(X, Y)Z := \nabla_X\nabla_Y Z - \nabla_Y\nabla_X Z - \nabla_{[X,Y]}Z, \tag{4.60}$$

a further object of interior geometry. Patient computation yields the following formula for vector fields X, Y, Z on the domain U of a chart x on M:

$$R(X, Y)Z = \left\{\partial\Gamma^l_{jk}/\partial x^i - \partial\Gamma^l_{ik}/\partial x^j + \Gamma^l_{i\nu}\Gamma^\nu_{jk} - \Gamma^l_{j\nu}\Gamma^\nu_{ik}\right\}\xi^i\eta^j\zeta^k\frac{\partial}{\partial x^l}. \tag{4.61}$$

We see that R is pointwise linear in each of the coefficients ξ^i, η^j, and ζ^k of X, Y, and Z, and no derivatives of these coefficients appear. This justifies the designation of R as a tensor.

---

[15] Georg Friedrich Bernhard Riemann (1826–1866).

Proof

The first claim follows directly from (4.38) and (4.57), the second from Proposition 4.3.5 and Definition 4.4.1. □

With (4.58), we see that the covariant derivative $\nabla_X Y$ with respect to a chart corresponds to the usual derivative of the coefficients of Y in the direction of X up to a correction term of order 0. Furthermore, Proposition 4.2.23 shows us that the covariant derivative belongs to the interior geometry of M.

Proposition 4.4.3 *For the map $\nabla\colon \mathcal{V}(M)\times\mathcal{V}(M)\longrightarrow\mathcal{V}(M)$, $(X, Y)\mapsto \nabla_X Y$, the following hold:*

1. *∇ is bilinear, that is, $\mathbb{R}$-linear in both X and Y.*
2. *For all $\varphi \in \mathcal{F}(M)$, $\nabla_{\varphi X} Y = \varphi\nabla_X Y$ and $\nabla_X(\varphi Y) = X(\varphi)Y + \varphi\nabla_X Y$.*
3. *∇ is* symmetric*: $\nabla_X Y - \nabla_Y X = [X, Y]$.*
4. *∇ is* metric *(product rule): $X\langle Y, Z\rangle = \langle\nabla_X Y, Z\rangle + \langle Y, \nabla_X Z\rangle$.*

Proof

The first two assertions follow from (4.58). By the symmetry of the second fundamental form and (4.59),

$$\begin{aligned} df \circ [X, Y] &= [X, Y]f = XYf - YXf \\ &= df \circ \nabla_X Y - df \circ \nabla_Y X = df \circ (\nabla_X Y - \nabla_Y X). \end{aligned}$$

Assertion 3 follows. The product rule follows from Proposition 4.2.18.3 together with Corollary 4.4.2.1. □

A map $\nabla\colon \mathcal{V}(M)\times\mathcal{V}(M)\longrightarrow\mathcal{V}(M)$ that satisfies the first two conditions of Proposition 4.4.3 is called a *connection* or sometimes a *covariant derivative* on M. We next discuss the *Riemann curvature tensor*,[15]

$$R(X, Y)Z := \nabla_X\nabla_Y Z - \nabla_Y\nabla_X Z - \nabla_{[X,Y]}Z, \tag{4.60}$$

a further object of interior geometry. Patient computation yields the following formula for vector fields X, Y, Z on the domain U of a chart x on M:

$$R(X, Y)Z = \left\{\partial\Gamma^l_{jk}/\partial x^i - \partial\Gamma^l_{ik}/\partial x^j + \Gamma^l_{i\nu}\Gamma^\nu_{jk} - \Gamma^l_{j\nu}\Gamma^\nu_{ik}\right\}\xi^i\eta^j\zeta^k\frac{\partial}{\partial x^l}. \tag{4.61}$$

We see that R is pointwise linear in each of the coefficients ξ^i, η^j, and ζ^k of X, Y, and Z, and no derivatives of these coefficients appear. This justifies the designation of R as a tensor.

---

[15] Georg Friedrich Bernhard Riemann (1826–1866).

Proposition 4.4.4 (Gauß Equations) *For vector fields X, Y, V, W on M,*

$$\langle R(X,Y)V, W\rangle = \langle S(X,W), S(Y,V)\rangle - \langle S(X,V), S(Y,W)\rangle.$$

Proof

Since Vf is a map to the vector space $\mathbb{R}^n$,

$$XYVf - YXVf = [X,Y]Vf.$$

With (4.59) and Proposition 4.4.3.4, we obtain

$$\begin{aligned}\langle XYVf, Wf\rangle &= X\langle YVf, Wf\rangle - \langle YVf, XWf\rangle \\ &= X\langle [YVf]^T, Wf\rangle - \langle [YVf]^T, [XWf]^T\rangle - \langle [YVf]^N, [XWf]^N\rangle \\ &= X\langle \nabla_X Y, W\rangle - \langle \nabla_Y V, \nabla_X W\rangle - \langle S(Y,V), S(X,W)\rangle \\ &= \langle \nabla_X \nabla_Y V, W\rangle - \langle S(Y,V), S(X,W)\rangle,\end{aligned}$$

and analogously, $\langle YXVf, Wf\rangle = \langle \nabla_Y \nabla_X V, W\rangle - \langle S(X,V), S(Y,W)\rangle$. Finally, by (4.59), it further holds that

$$\langle [X,Y]Vf, Wf\rangle = \langle df \circ \nabla_{[X,Y]}V + S([X,Y],V), Wf\rangle = \langle \nabla_{[X,Y]}V, W\rangle.$$

Altogether, we obtain

$$\begin{aligned}0 &= \langle XYVf - YXVf - [X,Y]Vf, Wf\rangle \\ &= \langle \nabla_X\nabla_Y V - \nabla_Y\nabla_X V - \nabla_{[X,Y]}V, W\rangle \\ &\qquad - \langle S(Y,V), S(X,W)\rangle + \langle S(X,V), S(Y,W)\rangle \\ &= \langle R(X,Y)V, W\rangle - \langle S(Y,V), S(X,W)\rangle + \langle S(X,V), S(Y,W)\rangle. \qquad \square\end{aligned}$$

Proposition 4.4.4 contains, in a more general form, one of the fundamental geometric insights of Gauß, namely, that the Gaußian curvature, defined with the aid of the second fundamental form, is a quantity belonging to interior geometry. In our formulation, Gauß's insight[16] reads as follows:

Theorema Egregium 4.4.5 (Gauß (1827)) *Let M be a surface and $f\colon M \longrightarrow \mathbb{R}^3$ be an immersion. Let $p \in M$, and let $v, w \in T_pM$ be linearly independent. Then*

$$K(p) = \frac{\langle R(v,w)w, v\rangle}{\|v^2\|\|w\|^2 - \langle v,w\rangle^2}.$$

---

[16] Gauß called this insight the *Theorema Egregium*, meaning "remarkable theorem". The word "egregium" is related etymologically to the word "egregious".

Proof

By Proposition 4.4.4, it follows that $\langle R(v,w)w,v\rangle = S^n_p(v,v)S^n_p(w,w) - S^n_p(v,w)^2$, independently of the choice of a normal vector n_p at p. Therefore, the right-hand side of the asserted equality becomes

$$\frac{S^n_p(v,v)S^n_p(w,w) - S^n_p(v,w)^2}{\|v\|^2\|w\|^2 - \langle v,w\rangle^2}.$$

The number does not depend on the choice of v and w, as long as v and w are linearly independent. We can, for example, choose a chart x around p, and set $v = (\partial/\partial x^1)(p)$ and $w = (\partial/\partial x^2)(p)$. Then

$$\begin{aligned}\frac{S^n_p(v,v)S^n_p(w,w) - S^n_p(v,w)^2}{\|v^2\|\|w\|^2 - \langle v,w\rangle^2} &= \frac{h^n_{11}h^n_{22} - (h^n_{12})^2}{g_{11}g_{22} - g^2_{12}}(p)\\ &= \det(h^n_{ik}g^{kj})(p) = K(p).\end{aligned}$$ □

More generally, the terms on the right-hand side of the equation in Proposition 4.4.4 coming from the second fundamental form are quantities belonging to interior geometry, since the Riemann curvature tensor is. Among these quantities is the *sectional curvature*, introduced by Riemann, that associates a curvature to tangent planes to M: if $p \in M$, P is a linear 2-dimensional subspace of T_pM, and (v, w) is a basis of P, then

$$K(P) := \frac{\langle R(v,w)w,v\rangle}{\|v^2\|\|w\|^2 - \langle v,w\rangle^2} \tag{4.62}$$

is the sectional curvature of P. This generalizes the Gaußian curvature and was introduced by Riemann in his famous Habilitation[17] lecture (1854) before he had defined his curvature tensor.

In the following examples we replace $\mathbb{R}^n$ by a general finite-dimensional Euclidean vector space W. By means of an orthonormal transformation, we can then identify W with $\mathbb{R}^{\dim W}$ and, accordingly, use the previous concepts and results with W as our ambient space.

Example 4.4.6

Let $\mathbb{K} \in \{\mathbb{R}, \mathbb{C}, \mathbb{H}\}$ and V be an n-dimensional vector space over $\mathbb{K}$ together with a positive definite sesquilinear form, denoted by (v, w). After a choice of an orthonormal basis, $V \cong \mathbb{K}^n$ with sesquilinear form $(x, y) = \sum \bar{x}_i y_i$.

1) Let $G = \{A \in \mathrm{End}(V) \mid A^*A = \mathrm{id}\}$ be the Lie group of all endomorphisms which preserve the sesquilinear form on V. In Example 2.3.8.3 we saw, modulo the

---

[17] In the German-speaking world, a Habilitation is a post-doctoral qualification necessary to teach at the university level.

identification of V with $\mathbb{K}^n$ seen as a Euclidean space, that G is a submanifold of $W = \mathrm{End}(V)$ with

$$T_E G = \{C \in \mathrm{End}(V) \mid C^* = -C\}. \tag{4.63}$$

The real part of the sesquilinear form $(A, B) := \mathrm{tr}(A^* B)$ is a scalar product on $\mathrm{End}(V) \cong \mathbb{R}^{dn \times n}$, $d = \dim_{\mathbb{R}} \mathbb{K}$. The corresponding orthogonal complement of $T_E G$ in $\mathrm{End}(V)$ is

$$N_E G = H(V) = \{C \in \mathrm{End}(V) \mid C^* = C\}. \tag{4.64}$$

For all $A \in G$, $A\, T_E G\, A^{-1} = T_E G$ and $A\, H(V)\, A^{-1} = H(V)$, and left and right translation by A preserve the sesquilinear form on $\mathrm{End}(V)$:

$$(AC, AD) = (CA, DA) = (C, D) = \mathrm{tr}(C^* D)$$

for all $C, D \in \mathrm{End}(V)$. In particular,

$$T_A G = A T_E G = T_E G A \quad \text{and} \quad N_A G = A H(V) = H(V) A. \tag{4.65}$$

For all $A \in G$ and $C \in \mathrm{End}(V)$, it therefore follows that

$$\pi_A^T(AC) = \frac{1}{2} A(C - C^*) \quad \text{and} \quad \pi_A^N(AC) = \frac{1}{2} A(C + C^*). \tag{4.66}$$

The (tangential) left-invariant vector fields on G are of the form $X_C(A) = AC$ with $C \in T_E G$, compare with Exercise 2.7.14.1. Since X_C is the restriction of right multiplication by C to G, and the latter is linear on $\mathrm{End}(V)$,

$$dX_C(A)(AD) = ADC = X_{DC}(A)$$

for all $A \in G$ and $D \in T_E G$. For left invariant vector fields X_C and X_D (with $C, D \in T_E G$), we can use (4.59) to show that

$$dX_D(X_C) = \nabla_{X_C} X_D + S(X_C, X_D) = X_{(CD-DC)/2} + X_{(CD+DC)/2} \tag{4.67}$$

for the covariant derivative and second fundamental form of G. For $B, C, D \in T_E G$, the curvature tensor R of G then becomes

$$R(X_B, X_C) X_D = X_F \quad \text{with} \quad F = -\frac{1}{4}[[B, C], D] \in T_E G. \tag{4.68}$$

Since $B^* = -B$ and $[B, C]^* = -[B, C]$, we therefore obtain

$$\langle R(X_B, X_C) X_C, X_B \rangle = \frac{1}{4} \mathrm{Re}\, \mathrm{tr}([[B, C], C] B) = \frac{1}{4} \|[B, C]\|^2 \tag{4.69}$$

for the sectional curvature of G. In particular, the sectional curvature is non-negative.

Now let $A = A(t) = Be^{tC}$, with $B \in G$, $C \in T_E G$, and let the exponential series be as in Exercise 2.7.6. Then A is a smooth curve in G with

$$\dot{A} = AC \quad \text{and} \quad \ddot{A} = AC^2. \tag{4.70}$$

Now $C^2 \in N_E G$, so $\ddot{A} \in N_A G$. Therefore, A is a geodesic, and so we have characterized all the geodesics of G.

2) Let $G_k(V)$ be the Grassmannian manifold of k-dimensional $\mathbb{K}$-linear subspaces in V as in Example 2.1.15.5. For $P \in G_k(V)$, let $F(P) \colon V \longrightarrow V$ be the orthogonal projection of V onto P with image P and kernel $P^\perp$. If $(e_1, \dots, e_k)$ is an orthonormal basis of P, then

$$F(P)(v) = \sum_{1 \le i \le k} e_i\,(e_i, v). \tag{4.71}$$

We now extend $(e_1, \dots, e_k)$ to an orthonormal basis $E = (e_1, \dots, e_n)$ of V and consider the chart κ_E on $G_k(V)$ around P associated to E as in Example 2.1.15.5. Then for $A = (a_i^\mu) \in \mathbb{K}^{n-k,k}$, $\kappa_E^{-1}(A)$ is the graph of the linear map $P \longrightarrow P^\perp$, $e_i u^i \mapsto e_{k+j} a_i^j u^i$. Therefore,

$$F(\kappa_E^{-1}(A)) = \begin{pmatrix} 1 & 0 \\ A & 0 \end{pmatrix} \begin{pmatrix} 1 & -A^* \\ A & 1 \end{pmatrix}^{-1} \tag{4.72}$$

is the matrix of $F(\kappa_E^{-1}(A))$ with respect to E. In particular, it therefore follows that F is smooth with differential

$$dF(P)(A) = \begin{pmatrix} 0 & A^* \\ A & 0 \end{pmatrix},$$

where $T_P G_k(V)$ is identified with $\mathrm{Hom}(V, V^\perp) \cong \mathbb{K}^{n-k,k}$ as in Example 2.2.3.3. In particular, $F \colon G_k(V) \longrightarrow \mathrm{End}(V)$ is an embedding.

We equip $\mathrm{End}\, V$ with the real part of the sesquilinear form $\mathrm{tr}(X^*Y)$ as a scalar product. Then the first fundamental form of F in P becomes

$$\begin{aligned} \langle A, B \rangle_P &= \langle dF(P)(A), dF(P)(B) \rangle \\ &= \mathrm{Re}(\mathrm{tr}(A^*B) + \mathrm{tr}(AB^*)) = 2\,\mathrm{Re}\,\mathrm{tr}(A^*B). \end{aligned}$$

To determine the geodesics and the second fundamental form, we now write P_0 in place of P. Again let $A \in \mathbb{K}^{n-k,k}$ and

$$P = P(t) = e^{tB} P_0 \quad \text{with} \quad B = \begin{pmatrix} 0 & -A^* \\ A & 0 \end{pmatrix}. \tag{4.73}$$

Then P is a smooth curve in $G_k(V)$ with $P(0) = P_0$ and $\dot{P}(0) = A$. Now $(e^{tB})^* = e^{-tB}$, so the e^{tB} preserve the sesquilinear form $(.,.)$ on V. It therefore follows that

$$F(P(t)) = e^{tB} F(P_0) e^{-tB} = e^{tB} \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} e^{-tB} \tag{4.74}$$

and $T_P F = e^{tB}\, T_{P_0} F\, e^{-tB}$. The second derivative of $F \circ P$ is computed to be

$$\frac{d^2(F \circ P)}{dt^2} = e^{tB} \begin{pmatrix} -2A^*A & 0 \\ 0 & 2AA^* \end{pmatrix} e^{-tB}. \tag{4.75}$$

Therefore, the second derivative of $F \circ P$ is normal to F, so $P = P(t)$ is a geodesic, and so we have characterized all the geodesics of $G_k(V)$. By polarization, we furthermore obtain the second fundamental form F at P_0,

$$S_{P_0}(A, B) = \begin{pmatrix} -A^*B - B^*A & 0 \\ 0 & AB^* + BA^* \end{pmatrix}.$$

Since the $F(P)$ are orthogonal projections onto k-dimensional subspaces of V, $F(P)^* = F(P)$ and $\operatorname{tr}(F(P)) = k$. The image of F therefore lies in a sphere of radius $\sqrt{k}$ in the space of self-adjoint endomorphisms $W = H(V) \subseteq \operatorname{End}(V)$. Thus, the $T_P F$ and the images of the second fundamental forms S_P of F are contained in $H(V)$, and our formulas above show this explicitly.

■

The curvature tensor and sectional curvature are quantities belonging to interior geometry. This is the beginning of Riemannian geometry based on Riemannian metrics, that is, smooth families g_p of scalar products on the T_pM, which are no longer required to be the first fundamental form of a given immersion $M \longrightarrow \mathbb{R}^n$. As in the case of the first fundamental form, one obtains a Levi-Civita connection, a curvature tensor, and the associated sectional curvature, and, armed with these, enters the realm of Riemannian geometry.

4.5 Supplementary Literature

Good sources to round off the discussion in this chapter are [Kl, dC], [Sp2, chapters 1&2], [Sp3, Ho] and [ST]. The more classical [MP] and [St1, St2, St3] are also interesting. In [Ch], introductory articles on many aspects of global differential geometry can be found. Beside these, there are also a number of newer introductions to differential geometry, for example [Bä, EJ, Le], and [Kü].

4.6 Exercises

Exercise 4.6.1

1. The length of a smooth curve $c\colon [a,b] \longrightarrow \mathbb{R}^n$ is invariant under monotone reparameterization: If $\varphi\colon [\alpha,\beta] \longrightarrow [a,b]$ is monotone, surjective, and smooth, then $L(c \circ \varphi) = L(c)$.
2. Show that analogues of the statements about length and energy in the corresponding part of ▶ Sect. 4.1 hold for piecewise smooth curves (as in (3.4)).
3. Let $c\colon [a,b] \longrightarrow \mathbb{R}^n$ be a piecewise smooth curve. For subdivisions

$$U : a = t_0 < \cdots < t_k = b$$

of $[a,b]$, let $\delta(U) = \max(t_i - t_{i-1})$ and $L(U)$ be the length of the piecewise linear curve with corners at $c(t_0), c(t_1), \dots, c(t_k)$. Show: if (U_n) is a sequence of subdivisions of $[a,b]$ with $\delta(U_n) \longrightarrow 0$, then $L(U_n) \longrightarrow L(c)$.

4. Let $c\colon [0,\infty) \longrightarrow \mathbb{R}^2$ be a smooth curve of the form $c(t) = (t, y(t))$. If $\dot{y}(t)$ converges for $t \to \infty$, then $\lim_{t\to\infty} L(c|_{[0,t]})/\|(t,y(t)) - (0,y(0))\| = 1$. ■

Exercise 4.6.2

Compute the speed and curvature of the curves $c\colon \mathbb{R} \longrightarrow \mathbb{R}^2$ given by

1. $c(t) = (t, t^k)$ with $k \geq 0$ and, more generally, $c(t) = (t, f(t))$;
2. $c(t) = \exp(t)(\cos t, \sin t)$ and, more generally, $c(t) = f(t)(\cos t, \sin t)$ with $f > 0$;
3. $c(t) = (a\cos t, b\sin t)$.

Sketch each curve or curve type. ■

Exercise 4.6.3

Let $c\colon I \longrightarrow \mathbb{R}^n$ be a regular curve with curvature κ.

1. If the image of c lies in a circle K of radius R, then, for all $t \in I$, K is the osculating circle of c and $\kappa \equiv 1/R$.
2. The image of c lies in a line if and only if κ vanishes.
3. For $x \in \mathbb{R}^n$, suppose the function $r = r(t) = \|c(t) - x\|$ has a relative maximum at $t_0 \in I$. Then $\kappa(t_0) = 1/R(t_0) \geq 1/r(t_0)$.
4. If $\varphi\colon J \longrightarrow I$ is a change of parameters, then $\tilde{\kappa} = \kappa \circ \varphi$, where $\tilde{\kappa}$ denotes the curvature of the curve $\tilde{c} := c \circ \varphi$.
5. If $B : \mathbb{R}^n \longrightarrow \mathbb{R}^n$ is a motion, then the curve $B \circ c$ has the same speed and curvature as c.

■

Exercise 4.6.4

Let $c\colon I \longrightarrow \mathbb{R}^2$ be a regular plane curve.

1. If $\varphi\colon J \longrightarrow I$ is a change of parameters with $\dot{\varphi} > 0$, then $\tilde{\kappa}_o = \kappa_o \circ \varphi$, where $\tilde{\kappa}_o$ denotes the oriented curvature of $\tilde{c} := c \circ \varphi$.
2. If $B : \mathbb{R}^2 \longrightarrow \mathbb{R}^2$ is an orientation-preserving motion, then the regular plane curve $B \circ c$ has the same oriented curvature as c.

■

Exercise 4.6.5

In the following, let $c\colon I \longrightarrow \mathbb{R}^2$ be a regular plane curve with field of directions e, principal normal field n and oriented curvature κ_o.

1. If $c+n$ is constant, then c moves along a circle of radius 1.
2. If $\kappa_o(t) \neq 0$ for all $t \in I$, then the curve $a = a(t) = c(t) + n(t)/\kappa_o(t)$ sending t to the center of curvature of c at t is called the *evolute* of c. Compute e, n, κ_o, and a for the parabola (t, t^2) and the catenary $(t, \cosh t)$.
3. Let $\kappa_o(t) \neq 0$ for all $t \in I$ and a be the evolute of c. Show that $\dot{a}(t)$ is a multiple of $n(t)$ for all $t \in I$ and conclude that, for all points where it is defined, the tangent to the evolute intersects the curve c perpendicularly at $c(t)$. For $s < t$ in I, compute the length of the arc $a|_{[s,t]}$ of the evolute, and compare it with the radius of curvature of c at s and t.
4. Again let $\kappa_o(t) \neq 0$ for all $t \in I$ and c be parameterized by arc length for simplicity. For $\beta \in \mathbb{R} \setminus I$, we then call $b = b(t) = c(t) + (\beta - t)\dot{c}(t)$, $t \in I$, the *evolvent* of c. One can image b as the endpoint of a thread wound tautly around c. Compute the field of directions, the principal normal field, and the curvature of b, and conclude that the curve c is the evolute of its evolvent.

■

Exercise 4.6.6

Compute the field of directions, principal normal field, and binormal field of the *helix* $c\colon \mathbb{R} \longrightarrow \mathbb{R}^3$, $c(t) = (r\cos t, r\sin t, ht)$ with $r, h \in \mathbb{R}$, $r > 0$. Show that the speed, curvature, and torsion of the helix are given by

$$\|\dot{c}(t)\| = \sqrt{r^2+h^2}, \quad \kappa(t) = \frac{r}{r^2+h^2}, \quad \text{and} \quad \tau(t) = \frac{h}{r^2+h^2},$$

and are therefore, in particular, constant. Up to reparameterization and motions we therefore obtain all space curves with constant curvature $\kappa > 0$ and torsion τ. Also verify that the helix is a *generalized helix*, that is, that $\dot{c}$ and the z-axis enclose a constant angle. ■

Exercise 4.6.7

Let $c\colon I \longrightarrow \mathbb{R}^3$ be a smooth space curve such that $\dot{c}(t)$ and $\ddot{c}(t)$ are linearly independent for all $t \in I$.

1. The curvature and torsion of c are given by

$$\kappa(t) = \frac{\|\dot{c}(t) \times \ddot{c}(t)\|}{\|\dot{c}(t)\|^3} \quad \text{and} \quad \tau(t) = \frac{\det(\dot{c}(t), \ddot{c}(t), \dddot{c}(t))}{\|\dot{c}(t) \times \ddot{c}(t)\|^2}.$$

2. The image of c lies in an affine plane in $\mathbb{R}^3$ if and only if the torsion of c vanishes.
3. If c is parameterized by arc length and $t_0 = 0 \in I$, then

$$c(t) = c(0) + \big(t - \frac{t^3}{6}\kappa_0^2\big)e_0 + \big(\frac{t^2}{2}\kappa_0 + \frac{t^3}{6}\dot{\kappa}_0\big)n_0 + \frac{t^3}{6}\kappa_0\tau_0 b_0 + o(t^3),$$

   where in each case the index 0 denotes the value at 0. Sketch the projections of c onto the *osculating*, *normal*, and *rectifying planes* of c at $t=0$, that is, the planes spanned by the pairs of vectors (e_0, n_0), (n_0, b_0), and (e_0, b_0) respectively.

■

Exercise 4.6.8 (Concerning Definition 4.1.13)

1. Determine the parallel normal fields along a regular space curve with vanishing torsion.
2. Determine the parallel normal fields along the helix; see Example 4.1.18 and Exercise 4.6.6.

■

Exercise 4.6.9

1. Write $S^2 \setminus \{(0, 0, \pm 1)\}$ as a surface of revolution.
2. Write the one-sheeted *hyperboloid* $x^2 + y^2 - z^2 = 1$ as a surface of revolution and—in two different ways—as a ruled surface.
3. Represent the Möbius strip as a ruled surface.

■

Exercise 4.6.10

Let $c = (r, h) : I \longrightarrow \mathbb{R}^2$ be the profile curve of a surface of revolution $f = f(t, \varphi)$ as in Example 4.2.3.2. Show that one can reparameterize c so that

(a) $g_{tt} \equiv 1$, or

(b) $g_{tt} = g_{\varphi\varphi}$, or

(c) $g_{tt} g_{\varphi\varphi} = 1$.

In each case, we have $g_{t\varphi} = g_{\varphi t} = 0$. Therefore f (or more precisely $df(t, \varphi)$ for all $(t, \varphi) \in I \times \mathbb{R}$) is *angle-preserving* or *conformal* in case b), and is *area-preserving* in case c).

■

Exercise 4.6.11

The *gradient* of a smooth function φ on M is the vector field grad φ, such that $\langle \operatorname{grad} \varphi(p), v\rangle = d\varphi(p)(v)$ for all p in M and $v \in T_pM$. Show: With respect to a chart (U, x) on M,

$$\operatorname{grad} \varphi = g^{ij} \frac{\partial \varphi}{\partial x^i} \frac{\partial}{\partial x^j} \quad \text{on } U. \tag{4.76}$$

■

Exercise 4.6.12

1. For a geodesic c, $\|\dot{c}\|$ is constant.
2. Up to reparameterization, the meridians of surfaces of revolution are geodesics. Under what conditions on the profile curve are they geodesics? Which latitudes are geodesics?
3. For $x, y \in \mathbb{R}^{m+1}$ such that $\|x\| = \|y\| = 1$ and $\langle x, y\rangle = 0$, the curve $c(t) = r\cos(t)x + r\sin(t)y$, $t \in \mathbb{R}$, is a geodesic on the sphere S^m_r as in Example 4.2.1.2. Up to reparameterization, every geodesic on S^m_r is of this form.
4. Let $c\colon I \longrightarrow \mathbb{R}^3$ be a space curve such that $\dot{c}$ and $\ddot{c}$ are pointwise linearly independent, and let $f = f(s, t) = c(t) + sb(t)$ be the ruled surface spanned by c and the binormal field b of c. Show: f is an immersion of $M = \mathbb{R} \times I$, and the curve $(t, 0)$, $t \in I$, is a geodesic in M.

■

Exercise 4.6.13

1. For a regular curve $c\colon I \longrightarrow M$ with field of directions $e := \dot{c}/\|\dot{c}\|$ in M, we call $\|\nabla\dot{c}/dt - \langle e, \nabla\dot{c}/dt\rangle e\|/\|\dot{c}\|^2$ the *geodesic curvature* of c; compare with (4.4). Show: Up to reparameterization c is a geodesic if and only if the geodesic curvature of c vanishes.
2. Let $f\colon M \longrightarrow \mathbb{R}^n$ be an immersion of the surface M and $c\colon I \longrightarrow M$ be a regular curve. Let n be one of the two vector fields along c with $\langle \dot{c}, n\rangle = 0$ and constant norm 1. The corresponding oriented geodesic curvature of c is then $\kappa_o := \langle \nabla\dot{c}/dt, n\rangle/\|\dot{c}\|^2$ with $e = \dot{c}/\|\dot{c}\|$. Prove that

$$\nabla e/dt = \|\dot{c}\|\kappa_o n \quad \text{and} \quad \nabla n/dt = -\|\dot{c}\|\kappa_o e.$$

3. Determine the oriented geodesic curvature of the latitudes of a surface of revolution as in Example 4.2.3.2. Discuss the special case of spheres.

■

Exercise 4.6.14

1. Let $M \subseteq \mathbb{R}^n$ be a linear subspace and let $c\colon I \longrightarrow M$ be a smooth curve. Show: A vector field $X\colon I \longrightarrow M$ along c is parallel in the sense of Definition 4.2.16 if and only if it is parallel in the usual sense.
2. Verify with the use of (4.37) that, with respect to the coordinates (t, φ), the Christoffel symbols of the surface of revolution with profile curve $c = (r, h)$ are given by

$$\Gamma^t_{tt} = \frac{\dot{r}\ddot{r} + \dot{h}\ddot{h}}{\|\dot{c}\|^2}, \quad \Gamma^t_{\varphi\varphi} = -\frac{r\dot{r}}{\|\dot{c}\|^2}, \quad \Gamma^\varphi_{\varphi t} = \Gamma^\varphi_{t\varphi} = \frac{\dot{r}}{r}$$

and $\Gamma^\varphi_{tt} = \Gamma^\varphi_{\varphi\varphi} = \Gamma^t_{\varphi t} = \Gamma^t_{t\varphi} = 0$. List the covariant derivatives of the basis fields $\partial/\partial t$ and $\partial/\partial\varphi$ as vector fields along the meridians and latitudes. Determine the space of parallel vector fields along these curves. Discuss the special case of spheres.
3. If the first fundamental form of an immersion $f\colon M \longrightarrow \mathbb{R}^n$ is in diagonal form with respect to a chart (U, x) on M, that is, if $g_{ij} \equiv 0$ for $i \neq j$, then $g^{ii} = g_{ii}^{-1}$, $g^{ij} = 0$ for $i \neq j$ and therefore

$$\Gamma^k_{ik} = \frac{1}{2g_{kk}}\frac{\partial g_{kk}}{\partial x^i} \quad \text{and, for } i \neq k, \quad \Gamma^k_{ii} = \frac{-1}{2g_{kk}}\frac{\partial g_{ii}}{\partial x^k}.$$

■

Exercise 4.6.15

Let $f\colon M \longrightarrow \mathbb{R}^3$ be an immersed surface together with a Gauß map $n\colon M \longrightarrow S^2$.

1. A smooth curve $c\colon I \longrightarrow M$ is a line of curvature if and only if there is a smooth function $\lambda\colon I \longrightarrow \mathbb{R}$ with $dn \circ \dot{c} = \lambda \cdot df \circ \dot{c}$.
2. (Joachimsthal's Theorem[18]) For $f_1\colon M_1 \longrightarrow \mathbb{R}^3$ and $f_2\colon M_2 \longrightarrow \mathbb{R}^3$, let c_1 in M_1 and c_2 in M_2 be curves with $f_1 \circ c_1 = f_2 \circ c_2 =: c$. Further let the intersection of f_1 and

---

[18] Ferdinand Joachimsthal (1818–1861).

f_2 along c be transversal, that is, $T_{c_1(t)}f_1 \neq T_{c_2(t)}f_2$ for all t. Show each two of the following statements implies the third:

(a) c_1 is a line of curvature;
(b) c_2 is a line of curvature;
(c) f_1 and f_2 intersect at a fixed angle along c.

3. We call $v \in T_pM$, $v \neq 0$, an *asymptotic direction* if $S^n_p(v, v) = 0$. Regular curves $c: I \longrightarrow M$, such that $\dot{c}(t)$ is an asymptotic direction for all $t \in I$, are called *asymptotes*. Check that the s-parameter lines on the ruled surface as in Example 4.3.12.3 are asymptotes. Note that $K(p) \leq 0$ if T_pM contains an asymptotic direction and that, up to collinearity, there are two asymptotic directions at p if $K(p) < 0$. ■

Exercise 4.6.16

1. The *catenoid* is the surface of revolution generated by the catenary,

$$f = f(t, \varphi) = (\cosh t \cos \varphi, \cosh t \sin \varphi, t).$$

Compare the first fundamental form of the catenoid with the (somewhat differently parameterized than above) helicoid

$$f = f(t, \varphi) = (\sinh t \cos \varphi, \sinh t \sin \varphi, \varphi).$$

Determine the second fundamental forms of the catenoid and the helicoid and show that they are *minimal surfaces*, that is, that their mean curvatures H vanish. Compute their Gaußian curvatures. Sketch both surfaces.

2. Classify surfaces of revolution with constant Gaußian curvature and surfaces of revolution that are minimal surfaces, that is, have mean curvature $H \equiv 0$.
3. Let $f: M \longrightarrow \mathbb{R}^3$ be an immersed surface. For $x \in \mathbb{R}^3$, suppose the function $r: M \longrightarrow \mathbb{R}$, $r(p) = \|f(p) - x\|$ has a maximum at $p_0 \in M$. Show that $K(p_0) \geq 1/r(p_0)^2$ and conclude that M has a point with positive Gaußian curvature, if M is compact. (Compare with Exercise 4.6.3.3.) ■

Exercise 4.6.17

Determine the curvature tensor of $G_k(V)$ and show that the sectional curvature of $G_k(V)$ is non-negative. ■

Book I

On the Straight Line

CHAPTER I

On Angles

10. The figure formed by two rays issuing from the same endpoint is called an angle. The point is called the vertex of the angle, and the two rays are its sides.

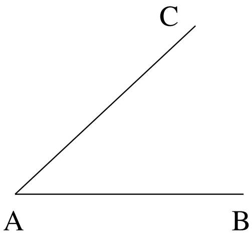

Figure 7

We denote an angle by the letter of its vertex, placed between two other letters which indicate the sides, often surmounted by a special symbol. If, however, the figure contains only one angle with the vertex considered, that letter will suffice to designate the angle. Thus, the angle formed by the two rays AB, AC (Fig. 7) will be denoted by BAC or, more simply, by A.

Two angles are said to be congruent, in agreement with the definition of congruent figures (3) if they can be superimposed by a rigid motion.[1]

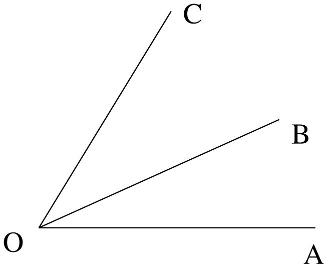

Figure 8

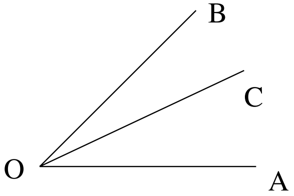

Figure 9

Two congruent angles, BAC, B′A′C′, can be superimposed in two different ways: namely, either AB takes the direction of A′B′ and AC the direction of A′C′, or the other way around. We pass from one to the other by turning the angle around onto itself, for instance, by moving the angle BAC in such a way that AC occupies the position previously occupied by AB, and vice-versa.

---

[1] But see the footnote to 3. transl.

11. We say that two angles are adjacent if they have the same vertex, a common side, and so that they are located on opposite sides of this common side.

When angles AOB, BOC are adjacent (Fig. 8), angle AOC is called the sum of the two angles.

The sum of two or more angles is independent of the order of the angles added.

To compare angles, we move them so they have a common vertex, and a common side, and lie on the same side of this common side. Assume that AOB, AOC are placed in this manner. If, rotating around point O, we encounter the sides in the order OA, OB, OC (Fig. 8), angle AOC is equal to the sum of AOB and another angle BOC; in this case angle AOC is said to be larger than AOB, and the latter is smaller than AOC; if, on the contrary (Fig. 9) the order is OA, OC, OB, then angle AOC is smaller than AOB. The angle BOC which, added to the smaller angle, yields the larger angle, is the difference of the two angles.

Finally, in the intermediate case in which OB coincides with OC, the two angles are congruent (see 10).

In the interior of every angle BAC there is a ray AM which divides this angle into two congruent parts; it is called the bisector of the angle. The rays contained in the angle BAM make a smaller angle with AB than with AC; the opposite is true for rays contained in the angle MAC.

An angle is said to be the double, triple, etc., of another if it is the sum of two, three, etc., angles equal to this other angle. The smaller angle will then be called a half, third, etc., of the larger one.

Remark. The size of an angle does not depend on the size of its sides, which are rays (5), and which we must imagine as extending indefinitely.

12. As we have said, an angle is determined by two rays, such as OA, OB (Fig. 10). If we extend OA past point O to form OA′, and in the same way extend OB to form OB′, we obtain a new angle A′OB′.

Two angles AOB, A′OB′ such that the sides of one are extensions of the sides of the other are called vertical angles.

Theorem. Two vertical angles are congruent.

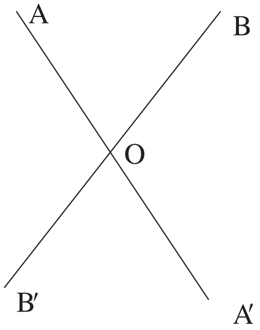

Figure 10

Indeed, let us turn (10) the angle BOA onto itself (Fig. 10). The side OB will take the place of OA , and, since 0A will take the former position of OB, this means that ray OA, which is the extension of OA , will coincide with OB , the extension of OB. Thus angle AOB is superimposed on angle A OB , and therefore these two angles are congruent.

13. Arcs and angles. Every ray issuing from the center of a circle meets this circle in one and only one point.

Every angle AOB (Fig. 4) with its vertex at the center O of a circle determines an arc $\overset{\frown}{AB}$ having as endpoints the intersections of the sides of the angle with the circle. In general, (see however 20b), we consider the arc which is less than a semicircle.

Conversely, every arc less than a semicircle can be thought of as determined by an angle with its vertex at the center of the circle, formed by the rays passing through the endpoints of the arc.

Theorem. On the same circle, or on equal circles:

1 . To equal arcs (smaller than a semicircle) there correspond equal central angles;[2]

2 . To unequal arcs (smaller than a semicircle) there correspond unequal central angles, and the greater angle corresponds to the greater arc;

3 . If an arc (smaller than a semicircle) is the sum of two others, the corresponding central angle is the sum of the angles associated with the smaller arcs.

1 , 2 . Let $\overset{\frown}{AB}$, $\overset{\frown}{AC}$ (Fig. 4) be the two arcs, drawn on the same circle, starting from the same point A, in the same direction (8). The two angles AOB, AOC are therefore placed as in 11. But then rays OA, OB, OC are placed in the same order as points A, B, C on the circle. Moreover, if rays OB, OC coincide, then so do the points B, C, and conversely.

3 . Let us recall that the sum of two arcs (8b) is formed by placing them as arcs $\overset{\frown}{AB}$, $\overset{\frown}{BC}$ are placed (Fig. 4). Then the angle AOC corresponding to the sum of these arcs will be the sum of AOB and BOC, because these angles are adjacent.

According to this result, in order to compare angles, one can draw circles with the same radius, centered at the vertices of the angles, and compare the arcs intercepted on these circles.

The division of angles into two or more equal parts corresponds to the division into equal parts of the corresponding arc of a circle centered at the vertex of the angle.

14. Perpendiculars. Right angles. We say that two lines are perpendicular to each other if, among the four angles they form, two adjacent angles are equal to each other. For example, line AOA (Fig. 11) is perpendicular to BOB if the angles numbered 1 and 2 in the figure are equal. In such a case, the four angles at O are equal to each other, since angles 3 and 4 (Fig. 11) are equal respectively to 1 and 2, because they are vertical angles.

An angle whose sides are perpendicular is called a right angle.

---

[2] This is the standard term in American texts. Hadamard uses the locution angles with their vertex at the center or angles at the center . transl.

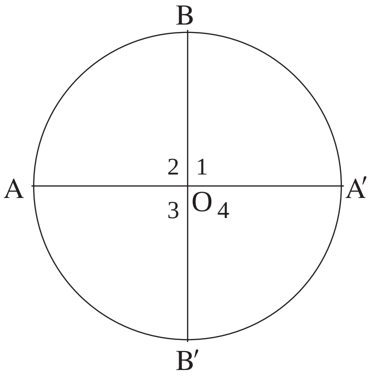

Figure 11

Theorem. In a given plane, through a given point on a line, one can draw one, and only one, perpendicular to this line.

Suppose we want to draw a perpendicular to line AA′ through point O (Fig. 11). It suffices to draw a circle with center O which cuts the line at A and A′, then find point B which divides semicircle AA′ into two equal parts. Then OB will be the required perpendicular; and conversely, a perpendicular to AA′ drawn through point O must divide arc $\overset{\frown}{AA'}$ in half.

Corollary. We see that a right angle intercepts an arc equal to one fourth of a circle centered at the vertex of the angle.

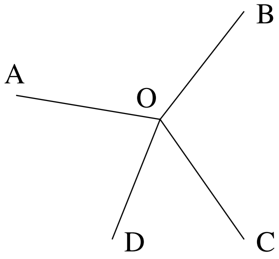

Figure 12

All right angles are equal, since two such angles will intercept equal arcs on equal circles centered at their vertices.

15. If several rays are drawn issuing from the same point, the sum of the successive angles thus formed (AOB, BOC, COD, DOA, Fig. 12) is equal to four right angles.

Indeed, the sum of the arcs intercepted by these angles on a circle centered at their vertex is the entire circle.

If several rays are drawn issuing from a point on a line, in such a way that all the rays are on one side of the line (Fig. 13), the sum of the successive angles thus formed is equal to two right angles.

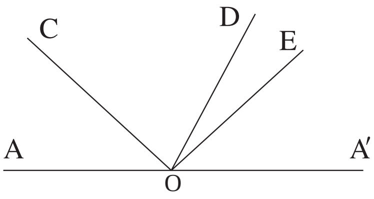

Figure 13

Indeed, the sum of the intercepted arcs is a semicircle.

Conversely, if two or more angles with the same vertex, and each adjacent to the next, (AOC, COD, DOE, EOA′, Fig. 13) have a sum equal to two right angles, then their outer sides form a straight line.

Indeed, these outer sides cut a circle centered at the common vertex of the angles at two diametrically opposite points, since the arc they intercept is a semicircle.

Remark. The angle AOA′ (Fig. 13) whose sides form a straight line is called a straight angle.

15b. Theorem. The bisectors of the four angles formed by two concurrent lines form two straight lines, perpendicular to each other.

Let AA′, BB′ (Fig. 14) be two lines which intersect at O and form the angles AOB, BOA′, A′OB′, B′OA, whose bisectors are Om, On, Om′, On′. We claim:

1. That Om, Om′ are collinear, as are On, On′.

2. That the two lines thus formed are perpendicular.

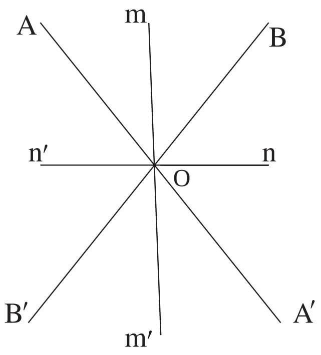

Figure 14

First, Om is perpendicular to On because, since the sum of AOB and BOA′ is two right angles, half of each, mOB and BOn, must add up to a right angle.

Applying the same reasoning to angles A′OB′ and B′OA, we see that Om′ and On are perpendicular. Therefore Om′ is the extension of Om, and likewise On′ is the extension of On.

16. An angle which is less than a right angle is called an acute angle; an angle greater than a right angle is called an obtuse angle.

Two angles are said to be complementary if their sum is a right angle; supplementary if their sum is equal to two right angles.

17. Angle Measure. The ratio of two quantities of the same kind is[3] the number which expresses how many times one of the quantities is contained in the other. For instance, if, in dividing the segment AB into five equal parts, one of these parts is contained exactly three times in the segment BC, then the ratio of BC to AB is said to be equal to 3/5. If, on the other hand, a fifth of AB is not contained an exact number of times in BC, for example if it is contained in BC more than three times, but less than four times, then 3/5 would be an approximate value of the ratio $\frac{BC}{AB}$: it would be within one fifth less than the value of the ratio (the value 4/5 would be within 1/5 more).

The ratio of two quantities a, b of the same kind is equal to the ratio of two other quantities a', b' also of the same kind (but not necessarily of the same kind as the first two) if, for every n, the approximation to within $1/n$ of the first ratio is equal to the approximation within $1/n$ of the second ratio.

The measure of a quantity, relative to a quantity of the same kind chosen as unit, is the ratio of the given quantity to the unit.

In addition we have the following properties (Leçons d'Arithmetique by J. Tannery):

1°. Two quantities of the same kind, which have the same measure relative to the same unit, are equal;

2°. The ratio of two quantities of the same kind is equal to the ratio of the numbers which serve as their measures relative to the same unit;

3°. The ratio of two numbers is the same as the quotient of the two numbers; etc.

Theorem. In the same circle, or in equal circles, the ratio of two central angles is equal to the ratio of their subtended arcs.

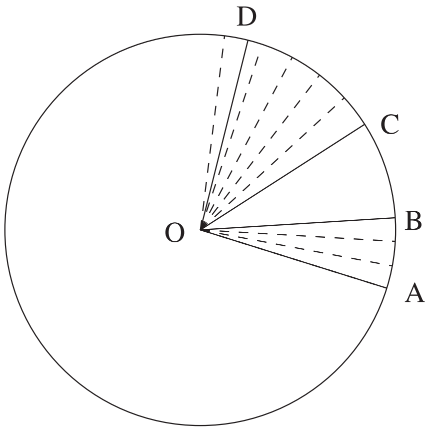

Figure 15

---

[3] See Leçons d'Arithmetique by J. Tannery, chapters X and XIII.

Consider[4] (Fig. 15) two arcs $\overset{\frown}{AB}$, $\overset{\frown}{CD}$ on circle O. Divide central angle COD into three equal parts (for example), and suppose that one of these thirds can fit four, but not five times, into the angle AOB; the value (smaller by less than 1/3) of the ratio $\frac{AOB}{COD}$ is $\frac{4}{3}$.

But dividing the angle COD into three equal parts, we have at the same time divided arc $\overset{\frown}{CD}$ into three equal parts (13). If a third of COD fits four, but not five times, into angle AOB, it follows the same way that a third of arc $\overset{\frown}{CD}$ fits four, but not five times, into arc AB. The values to within 1/3 of the two ratios are therefore equal, and similarly the values to within $1/n$ will be equal for any integer n. The theorem is therefore proved.

Corollary. If we take as the unit of angle measure the central angle which intercepts a unit arc, then every central angle will have the same measure as the arc contained between its sides.

This statement is exactly the same as the preceding one, since the measure of a quantity is its ratio to the unit.

Supposing, as we will from now on, that on each circle we choose as unit arc an arc intercepted by a unit central angle, the preceding corollary can be stated in the abridged form: A central angle is measued by the arc contained between its sides.

18. The definitions reviewed above allow us to establish an important convention.

From now on, we will be able to suppose that all the quantities about which we reason have been measured with an appropriate unit chosen for each kind of quantity. Then, in all the equations we write, the quantities which appear on the two sides of an equality will represent not the quantities themselves, but rather their measures.

This will allow us to write a number of equations which otherwise would have no meaning. For instance, we might equate quantities of different kinds, since we will be dealing only with the numbers which measure them, the meaning of which is perfectly clear. We will also be able to consider the product of any two quantities, since we can talk about the product of two numbers, etc.

In fact, whenever we write the equality of two quantities of the same kind, this equality will have the same meaning as before, since the equality of these quantities is the same as the equality of their measures.

Following this convention we can write:

$$AOB = \text{arc } \overset{\frown}{AB},$$

where AB is an arc of a circle and O is the center. It is important however to insist on the fact that the preceding equality assumes that the unit of angle measure and the unit of arc measure have been chosen in the manner specified above.

---

[4] This theorem becomes obvious if we consider the following proposition from arithmetic (Tannery, Leçons d'Arithmetique: Two quantities are proportional if: 1 To any value of the first, there corresponds an equal value of the second, and 2 the sum of two values of the first corresponds to the sum of the corresponding values of the second. These two conditions hold here (13).

The argument in the text does no more than reproduce, for this particular case, the proof of this general theorem of arithmetic.

18b. Traditionally, the circle has been divided into 360 equal parts called degrees, each of which contains 60 minutes, which are themselves divided into 60 seconds. One can then measure arcs in degrees and, correspondingly, angles will also be measured in degrees, and the number of degrees, minutes, and seconds of the angle will be the same as the number of degrees, minutes, and seconds of the arc intercepted by this angle on a circle centered at its vertex. A right angle corresponds to one fourth of a circle; that is, to 90 degrees. It follows that the measure of an angle at the center of a circle does not depend on the radius of the circle on which one measure the arcs, since the chosen unit of angle measure (the degree) has a value independent of this radius, namely one ninetieth of a right angle.

In writing angles (or arcs) in degrees, minutes, and seconds, we use an abridged notation: an angle of 87 degrees, 34 minutes, and 25 seconds is written: 87 34 25 .

The introduction of decimal notation in all other kinds of measurements has led to the use of another mode of division, in which the circle is divided into 400 equal parts called gradients (or grads). The grad, a little smaller than the degree, is, as we see, one hundredth of a right angle. The grad is divided decimally, so there is actually no need for special names for its parts, which are written using the rules of decimal notation. Thus we can speak of the angle $3^G.5417$ (that is, 3 grads and 5417 ten-thousandths).

Nonetheless, a hundredth of a grad is often called a centesimal minute, and is indicated by the symbol ‘ (to distinguish it from the hexagesimal minute, which is a sixtieth of a degree). Likewise, one hundredth of a centesimal minute is called a centesimal second, denoted by the symbol ‘‘. The angle just considered could then be written as $3^G.54$‘17‘‘.

A grad is equal to $\frac{360}{400}$, that is $\frac{9}{10}$ of a degree, or 54 . A degree equals $\frac{400}{360}^G$ = $1^G.11$‘11‘‘1... (in other words, $\frac{10}{9}$ of a grad).

19. Theorem. Given a line, and a point not on the line, there is one, and only one, perpendicular to the line passing through the given point.

1 . There is one perpendicular. Consider point O and line xy (Fig. 16). Using xy as a hinge, let us turn the half-plane containing O until it overlaps the other half-plane. Supposing point O falls on O , we join OO . This line intersects xy because it joins two points in different half-planes. If I is the point of intersection, the angles O Ix and OIx are equal because one of them can be superimposed on the other by rotation around xy. Thus the lines xy and OO are perpendicular.

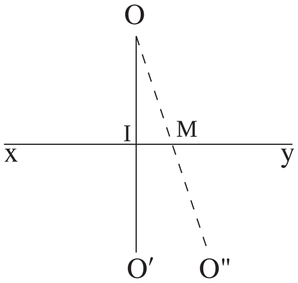

Figure 16

2 . There is only one perpendicular. Indeed, assume that OM is a perpendicular to xy passing through O. Extend the segment OM by its own length to MO .

Again turning the half-plane containing O around xy, the segment MO will fall on MO because the angles OMx and O Mx are right angles, and hence are equal. Since MO = MO, the point O falls on O, and therefore O and O coincide, as do the lines OO and OO. QED

19b. The reflection of a point O in a line xy is the endpoint of the perpendicular from O to the line, extended by the length of a segment equal to itself. It follows from the preceding considerations that this reflection is none other than the new position occupied by O after a rotation around xy.

Given an arbitrary figure, we can take the reflection of each of its points. The set of these reflections constitutes a new figure, called the reflection of the first. We see that in order to obtain the reflection of a given figure in line xy, we can turn the plane of the figure around xy, so that each half-plane determined by the line falls on the other, then note the position taken by the original figure. It follows that:

Theorem. A plane figure is congruent to its reflection.

Corollary. The reflection of a line is a line.

When a figure coincides with its reflection in line xy, we say that it is symmetric in this line, or that this line is an axis of symmetry of the figure.

20. To make a figure F coincide with its reflection F, we had to use a motion which took the figure out of its plane. We must note that this superposition is not possible without such a movement; this holds because the sense of rotation is reversed in the two figures. We will now explain what this means.

First, let us remark that the plane of the figure divides space into two regions. For brevity, let us call one of these the region situated above the plane; the other, the region below the plane.

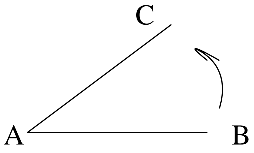

Figure 17

Consider now an angle BAC in the figure F, which can be viewed as being described by a ray moving inside this angle from the position AB to the position AC (Fig. 17). Viewed from above this angle BAC will be said to have an inverse sense of rotation or a direct sense, according as the moving ray turns clockwise or counterclockwise.[5] To be definite, let us consider the second situation. In this case, an observer lying along AB, with his feet at A, his head in the direction of B, and looking down, will see the side AC on his left; and therefore, if still lying on AB, he faces AC, the region below the plane will be on his right.

It is clear that to describe the sense of rotation of an angle viewed from below, this discussion can be repeated, with the word above replaced by the word below, and vice-versa.

---

[5] We note that in order to define the sense of rotation, we must take into account the order of the sides. Thus angle BAC has the opposite sense from CAB.

Since an observer lying on AB and facing AC will necessarily have the region above the plane on his left, if the region below is on his right, and vice-versa, we see that the sense of rotation changes depending on whether we view the angle from one side of the plane or from the other.[6]

Let us now suppose that an angle is moved in any way at all, without ever leaving the plane. An observer moving along with the angle will not change his position relative to the regions of space above and below the plane, and therefore the sense of rotation is not altered by a motion which does not leave the plane.

To prove that such a motion cannot make a figure F coincide with its reflection F′, it suffices therefore to see that the senses of rotation of the two figures are opposite. But we have seen that we can make F coincide with F′ by turning the plane around xy (19). As a result of this rotation, the points above the plane are moved below it, and vice-versa. The sense of rotation of an angle in F, viewed from above, is therefore the same as the sense of F′ viewed from below, so that the two angles, viewed from the same side, have opposite senses of rotation. QED

20b. **Remarks.** I. We say that a plane is oriented when a sense of rotation for angles has been chosen as the direct sense. According to the preceding paragraph, orienting a plane amounts to deciding which region of space will be said to be above the plane.

II. It is convenient to regard an angle with vertex O as being described by a ray starting from O which at first coincides with the first side, and then turns about O in the plane (in the direct or inverse sense) until it coincides with the second side. If the ray has made a quarter of a complete turn, the angle is a right angle. If it has made one half of a complete turn, the angle is a straight angle, such as AOA′ (Figures 11 or 13).

Nothing prevents us, by the way, from considering angles greater than two right angles, since our ray can make more than half a complete turn.

III. Clearly, an arc of a circle, like an angle, can have a direct or an inverse sense, which depends, of course, on the order in which one gives its endpoints.

Two points A, B on a circle divide it into two different arcs of which (unless the two points are diametrically opposite) one is a minor arc (less than a semicircle), and the other a major arc. It must be noted that, since the endpoints A, B are given in a certain order (for example if A is first and B is second), these two arcs have opposite senses.

Exercises

Exercise 1. Given a segment AB and its midpoint M, show that the distance CM is one half the difference between CA and CB if C is a point on the segment. If C is on line AB, but not between A and B, then CM is one half the sum of CA and CB.

Exercise 2. Given an angle AOB, and its bisector OM, show that angle COM is one half the difference of COA and COB if ray OC is inside angle AOB; it is the supplement of half the difference if ray OC is inside angle A′OB′ which is vertical to AOB; it is one half the sum of COA and COB if OM is inside one of the other angles AOA′ and BOB′ formed by these lines.

---

[6] For this reason, writing viewed through a transparent sheet of paper appears reversed.

Exercise 3. Four rays OA, OB, OC, OD issue from O (in the order listed) such that AOB = COD and BOC = DOA. Show that OA and OC are collinear, as are OB and OD.

Exercise 4. If four consecutive rays OA, OB, OC, OD are such that the bisectors of angles AOB, COD are collinear, as are the bisectors of BOC, AOD, then these rays are collinear in pairs.

CHAPTER II

On Triangles

21. A plane region bounded by line segments is called a polygon (Fig 18). The segments are called the sides of the polygon, and their endpoints are called its vertices.

In fact, we will generally use the term polygon only for a portion of the plane bounded by a single contour which can be drawn with a single continuous stroke. The plane region which is shaded in Figure 19 will not be a polygon for us.

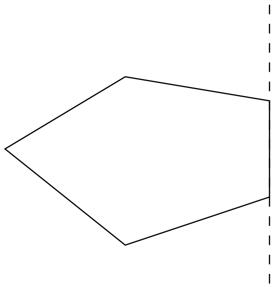

Figure 18

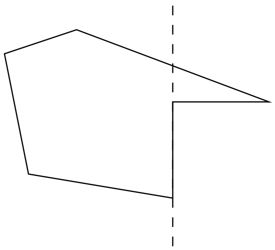

Figure 18b

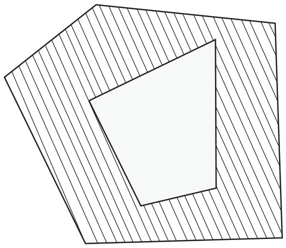

Figure 19

A polygon is said to be convex (Fig. 18) if, when we extend any side indefinitely, none of the lines thus formed crosses the polygon. In the opposite case (Fig. 18b) the polygon is said to be concave.

Polygons are classified according to the number of sides they have. Thus the simplest polygons are: the polygon with three sides or triangle, the polygon with 4 sides or quadrilateral, the polygon with 5 sides, or pentagon, the polygon with six sides or hexagon. We will also consider polygons with 8, 10, 12, and 15 sides, called octagons, decagons, dodecagons, and pentadecagons.

Any segment joining two non-consecutive vertices of a polygon is called a diagonal.

Remark. More generally, an arbitrary broken line, even one whose sides cross (as in Fig. 19b), will sometimes be called a polygon. In this case, when the broken line does not bound a unique region, the polygon is said to be improper. However, when we want to specify that the polygon is of the first type (Figures 18 and 18b), and not like the one in Figure 19b, we will speak of a proper polygon.

22. Among triangles we distinguish in particular:

The isosceles triangle. This name is used for a triangle with two equal sides. The common vertex of the equal sides is called the vertex of the isosceles triangle, and the side opposite the vertex is called the base;

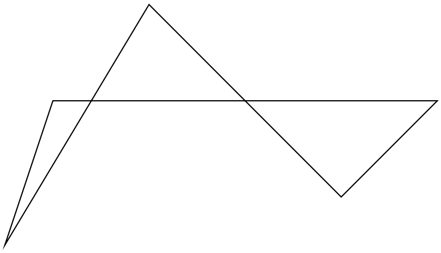

Figure 19b

The equilateral triangle, which has all three sides equal;

The right triangle, which has a right angle. The side opposite the right angle is called the hypotenuse.[1]

A perpendicular dropped from a vertex of a triangle onto the opposite side is called an altitude of the triangle; a median is a line which joins a vertex with the midpoint of the opposite side.

23. Theorem. In an isosceles triangle, the angles opposite the equal sides are equal.

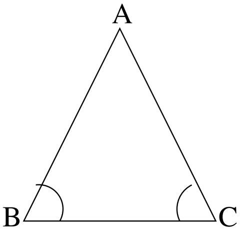

Figure 20

Suppose ABC is an isosceles triangle (Fig. 20). Let us turn angle BAC onto itself (10) so that AB lies along the line of AC and vice-versa. Since AB and AC are equal, point B will fall on C, and C on B. Angle ABC will therefore fall on ACB, so that these angles are equal. QED

Converse. If two angles of a triangle are equal, the triangle is isosceles.

In triangle ABC, suppose B = C. Let us move this triangle so that side BC is turned around, switching points B and C. Since ABC = ACB, side BA will assume the direction of of CA, and conversely. Point A, which is the intersection of BA and CA, will therefore retain its original position, so that segment AB falls on segment AC. QED

Corollary. An equilateral triangle is also equiangular (that is, its three angles are equal), and conversely.

---

[1] The original text does not use term leg for a side of a right triangle that is not the hypotenuse. However, we will use this standard English term freely in the translation. transl.

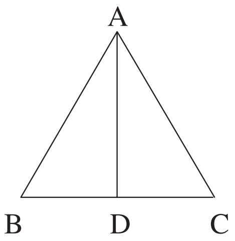

Figure 21

Theorem. In an isosceles triangle, the bisector of the angle at the vertex is perpendicular to the base, and divides it into two equal parts.

In isosceles triangle ABC (Fig. 21), let AD be the bisector of A. In turning angle BAC around on itself, this bisector does not move, and therefore neither does the point D where this bisector cuts the base. Segment DB falls on DC and angle ADB on ADC. Therefore DB = DC and ADB = ADC. QED

Remark. In triangle ABC we can consider:

1. The bisector of A;
2. The altitude from A;
3. The median from the same point;
4. The perpendicular to the midpoint of BC.

In general, these four lines are distinct from each other (see Exercise 17). The preceding theorem shows that, in an isosceles triangle, all of these are the same line, which is a line of symmetry of the triangle (19b).

This theorem can thus be restated: the altitude of an isosceles triangle is also an angle bisector and a median; or the median of an isosceles triangle is at the same time an angle bisector and an altitude; the perpendicular bisector of the base passes through the vertex and bisects the angle at the vertex.

Corollary. In an isosceles triangle, the altitudes dropped from the endpoints of the base are equal; the same is true about the medians from the endpoints of the base, about the bisectors of the angles at these points, etc., because these segments are symmetric to each other.

24. The following propositions, known under the name of cases of congruence of triangles, give necessary and sufficient conditions for two triangles to be congruent.

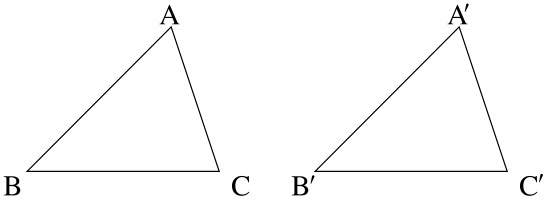

Figure 22

1st case: ASA. Two triangles are congruent if they have an equal side contained between corresponding equal angles.

Suppose the triangles are ABC, A B C (fig. 22) in which BC = B C , B = B , and C = C . Let us move angle B onto angle B so that side B A lies along the line of BA and B C along the line of BC. Since BC = B C , the point C falls on C. Now, since C = C, side C A assumes the direction of CA, and therefore point A falls on the intersection of BA and CA; that is, on A. This establishes the congruence of the two figures.

2nd case: SAS. Two triangles are congruent if they have an equal angle contained between corresponding equal sides.

Suppose the two triangles are ABC, A B C (Fig. 22) in which A = A , AB = AC, and AC = A C .

Let us move angle A over angle A so that A B assumes the direction of AB and A C assumes the direction of AC. Since A B = AB, point B will fall on B, and likewise C on C. Therefore side B C coincides with BC, and the superposition of the two figures is complete.

3rd case: SSS. Two triangles are congruent if they have three equal corresponding sides.

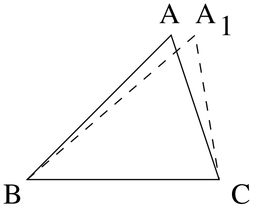

Figure 23

Consider triangles ABC and A B C such that AB = A B , AC = A C , and BC = B C , and let us move the second triangle so that side B C coincides with BC, and the two triangles are on the same side of line BC. Denote the new position of A by A_1. We claim that point A_1 coincides with A. This is obvious if BA_1 has the same direction as BA or if CA_1 has the same direction as CA. If this were not the case, we would have formed isosceles triangles BAA_1 and CAA_1 (Fig. 23) and the perpendicular bisector of AA_1 would have to pass through B and C (23, Corollary); in other words, this bisector would have to be line BC. This however is not possible, because points A and A_1 are on the same side of BC, so that BC cannot pass through the midpoint of AA_1. Thus the only possibility is that points A and A_1 must be the same point; in other words, the given triangles coincide.

Remarks. I. In order to establish that $A = A_1$, we have investigated what would happen if these two points were distinct. Arriving, in this case, at a conclusion which is clearly false, we concluded that this possibility does not arise. This is a very useful method of reasoning, called proof by contradiction.

II. In a triangle there are six main elements to consider; namely, the three angles and the three sides. We have seen that if we establish the equality of three of these elements (properly chosen) in two triangles, we can conclude that the two triangles are congruent and, in particular, that the remaining elements are equal as well.

III. Two congruent triangles (or, more generally, polygons) may differ in their sense of rotation (20). In this case, they can only be superimposed by a motion outside the plane. On the other hand, if the sense of rotation is the same, the two polygons can be superimposed by moving them within the plane, as we will have occasion to see later on.

25. The angle formed by a side of a convex polygon and the extension of the next side is called an exterior angle of the polygon.

Theorem. An exterior angle of a triangle is greater than either of the non-adjacent interior angles.

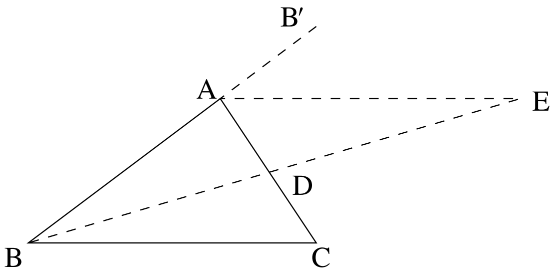

Figure 24

Let the triangle be ABC, and construct the exterior angle B AC (Fig. 24). We claim that this angle is greater, for example, than the interior angle C. To show this, we construct median BD, which we extend by its own length to a point E. The point E being inside[2] angle B AC, this last must be greater than angle EAC.

But this last angle is precisely equal to C; indeed, triangles DAE, DBC are congruent, having an equal angle between equal sides: the angles at D are equal because they are vertical angles, and $AD = DC$, $BD = DE$ by construction. Thus exterior angle B AC is greater than interior angle C. QED

Exterior angle B AC is the supplement of interior angle A. Since angle C is smaller than the supplement of A, the sum $A + C$ is less than two right angles. Our theorem can thus be restated: The sum of any two angles of a triangle is less than two right angles. In particular, a triangle cannot have more than one right or obtuse angle.

Theorem. In any triangle, the greater angle lies opposite the greater side.

In triangle ABC, suppose $AB > AC$. we will show that $C > B$. To show this, we take, on AB, a length $AD = AC$ (Fig. 25). It follows from the hypothesis that point D is between A and B, and therefore angle ACD is less than C. But in

---

[2] Point E is on the same side of line BAB as D (otherwise line DE, which has the common point B with BAB , would have to cut it again between D and E, and this is impossible), and thus on the same side as C. But B and E are on different sides of AC, which BE crosses at D.

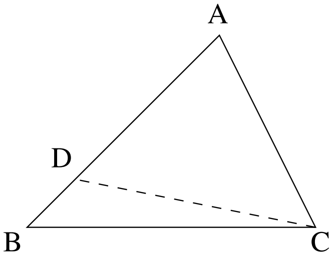

Figure 25

isosceles triangle ACD, $ACD = ADC$, which is greater than B by the preceding theorem applied to triangle DCB. The theorem is thus proved.

Conversely, the greater side corresponds[3] to the greater angle.

This statement is obviously equivalent to the preceding one.

26. *Theorem.* Any side of a triangle is less than the sum of the other two.

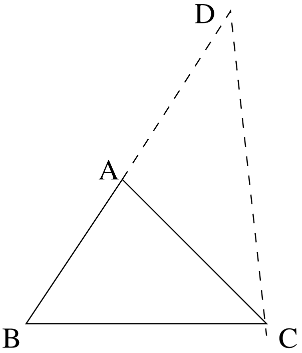

Figure 26

In triangle ABC, we extend side AB to a point D such that $AD = AC$ (Fig. 26). We must prove that[4] $BC < BD$. Drawing CD, we see that angle D, which is equal to angle ACD (23), is therefore less than BCD.

The desired inequality thus follows from the preceding theorem applied to the triangle BCD.

Corollaries. I. Any side of a triangle is greater than the difference between the other two.

Indeed, the inequality $BC < AB + AC$ gives, after subtracting AC from both sides:

$$BC - AC < AB.$$

---

[3] The side corresponding to an angle is the side opposite it.

[4] The theorem is obvious if BC is not the largest side of the triangle.

II. For any three points A, B, C, each of the distances AB, BC, AB is at most equal to the sum of the other two, and at least equal to the difference of the other two, equality holding if the three points are collinear.

Theorem. A line segment is shorter than any broken line with the same endpoints.

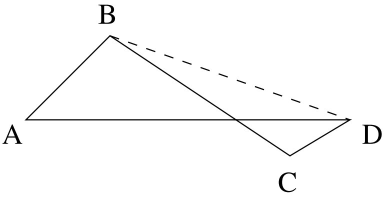

Figure 27

If the broken line has only two sides, the theorem reduces to the preceding one. Consider next a broken line with three sides ABCD (Fig. 27). Drawing BD, we will have $AD < AB + BD$ and, since $BD < BC + CD$, we have

$$AD < AB + BD < AB + BC + CD.$$

The theorem is thus proven for a broken line with three sides. The same reasoning can be used successively for broken lines with 4 sides, 5 sides, etc. Therefore the theorem is true no matter how large the number of sides.

27. The sum of the sides of a polygon, or of a broken line, is called its perimeter.

Theorem. The perimeter of a convex broken line is less than that of any broken line with the same endpoints which surrounds it.

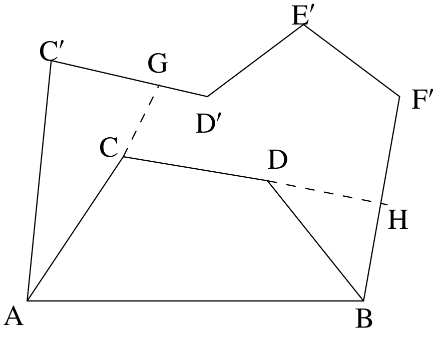

Figure 28

Consider the convex line ACDB and the surrounding line AC D E F B (Fig. 28). We extend sides AC, CD in the sense indicated by ACDB; that is, the side AC past C and the side CD past D. These extensions do not intersect the interior of polygon ACDB because of its convexity. Suppose they cut the surrounding line in G and H respectively.

The path ACDB is shorter than ACHB because they have a common portion ACD, and the remainder BD of the first is less than the remainder DHB of the second. In turn, the path ACHB is shorter than AGD E F B because, after removing the common parts AC, HB, the segment CH which is left is smaller than the broken line CGD E F H. In the same way, AGD E F B is less than AC D E F B, because AG is less than AC G. Thus

ACDB < ACHB < ACGD E F B < AC D E F B.

QED

Corollary. The perimeter of a convex polygon is less than the perimeter of any closed polygonal line surrounding it completely.

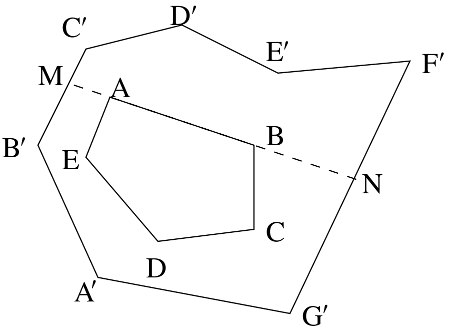

Figure 29

Consider (Fig. 29) convex polygon ABCDE, and polygonal line A B C D E F G A which surrounds it completely. We extend side AB in both directions until it intersects the surrounding polygon at M, N. By the preceding result, the length of the path AEDCB is less than AMB A G NB, and therefore the perimeter of AEDCBA is less than the perimeter of the polygon NMB A G N. This perimeter, in turn, is less than the surrounding line because the part MB A G N is common to both, and MN < MC D E F N.

28. Theorem. If two triangles have a pair of unequal angles contained by two sides equal in pairs, and the third sides of the triangles are unequal, then the greater side is opposite the greater angle.

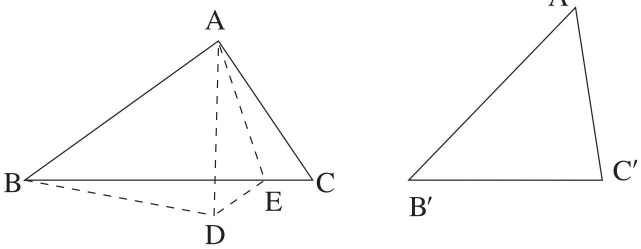

Figure 30

Consider triangles ABC, $A'B'C'$ such that $AB = A'B'$, $AC = A'C'$, and $A > A'$ (Fig. 30). We want to prove that $BC > B'C'$. Let us move the second triangle so that $A'B'$ coincides with AB. Since A' is less than A, side $A'C'$ will move to a position AD in the interior of angle BAC. We construct the bisector AE of DAC. This segment is also inside BAC, and, as B and C lie on different sides of this line, it must intersect side BC in some point E located between B and C. If we draw DE, we see that triangles ACE and ADE are congruent, because they have an equal angle (with vertex A) between two corresponding equal sides (AE in common, $AC = A'C' = AD$). Therefore $DE = EC$. The inequality $BD < BE + ED$ provided by the triangle BDE then gives us

$$BD < BE + EC,$$

or

$$BD < BC.$$

QED

Conversely. If, in two triangles, two pairs of sides are equal, but the third sides are unequal, then the angles opposite the unequal sides are unequal, and the greater angle is opposite the greater side.

This statement is equivalent to the preceding one.

Remark. The preceding theorem does not require the third case of congruence for triangles (SSS). It therefore provides another proof of that case.

Indeed, if we have $AB = A'B'$, $AC = A'C'$ and, in addition $BC = B'C'$, the angles A and A' would have to be equal, or else BC and $B'C'$ could not be equal. Knowing now that $A = A'$ the two triangles are congruent by the second case (SAS).

Exercises

Exercise 5. Prove that a triangle is isosceles:

1. if an angle bisector is also an altitude;
2. if a median is also an altitude;
3. if an angle bisector is also a median.

Exercise 6. On side Ox of some angle, we take two lengths OA, OB, and on side Ox' we take two lengths OA', OB', equal respectively to the first two lengths. We draw AB', BA', which cross each other. Show that point I, where these two segments intersect, lies on the bisector of the given angle.

Exercise 7. If two sides of a triangle are unequal, then the median between these two sides makes the greater angle with the smaller side. (Imitate the construction in 25.)

Exercise 8. If a point in the plane of a triangle is joined to the three vertices of a triangle, then the sum of these segments is greater than the semi-perimeter of the triangle; if the point is inside the triangle, the sum is less than the whole perimeter.

Exercise 8b. If a point in the plane of a polygon is joined to the vertices of the polygon, then the sum of these segments is greater than the semi-perimeter of the polygon.

Exercise 9. The sum of the diagonals of a [convex[5]] quadrilateral is between the semi-perimeter and the whole perimeter.

Exercise 10. The intersection point of the diagonals of a [convex[6]] quadrilateral is the point in the plane such that the sum of its distances to the four vertices is as small as possible.

Exercise 11. A median of a triangle is smaller than half the sum of the sides surrounding it, and greater than the difference between this sum and half of the third side.

Exercise 12. The sum of the medians of a triangle is greater than its semi-perimeter and less than its whole perimeter.

Exercise 13. On a given line, find a point such that the sum of its distances to two given points is as small as possible. Distinguish two cases, according to whether the points are on the same side of the line or not. The second case can be reduced to the first (by reflecting part of the figure in the given line).

Exercise 14. (Billiard problem.) Given a line xy and two points A, B on the same side of the line, find a point M on this line such that $AMx = BMy$.

We obtain the same point as in the preceding problem.

Exercise 15. On a given line, find a point with the property that the difference of its distances to two given points is as large as possible. Distinguish two cases, according to whether the points are on the same side of the line or not.

---

[5] This condition is not in the original text. See solution. transl.

[6] See the previous footnote. transl.

CHAPTER III

Perpendiculars and Oblique Line Segments

29. Theorem. If, from a given point outside a line, we draw a perpendicular and several oblique line segments:

1. The perpendicular is shorter than any oblique segment;

2. Two oblique segments whose feet are equally distant from the foot of the perpendicular are equal;

3. Of two oblique segments, the longer is the one whose foot is further from the foot of the perpendicular.

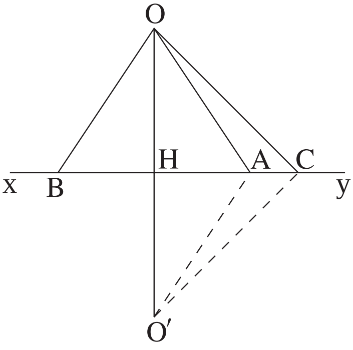

Figure 31

1. Consider perpendicular OH and oblique segment OA from point O to line xy (Fig. 31). If we extend OH by a length HO' equal to itself, then O' is symmetric to O with respect to line xy. Therefore $O'A$ is the symmetric image of OA, and the two are equal. Now in triangle $OO'A$ we have

$$OO' < OA + O'A,$$

and we can replace OO' with $2OH$ and $OA + O'A$ with $2OA$. Thus we find $2OH < 2OA$, or $OH < OA$.

2. Consider next the oblique segments OA, OB such that $HA = HB$. These two oblique segments will be equal by symmetry with respect to line OH.

3. Finally, let OA and OC be oblique segments such that $HC > HA$ (Fig. 31). Suppose first that points A and C are on the same side of H. Then point A is inside triangle $OO'C$. By (27) we have

$$OA + O'A < OC + O'C$$

and, as we saw before, $OA = O'A$ and $OC = O'C$. Dividing by two, we have, as before,

$$OA < OC.$$

If we had started with an oblique segment OB less distant than OC, but on the other side of H, it would suffice to construct a length HA = HB in the direction of HC. The oblique segment OB then would be equal to OA (2°), and hence smaller than OC as we have seen above.

30. Conversely. If two oblique segments are equal, their feet are equally distant from the foot of the perpendicular, otherwise they are unequal; if they are unequal, the longer is the more distant from the perpendicular.

Corollary. There are no more than two oblique segments of the same length from the same point O to a line xy.

This is true because the feet of these oblique segments are equally distant from H, and there are only two points on xy at a given distance from H.

31. The length of the perpendicular dropped from a point to a line is called the distance from the point to the line. The preceding theorem shows that this perpendicular is in fact the shortest path from the point to the line.

32. Theorem.

1°. Every point on the perpendicular bisector of a segment is equally distant from the endpoints of the segment;

2°. A point not on the perpendicular bisector is not equally distant from the endpoints of the segment.

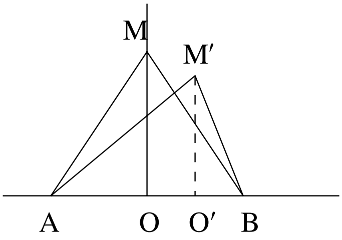

Figure 32

1°. If M is on the perpendicular bisector of AB (Fig. 32), the segments MA, MB are equal, because they are oblique lines which are equally distant from the foot of the perpendicular MO.

2°. Let M′ be a point not on the perpendicular bisector, and suppose it is on the same side of the bisector as point B. The foot O′ of the perpendicular dropped from M′ onto line AB will be on the same side of the bisector (otherwise this perpendicular would meet the bisector and, from their intersection, there would be two lines perpendicular to AB).

We will then have O′A > O′B and therefore (29)

$$M'A > M'B.$$

QED

Remark I. We could have proved the second part in a different way by establishing the following equivalent proposition: Any point which is equidistant from A and B is on the perpendicular bisector of AB. This follows from the converse of 30 (the feet of two equal oblique segments are equidistant from the foot of the perpendicular). One could also use the properties of isosceles triangles (23, Remark). However, one must observe that our way of proceeding has the advantage of showing which of the two distances is the greater when they are unequal.

Remark II. The proposition which we just stated: Any point which is equidistant from A and B is on the perpendicular bisector of AB, is the converse of the first part of the preceding theorem. We have here two different ways of proving a converse. The first consists in following the original reasoning in reverse. This is what we did in the preceding remark. The original reasoning (1° in the previous theorem) started from the hypothesis that point M is on the perpendicular bisector; in other words, that the feet of MA, MB were equally distant from the perpendicular from M, and deduced from this that MA and MB are equal. This time, we started from the hypothesis that MA and MB are equal, and we concluded that their feet are equally distant.

The second method of proving the converse consists in proving what we call the inverse statement. This name is given to the statement whose hypothesis is the negation of the original hypothesis, and whose conclusion is the negation of the original conclusion. Thus the second part of the preceding theorem is the inverse of the first, and is equivalent to its converse.

We will find later on (see, for example, 41) a third method of proving a converse.

33. Let us now make use of the definition of 1b.

Using this definition, the preceding theorem can be restated as follows:

Theorem. The locus of points equidistant from two given points is the perpendicular bisector of the segment joining these two points.

This is true because the figure formed by the points equidistant from A and B is in fact the perpendicular bisector of AB.

We remark that, to establish this fact, one must prove, as we have, that:

1°. every point on the perpendicular bisector satisfies the given condition;

2°. every point satisfying this condition is on the perpendicular bisector; or, equivalently, that no point outside the bisector satisfies the condition. This kind of double argument is necessary in all problems about geometric loci.

Exercises

Exercise 16. If the legs of a first right triangle are respectively smaller than the legs of a second, then the hypotenuse of the first is smaller than the hypotenuse of the second.

Exercise 17. If the angles B and C of a triangle ABC are acute, and the sides AB, AC unequal, then the lines starting from A are, in decreasing order of length, as follows: larger side, median (see Exercise 7 in Chapter II), angle bisector, smaller side, altitude.

Exercise 18. The median of a non-isosceles triangle is greater than the bisector from the same vertex, bounded by the third side.

CHAPTER IV

Cases of Congruence for Right Triangles. A Property of the Bisector of an Angle

34. Cases of congruence for right triangles. The general cases of congruence for triangles apply, of course, to right triangles as well. For instance, two right triangles are congruent if their legs are respectively equal (2^{nd} case of congruence for any triangles).

Aside from these general cases, right triangles present two special cases of congruence.

First case of congruence. Two right triangles are congruent if they have equal hypotenuses, and an equal acute angle.

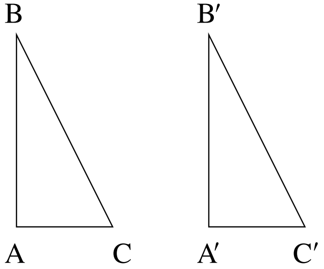

Figure 33

Consider two right triangles $ABC, A'B'C'$ (Fig. 33) in which $BC = B'C'$, $B = B'$. We move the second triangle over the first so that the angles B and B' coincide. Then $B'C'$ will assume the direction of BC, and, since these two segments are equal, C' will fall on C. $B'A'$ will assume the direction of BA, and therefore $C'A'$ will coincide with the perpendicular dropped from C on BA; that is, with CA.

Second case of congruence. Two right triangles are congruent if they have equal hypotenuses and one pair of corresponding legs equal.

Suppose the two triangles are ABC, $A'B'C'$, and that $BC = B'C'$, $AB = A'B'$. We move the second triangle onto the first so that $A'B'$ coincides with AB. The side AC will assume the direction of $A'C'$. We then have two oblique lines from point B to line AC; namely, BC and the new position of $B'C'$. These oblique lines are equal by hypothesis and therefore (30), equidistant from the foot of the perpendicular. This gives $A'C' = AC$, from which the congruence of the triangles follows.

35. Theorem. If two right triangles have equal hypotenuses and an unequal acute angle, then the sides opposite the unequal angles are unequal, and the larger side is opposite the larger angle.

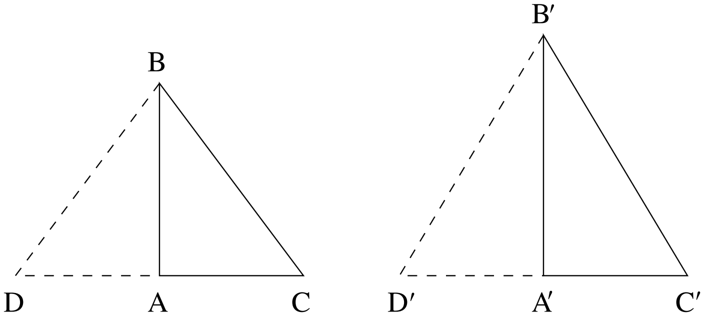

Figure 34

Let the two triangles be ABC, $A'B'C'$ (Fig. 34), for which $BC = B'C'$, $B > B'$. We claim that $AC > A'C'$.

To see this, we extend AC by its own length to get AD, and similarly extend $A'C'$ to get $A'D'$. We immediately have (29) $BD = BC = B'C' = B'D'$. Moreover, in isosceles triangle BDC median BA is also an angle bisector, so that angle DBC is twice the original angle B. Likewise, angle $D'B'C'$ is twice the original angle B', from which we have $DBC > D'B'C'$.

The two triangles DBC, $D'B'C'$ therefore have an unequal angle between equal sides, from which it follows that $DC > D'C'$, and therefore $AC > A'C'$.

36. Theorem. The bisector of an angle is the locus of points in the interior of the angle which are equidistant from the two sides.

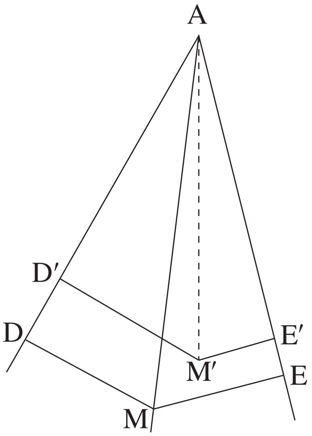

Figure 35

As explained earlier (33), the proof consists of two parts:

1°. Every point on the bisector is equidistant from the two sides.

Suppose the angle is ABC, and M is a point on its bisector. If we drop perpendiculars MD, ME to the sides of the angle, then right triangles AMD and AME are congruent, because they have a common hypotenuse, and an equal acute angle (at A) by hypothesis. Therefore the perpendiculars MD, ME are equal.

2. The distances from any point inside the angle, but not on its bisector, to the two sides are unequal.

Suppose point M lies, for instance, between the bisector and side AC. Then angle BAM will be greater than M AC. If we drop perpendiculars M D, M E onto sides AB, AC, then right triangles AM D, AM E will have a common hypotenuse and an unequal angle at A. Therefore M D will (35) be greater than M E.

As in the case of the theorem of 32, we could have proved, in place of the inverse proposition in 2 above, the converse proposition: Any point inside an angle, and equidistant from its two sides, is on its bisector. To do this, following the original reasoning in reverse, we would have considered a point M equidistant from the two sides, and would have applied the second case of congruence (34) to the two right triangles AMD, AME, which have a common hypotenuse and in which MD = ME. We would have concluded that the angles at A are equal, so that AM is the angle bisector. However, we would not have established which is the larger distance when they are unequal.

Corollaries. I. This theorem allows us to give a second definition of the bisector of an angle, namely: The bisector of an angle is the locus of the points inside the angle which are equidistant from the sides.

We observe that this second definition is exactly equivalent to the one given in 11.

II. The locus of all points equidistant from two intersecting lines is composed of the two bisectors (16) of the angles formed by these two lines.

Exercises

Exercise 19. Show that a triangle is isosceles if it has two equal altitudes.

Exercise 20. More generally, in any triangle, the smaller altitude corresponds to the larger side.

CHAPTER V

Parallel Lines

37. When two lines (Fig. 36) are intersected by a third (called a transversal), this last line forms eight angles with the first two, which are numbered in the figure. The relative positions of these angles are described as follows.

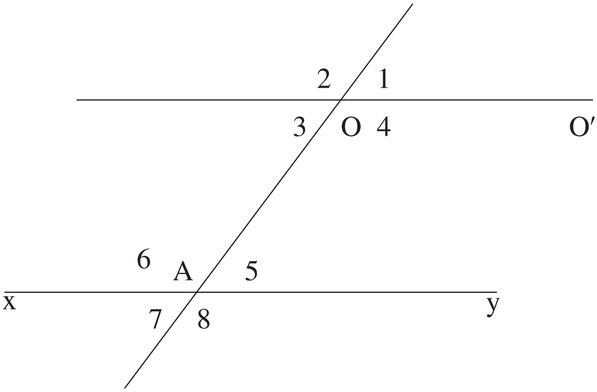

Figure 36

Two angles such as 3 and 5, situated between the two lines, and on different sides of the transversal, are called alternate interior angles.

Two angles such as 3 and 6 situated between the two lines, but on the same side of the transversal, are said to be interior on the same side.

Two angles such as 6 and 2 on the same side of the transversal, one between the two lines, one outside, are said to be corresponding.

38. Definition. Two lines in the same plane are said to be parallel if they do not intersect, no matter how far extended in either direction.

Theorem. Two lines intersected by the same transversal are parallel:

1. If the interior angles on the same side are supplementary;[1]
2. If alternate interior angles are equal;
3. If corresponding angles are equal.

1. If the two lines were to intersect, on either side of the transversal, they would form a triangle in which (25) the sum of two interior angles on the same side would have to be less than two right angles.

---

[1] If the angles 3 and 6 are supplementary, then so are 4 and 5, since the sum of these four angles is four right angles.

The other two cases can be reduced to the first:

2 . If 3 = 5, this is equivalent to saying that 3 is the supplement of 6, or that the interior angles on the same side are supplementary.

3 . If 6 = 2, then again 3 and 6 are supplementary, because 3 is the supplement of 2.

This theorem can be used to prove that two lines are parallel.

Corollary. In particular, two lines perpendicular to a third line are parallel.

39. Theorem. Through any point not on a given line, a parallel to the given line can be drawn.

Consider point O and line xy (Fig. 36). If we join point O to any point A of xy, then line OO , which makes an angle with OA such that AOO + OAy is equal to two right angles, will be parallel to xy.

40. Because the preceding construction can be made in infinitely many ways (since point A can be chosen anywhere on line xy), it would seem that there are infinitely many different parallels.

This is not true, however, if we adopt the following axiom:

Axiom. Through any point not on a given line, only one parallel to the given line can be drawn.[2]

Corollaries. I. Two distinct lines parallel to a third line are themselves parallel; since if the two lines had a point in common, two lines would pass through it, each parallel to the third line.

II. If two lines are parallel, any third line which intersects one of them must intersect the other, otherwise two parallels to the second line would intersect each other.[3]

41. The most important proposition in the theory of parallels is the following converse of the theorem in 38.

Converse. When two parallel lines are intersected by the same transversal:

1 . The interior angles on the same side are supplementary;

2 . The alternate interior angles are equal;

3 . The corresponding angles are equal.

The proof is the same in all three cases. Consider the parallel lines AB, CD intersected by the transversal EFx (Fig. 37). We claim, for example, that the corresponding angles xEB and xFD are equal. Indeed, we can construct, at point E, an angle xEB equal to angle xFD. Line EB will then be parallel to CD, and therefore it will coincide with EB.

Corollaries. I. If two lines determine, with a common transversal, two interior angles on the same side which are not supplementary, then the two lines are not parallel, and they intersect on the side of the transversal where the sum of the interior angles is less than two right angles.

II. When two lines are parallel, any line perpendicular to one of them is perpendicular to the other.

---

[2] This axiom is known as Euclid's Postulate. In fact it should be viewed as part of the definition in fundamental notions. (See Note B at the end of this volume.)

[3] We have here another example of a proof by contradiction (see 24, Remark I.)

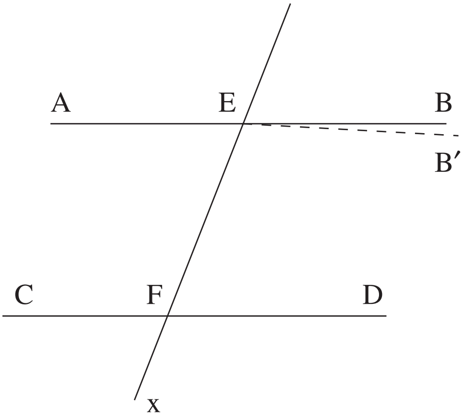

Figure 37

This is true because the perpendicular must intersect the other line (40, Corollary II) and the angle it forms will be a right angle, because of the theorem we have just proved.

Remarks. I. The corresponding equal angles xEB and xFD have the same direction of rotation.

The two parallel directions EB, FD, both situated on the same side of a common transversal, are called parallel and in the same direction.

II. We have used a new method of proof of a converse, different from the ones used in 32, and which consists in establishing the converse with the help of the original theorem. It should be noted here that the argument basically depends on the fact that the parallel through E to CD is unique.

42. According to the theorem of 38 and its converse, the definition of parallels amounts to the following: Two lines are parallel if they form, with an arbitrary transversal, equal corresponding angles (or equal alternate interior angles, or supplementary interior angles on the same side of the transversal).

This definition, equivalent to the first, is usually more convenient to use.

In place of the phrase parallel lines we often substitutes lines with the same direction, whose meaning is clear from the preceding propositions.

Remark. Because of what we have just noted, two lines which coincide must be viewed as a particular case of two parallel lines.

43. Theorem. Two angles with two pairs of parallel sides are either equal or supplementary. They are equal if the sides both lie in the same direction or both in opposite directions; they are supplementary if a pair of sides lie in the same direction, and the other pair opposite.

First, two angles with a common side, and whose second sides are parallel in the same direction (Fig. 38) are equal because they are corresponding angles. Two angles whose sides are parallel and in the same direction are then equal because one side of the first angle and one side of the second angle will form a third angle equal to the first two. If one of the sides is in the same direction, with the other

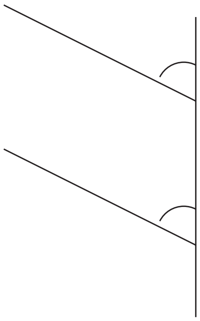

Figure 38

opposite, then extending the side which is in the opposite direction we obtain an angle supplementary to the first angle, and equal to the second.

If both sides are in opposite directions, we extend both sides of the first angle. Thus we form an angle equal to the first because they are vertical angles, and also equal to the second.

Remark. Two corresponding angles and, therefore, two angles with sides parallel and in the same direction, have the same sense of rotation. We can therefore say: Two angles with parallel sides are equal or supplementary, according as whether they have the same sense of rotation or not.

Theorem. Two angles whose sides are perpendicular in pairs are equal or supplementary, according as whether they have the same sense of rotation or not.

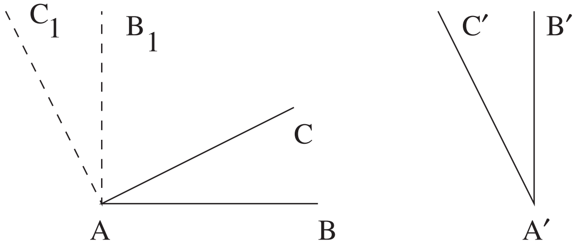

Figure 39

Consider angles BAC, $B'A'C'$ (Fig. 39) such that $A'B'$ and $A'C'$ are perpendicular respectively to AB and AC. We draw AB_1 perpendicular to AB, and turn angle B_1AC around on itself: side AB_1 falls on AC, and hence line AB, perpendicular to AB_1, will occupy a position AC_1 perpendicular to AC. We now have an angle B_1AC_1 which is equal to BAC and has the same sense (because it was constructed by reflection of angle CAB, whose sense is opposite to that of BAC) and whose sides, perpendicular respectively to those of the first angle, are therefore parallel to those of $B'A'C'$. Since the angles BAC, $B'A'C'$ are equal or supplementary, according as their sides have the same or opposite senses of rotation, the same is true of the given angles.

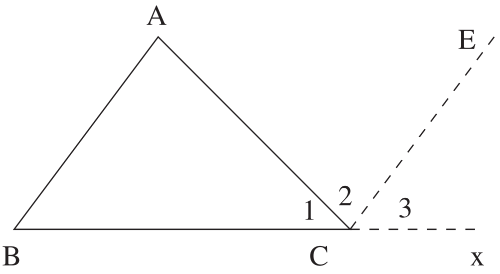

Figure 40

44. Theorem. The sum of the angles of a triangle is equal to two right angles.

In triangle ABC (Fig. 40), we extend BC in the direction Cx, and draw CE parallel to AB. We form three angles at C (numbered 1 to 3 in the figure), whose sum is equal to two right angles. These angles are equal to the three angles of the triangle; namely: 1 is the angle C of the triangle; 2 = A (these are alternate interior angle formed by transversal AC with the parallel lines AB, CE); 3 = B (these are corresponding angles formed by transversal BC with the same parallels).

Corollaries. I. An exterior angle of a triangle is equal to the sum of the non-adjacent interior angles.

II. The acute angles of a right triangles are complementary.

III. If two triangles have two pairs of equal angles, then the third pair of angles is equal as well.

44b. Theorem. The sum of the interior angles of a convex polygon[4] is equal to two less than the number of sides times two right angles.

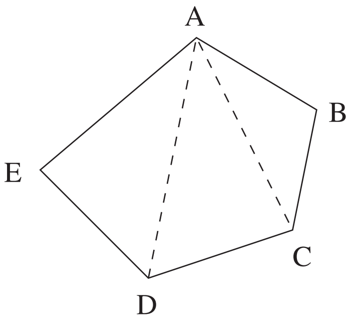

Figure 41

Let the polygon be ABCDE (Fig. 41). Joining A to the other vertices, we decompose the polygon into triangles. The number of triangles is equal to the number of sides minus two because if A is taken as the common vertex of these triangles, all the other sides of the polygon are the sides opposite A, except the two sides which end at A. The sum of the angles of these triangles gives us the sum of the angles of the polygon. The theorem is proved.

---

[4] The theorem remains true if one takes, as the interior angle at any vertex pointing inwards (Fig. 19b), the one which is directed towards the interior of the polygon, an angle which in this case is greater than two right angles. In the case of Fig. 19b the proof would proceed as in the text, drawing the diagonals starting from the vertex pointing inwards. If there are several inward-pointing vertices, the theorem would still be true, but the proof would be more difficult.

If n is the number of sides of the polygon, the sum of the angles is $2(n - 2)$ or $2n - 4$ right angles.

Corollary. The sum of the exterior angles of a convex polygon, formed by extending the sides in the same sense, is equal to four right angles.

Indeed, an interior angle plus the adjacent exterior angle gives us two right angles. Adding the results for all the n vertices we obtain 2n right angles, of which $2n - 4$ are given by the sum of the interior angle. The sum of the exterior angles is equal to the four missing right angles.

Exercises

Exercise 21. In a triangle ABC, we draw a parallel to BC through the intersection point of the bisectors of B and C. This parallel intersects AB in M and BC in N. Show that $MN = BM + CN$.

What happens to this statement if the parallel is drawn through the intersection point of the bisectors of the exterior angles at B and C? Or through the intersection of the bisector of B with the bisector of the exterior angle at C?

Sum of the angles of a polygon.

Exercise 22. Prove the theorem in 44b by decomposing the polygon into triangles using segments starting from an interior point of the polygon.

Exercise 23. In triangle ABC we draw lines AD, AE from point A to side BC, such that the first makes an angle equal to C with AB, while the second makes an angle equal to B with AC. Show that triangle ADE is isosceles.

Exercise 24. In any triangle ABC:

1. The bisector of A and the altitude from A make an angle equal to half the difference between B and C.

2. The bisectors of B and C form an angle equal to $\frac{1}{2}A$ + one right angle.

3. The bisectors of the exterior angles of B and C form an angle equal to one right angle $- \frac{1}{2}A$.

25. In a convex quadrilateral:

1. The bisectors of two consecutive angles form an angle equal to one half the sum of the other two angles.

2. The bisectors of two opposite angles form a supplementary angle to the half the difference of the other two angles.

CHAPTER VI

On Parallelograms. On Translations

45. Among quadrilaterals, we consider in particular trapezoids and parallelograms. A quadrilateral is called a trapezoid (Fig. 42) if it has two parallel sides. These parallel sides are called the bases of the trapezoid. A quadrilateral with two pairs of parallel sides is called a parallelogram. (Fig. 43).

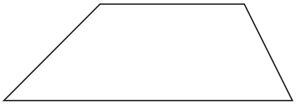

Figure 42

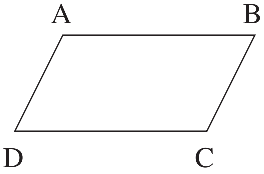

Figure 43

Theorem. In a parallelogram, opposite angles are equal, and angles adjacent to the same side are supplementary.

Indeed, in parallelogram ABCD (Fig. 43), angles A and C, adjacent to side AB, are interior angles on the same side formed by parallels AD, BC cut by transversal AB; therefore they are supplementary. The opposite angles A, C are equal because they have parallel sides in opposite directions.

Remark. We see that it suffices to know one angle of a parallelogram in order to know all of them.

Converse. If, in a quadrilateral, the opposite angles are equal, then the quadrilateral is a parallelogram.

Indeed, the sum of the four angles of a quadrilateral equals four right angles (44b). Since A = C, B = D, the sum of the four angles A + B + C + D can be writen as 2A + 2B. We then have A + B = two right angles, so the lines AD, BC are parallel, since they form two supplementary interior angles on the same side of transversal AB. Similarly, we can show that AB is parallel to CD.

46. Theorem. In any parallelogram, the opposite sides are equal.

In parallelogram ABCD (Fig. 44), we draw diagonal AC. This diagonal divides the parallelogram into two triangles ABC, CDA, which are congruent because they have the common side AC between equal angles: $A_1 = C_1$ are alternate interior angles formed by parallels AB, CD, and $A_2 = C_2$ are alternate interior angles formed by parallels AD, BC.

These congruent triangles yield AB = CD, AD = BC.

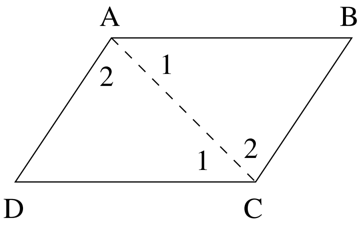

Figure 44

In this theorem, the hypothesis consists of two parts:
1 . two sides are parallel;
2 . the other two sides are also parallel.

The conclusion also has two parts:
1 . two opposite sides are equal;
2 . the other two sides are also equal.

Since we can form a converse by using either the whole or a part of the original conclusion, and vice versa, this theorem has two converses.

Converses. A quadrilateral is a parallelogram:
1 . If the opposite sides are equal;
2 . If two opposite sides are parallel and equal.

1 . Suppose that AB = CD and AD = BC in quadrilateral ABCD (Fig. 44). We again draw diagonal AC. Triangles ABC, CDA will be congruent, since they have three sides equal in pairs. Thus angles A_1 and C_1 are equal, and since these are alternate interior angles with respect to transversal AC, lines AB, CD must be parallel. Likewise, the equality of A_2, C_2 proves that AD and BC are parallel.

2 . Assume now that AB = CD and AB is parallel to CD. Triangles ABC, CDA are again congruent, because they have an equal angle ($A_1 = C_1$ are alternate interior angles) between two pairs of equal sides: AC is a common side and AB = CD. From this congruence we again find that $A_2 = C_2$, and that sides AD, BC are parallel.

46b. Remark I. A quadrilateral can have two sides AB, CD equal, and the other two BC, AD parallel, without being a parallelogram (it is then called an isosceles trapezoid).

Choosing an arbitrary side AB, it suffices to take the line symmetric to AB (D_1C, Fig. 45) with respect to any line xy in the plane, provided that the line xy is not parallel to AB, and that xy intersects the line AB in a point I on the extension of AB (and not on segment AB itself). Then quadrilateral $ABCD_1$ will have two parallel sides (both perpendicular to xy) and the other two equal (because they are symmetric to each other). These last two sides are not parallel because they intersect at point I.

Conversely, every quadrilateral with two sides BC, AD parallel, and the other two equal is either a parallelogram, or (in the case of an isosceles trapezoid) a figure with a line of symmetry. Indeed, let xy be the perpendicular bisector of BC. We have already found two oblique lines from C to the line AD, both equal to AB, namely: CD_1 which is symmetric to AB with respect to xy, and CD_2 which,

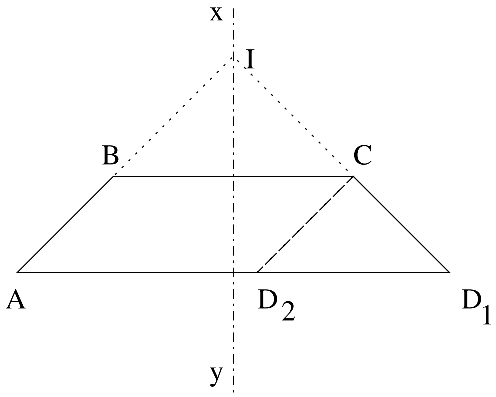

Figure 45

together with A, B, and C forms a parallelogram. These oblique lines certainly have endpoints on AD, since that line is parallel to BC. It follows that D must be either D_1 or D_2, since there are only two oblique lines equal to AB from C to AD.

The reasoning above may seem to be incorrect if D_2 coincides with D_1; that is, when CD_1 is parallel to AB. This requires, as we have just seen, that AB also be parallel to xy, and therefore perpendicular to AD, and indeed in this case there is only one oblique line from C with length equal to AB (the perpendicular).

Remark II. In the first part of the preceding converse it is essential that the quadrilateral be proper (21, Remark): it is only if the triangles ABC, ADC of Fig. 44 are on different sides of the common side AC that the angles A_1, C_1 are alternate interior.

It is easy to construct an improper quadrilateral (called a anti-parallelogram) whose opposite sides are equal. It suffices, in parallelogram ABCD (Fig. 45b), to replace the point D by point E symmetric to it with respect to the diagonal AC.

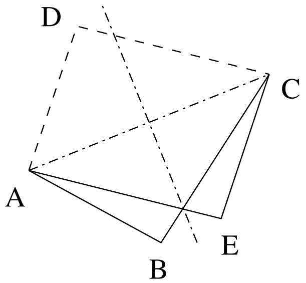

Figure 45b

We can also obtain an anti-parallelogram $ABCE_1$ by taking E_1 to be symmetric to B with respect to the perpendicular bisector of AC, so that ABE_1C is an isosceles trapezoid. But this point E_1 is none other than E, because (24, case 3) there is, on any one side of AC, only one point E which is both at a distance AE = BC from A and also at a distance CE = AB from C. Every improper quadrilateral with equal opposite sides is thus formed by the non-parallel sides and the diagonals of an isosceles trapezoid.

Remark III. Two quadrilaterals with four pairs of equal sides need not be congruent. In other words, we can deform a quadrilateral ABCD (proper or not) without changing the lengths of its sides.

Indeed, let AB = a, BC = b, CD = c, DA = d be the constant lengths of the four sides. With sides a, b and an arbitrary included angle B, we can construct a triangle ABC, whose construction will determine the length of AC (a diagonal of the quadrilateral). To each value of this diagonal (under the conditions for existence given in 86, Book II) there corresponds a triangle ACD with this base AC and with the other two sides CD, DA having length c, d. The angle B can therefore be arbitrary (at least within certain limits).

A quadrilateral which can be deformed under these conditions is called an articulated quadrilateral. This notion is important in practical applications of geometry.

According to the preceding results, a parallelogram remains a parallelogram when it is articulated and, likewise, an anti-parallelogram remains an anti-parallelogram under these conditions.[1]

47. Theorem. In a parallelogram, the two diagonals divide each other into equal parts.

In parallelogram ABCD (Fig. 46), we draw diagonals AC, BD, which intersect at O. Triangles ABO, CDO are congruent because they have equal angles, and an equal side AB = CD (by the preceding theorem). Therefore AO = CO, BO = DO. QED

Converse. A quadrilateral is a parallelogram if its diagonals divide each other into equal parts.

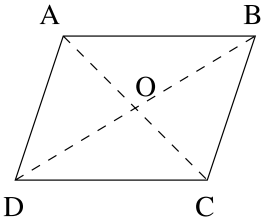

Figure 46

Indeed, assume (Fig. 46) that AO = CO, BO = DO. Triangles ABO, CDO are again congruent because they have an equal angle (the angles at O are vertical) included between pairs of equal sides. Therefore their angles at A and C will be equal, so that AB is parallel to CD. The congruence of triangles ADO, BCO also shows that AD is parallel to BC.

---

[1] This reasoning fails only if a parallelogram is transformed into an anti-parallelogram, or inversely (since a parallelogram and an anti-parallelogram are the only quadrilaterals with opposite sides equal). If the deformation occurs continuously, this requires that the quadrilateral first flatten into a line, so that one pair of adjacent sides ends up as extensions of each other, as does the other pair.

Remark. We have proved the converses in 46 and 47 by retracing the original reasoning in the opposite direction, as explained in 32, Remark II.

48. A quadrilateral whose angles are all equal, and are therefore are all right angles, is called a rectangle. A rectangle is a parallelogram, since its opposite angles are equal.

A quadrilateral whose sides are all equal is called a rhombus. A rhombus is a parallelogram since it has equal opposite sides.

Thus, in a rectangle, as in a rhombus, the diagonals intersect at their common midpoint.

Theorem. The diagonals of a rectangle are equal.

In rectangle ABCD (Fig. 47), the diagonals are equal because triangles ACD, BCD are congruent: they have side DC in common, ADC = DCB since they are both right angles, and AD = BC since they are opposite sides of a parallelogram.

Corollary. In a right triangle, the median from the vertex of the right angle equals half the hypotenuse.

This is true because if we draw parallels to the sides of the right angle through the endpoints of the hypotenuse, we form a rectangle, in which the median in question is half the diagonal.

Converse. A parallelogram with equal diagonals is a rectangle.

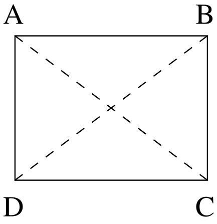

Figure 47

Suppose (Fig. 47) that AD = BC in parallelogram ABCD. We know that AD = BC: consequently, triangles ADC, BCD are congruent, since their three sides are equal in pairs. Angles ADC, BCD are therefore equal and, since they are supplementary, they must be right angles, which shows that the parallelogram is a rectangle.

Corollary. A triangle in which a median is one half the corresponding side is a right triangle.

Corollary. In a rhombus, the diagonals are perpendicular, and bisect the vertex angles.

If ABCD (Fig. 48) is a rhombus, then triangle ABD is isosceles. Diagonal AC, being a median of this triangle, is also an altitude and an angle bisector.

Converse. A parallelogram with perpendicular diagonals is a rhombus.

Indeed, each vertex is equidistant from the adjacent vertices, since it lies on the perpendicular bisector of the diagonal joining these vertices.

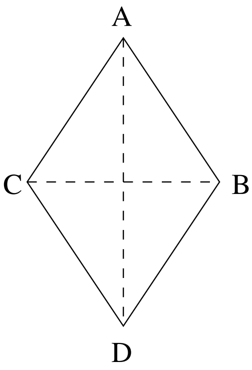

Figure 48

49. A square is a quadrilateral in which all sides are equal, and all the angles right angles.

Thus a square is both a rhombus and a rectangle, so that the diagonals are equal, perpendicular, and intersect each other at their common midpoint.

Conversely, any quadrilateral whose diagonals are equal, perpendicular, and bisect each other is a square.

Two squares with the same side are congruent.

50. Translations.

Lemma. Two figures F, F' are congruent, with the same sense of rotation, if their points correspond in such a way that, if we take points A, B, C from one figure, and the corresponding points A', B', C' from the other, then the triangles thus formed are always congruent, with the same sense of rotation, no matter which point we take for C.

Indeed, take two points A, B in figure F, and the homologous[2] points A', B'. Segment AB is then clearly equal to $A'B'$. Let us move the second figure onto the first in such a way that these two equal segments coincide. We claim that then the two figures coincide completely. Indeed, let C be a third point of the first figure, and let C' be its homologous point. Since the two triangles ABC, $A'B'C'$ are congruent, angle $B'A'C'$ is equal to BAC, and has the same sense of rotation. Therefore, when $A'B'$ is made to coincide with AB, the line $A'C'$ will assume the direction of AC. Since $A'C' = AC$ as well, we conclude that C' coincides with C. This argument applies to all the points of the figure, so the two figures must coincide completely.

Remarks. I. We have just provided a sufficient condition for two figures to be congruent; this conditions is also clearly necessary.

From the preceding reasoning it also follows that:

II. In order to superimpose two equal figures with the same orientation, it suffices to superimpose two points of one of the figures onto their homologous points.

---

[2] This is the name given to pairs of corresponding points in the two figures.

51. Theorem. If, starting at each point of a figure, we draw equal parallel segments in the same direction, then their endpoints will form a figure congruent to the first.

First consider two points A, B of the first figure, and the corresponding points A', B' of the second. Since the segments AA' and BB' are parallel and equal, $ABA'B'$ is a parallelogram. Therefore $A'B'$ is equal and parallel to AB, with the same orientation. Thus segments joining homologous pairs of points are equal, parallel, and have the same direction.

It follows that any three points of the first figure correspond to three points forming a congruent triangle, and since the angles of these triangles have their sides parallel and in the same sense, their sense of rotation is the same. The figures are therefore congruent.

The operation by which we pass from the first figure to the second is called a translation. We note that a translation is determined if we are given the length, direction, and sense of a segment, such as AA', joining a point to its homologue. We can therefore designate a translation by the letters of such a segment: for example, we speak of the translation AA'.

Corollaries. I. If, through each point on a line, we draw equal parallel segments in the same sense, the locus of their endpoints is a line parallel to the first.

In particular, the locus of points on the same side of a line, and a at a given distance from the line, is a parallel line.

II. Two parallel lines are everywhere equidistant.

We can therefore speak of the distance between two parallel lines.

III. The locus of points equidistant from two parallel lines is a third line, parallel to the first two.

Exercises

Parallelograms.

Exercise 26. The angle bisectors of a parallelogram form a rectangle. The bisectors of the exterior angles also form a rectangle.

Exercise 27. Any line passing through the intersection of the diagonals of a parallelogram is divided by this point, and by two opposite sides, into two equal segments.

For this reason, the point of intersection of the diagonals of a parallelogram is called the center of this polygon.

Exercise 28. Two parallelograms, one of which is inscribed in the other (that is, the vertices of the second are on the sides of the first) must have the same center.

Exercise 29. An angle of a triangle is acute, right, or obtuse, according as whether its opposite side is less than, equal to, or greater than double the corresponding median.

Exercise 30. If, in a right triangle, one of the acute angles is double the other, then one of the sides of the right angle is half the hypotenuse.

Translations.

Exercise 31. Find the locus of the points such that the sum or difference of its distances to two given lines is equal to a given length.

Exercise 32. Given two parallel lines, and two points A, B outside these two parallels, and on different sides, what is the shortest broken line joining the two points, so that the portion contained between the two parallels has a given direction?

CHAPTER VII

Congruent Lines in a Triangle

52. Theorem. In any triangle, the perpendicular bisectors of the three sides are concurrent.

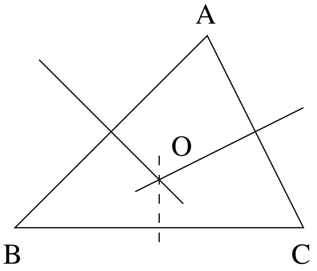

Figure 49

Suppose the triangle is ABC (Fig. 49). The perpendicular bisectors of sides AB, AC are not parallel (otherwise lines AB, AC would coincide), so they intersect at some point O. We must show that point O is also on the perpendicular bisector of BC.

Because point O, is on the perpendicular bisector of AB, it is equidistant from A and B; likewise, because it is on the perpendicular bisector of AC, it is equidistant from A and C. It is therefore equidistant from B and C and thus it is on the perpendicular bisector of BC.

53. Theorem. In any triangle, the three altitudes are concurrent.

Suppose the triangle is ABC (Fig. 50). We draw a parallel to BC through A, a parallel to AC through B, and a parallel to AB through C. This forms a new triangle A B C . We will show that the altitudes of ABC are the perpendicular bisectors of the sides of the new triangle, from which it follows that they are concurrent.

Parallelogram ABCB gives us BC = AB , and parallelogram ACBC gives BC = AC , so that A is indeed the midpoint of B C . Altitude AD of ABC thus passes through the midpoint of B C , and is perpendicular to it because it is perpendicular to the parallel line BC.

Since this reasoning can be repeated for the other altitudes, the proof is complete.

54. Theorem. In any triangle:

1 . the three angle bisectors are concurrent;

2 . the bisector of an angle, and the bisectors of the two non-adjacent exterior angles, are concurrent.

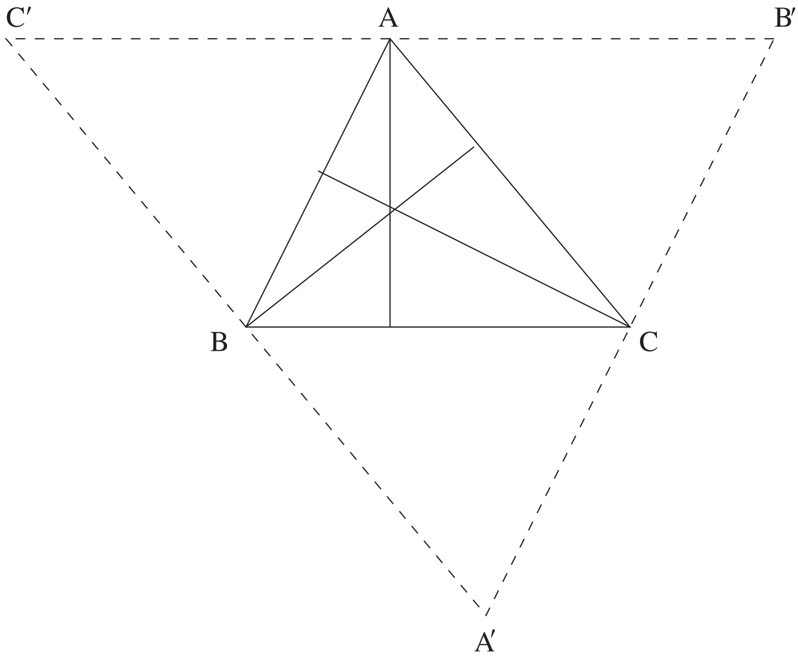

Figure 50

1 . In triangle ABC (Fig.51), we draw the bisectors of angles B and C; they intersect at a point O inside the triangle. This point, being on the bisector of angle B, is equidistant from the sides AB and BC. Likewise, being on the bisector of angle C, the point O is equidistant from AC and BC. It is therefore equidistant from AB and AC and, being interior to angle A, is on the bisector of this angle.

2 . Since the exterior angles CBx, BCy have a sum less than four right angles, halves of each have a sum less than two right angles. The bisectors of these angles will therefore meet (41, Corollary) at a point O inside angle A. This point O , like point O, will be equidistant from the three sides of the triangle. Therefore it will belong to the bisector of A.

55. Theorem. The segment joining the midpoints of two sides of a triangle is parallel to the third side, and equal to half of it.

In triangle ABC (Fig. 52), let D be the midpoint of AB and let E be the midpoint of AC. We extend line DE past E by its own length, to a point F. Quadrilateral ADCF will be a parallelogram (47), and therefore CF will be equal and parallel to DA, or, equivalently, to BD. Thus quadrilateral BDCF is also a parallelogram. Therefore:

1 . DE is parallel to BC;
2 . DE, which is equal to half of DF, is also half of BC.

56. Theorem. The three medians of a triangle are concurrent at a point situated on each of them one third of its length from the corresponding side.

First, let BE, CF be two medians of triangle ABC (Fig. 53). We claim that their intersection G lies at one third the length of each of them. To see this, let M

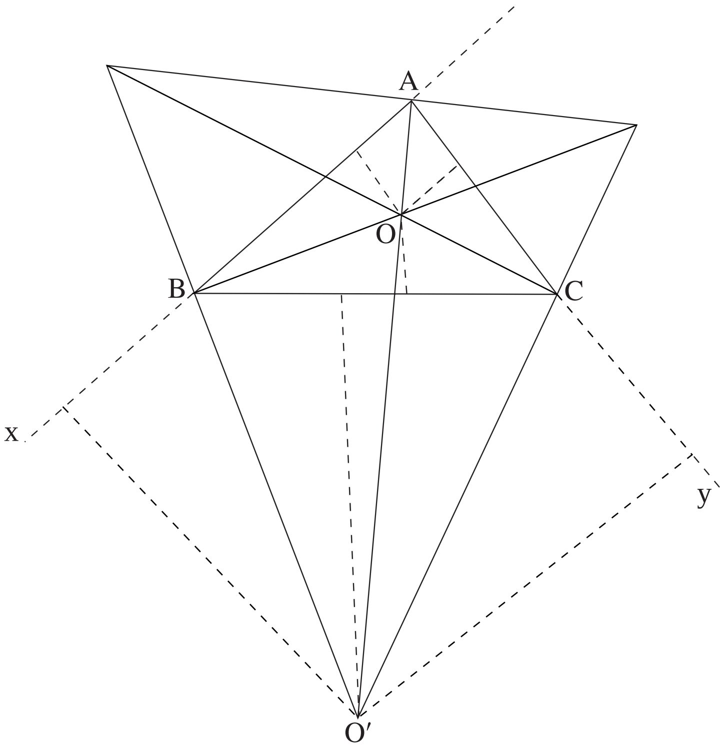

Figure 51

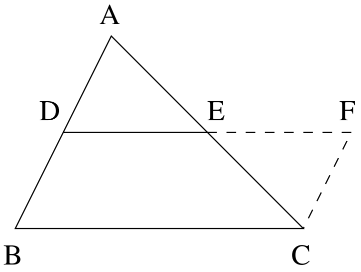

Figure 52

and N be the midpoints of BG and CG. Segment MN, which joins the midpoints of two sides of triangle BCG, is parallel to BC and equal to half of it. But EF is parallel to BC and equal to half of it. This means that EFMN is a parallelogram, whose diagonals divide each other in half. Therefore EG = GM = MB and FG = GN = NC.

Thus median BE passes through the point situated at one third the length of CF. But the same reasoning can also be applied to show that the median AD passes through the same point. The thereom is proved.

Remark. The point where the medians meet is also called the center of mass of the triangle. The reason for this name is given in the study of mechanics.

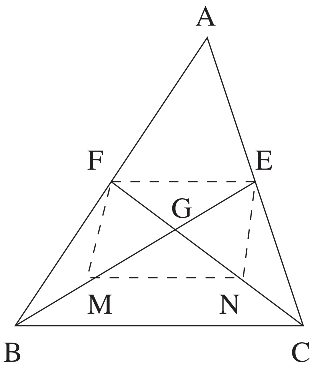

Figure 53

Exercises

Exercise 33. Join a given point to the intersection of two lines, which intersect outside the limits of the diagram (53).

Exercise 34. In a trapezoid, the midpoints of the non-parallel sides and the midpoints of the two diagonals are on the same line, parallel to the bases. The distance between the midpoints of the non-parallel sides equals half the sum of the bases; the distance between the midpoints of the diagonals is equal to half their difference.

Exercise 35. If, from two points A, B and the midpoint C of AB, we drop perpendiculars onto an arbitrary line, the perpendicular from C is equal to half the sum of the other two perpendiculars, or to half their difference, according as whether these two perpendiculars have the same or opposite sense.

Exercise 36. The midpoints of the sides of any quadrilateral are the vertices of a parallelogram. The sides of this parallelogram are parallel to the diagonals of the given quadrilateral, and equal to halves of these diagonals. The center of the parallelogram is also the midpoint of the segment joining the midpoints of the diagonals of the given quadrilateral.

Exercise 37. Prove that the medians of a triangle ABC are concurrent by extending the median CF (Fig. 53) beyond F by a length equal to FG.

Exercise 38. Given three lines passing through the same point O (all three distinct), and a point A on one of them, show that there exists:

1 . A triangle with a vertex at A and having the three lines as its altitudes (one exception);

2 . A triangle with a vertex at A and having the three lines as its medians;

3 . A triangle with a vertex at A and having the three lines as bisectors of its interior or exterior angles (one exception);

4 . A triangle with a midpoint of one of its sides at point A and having the three lines as perpendicular bisectors of the sides (reduce this to 1).

Problems for Book 1

Exercise 39. In a triangle, the larger side corresponds to the smaller median[1]. (Consider the angle made by the third median with the third side.) A triangle with two equal median is isosceles.

Exercise 40. Let us assume that a billiard ball which strikes a flat wall will bounce off in such a way that the two lines of the path followed by the ball (before and after the collision) make equal angles with the wall. Consider n lines $D_1, D_2, \ldots, D_n$ in the plane, and points A, B on the same side of all of these lines. In what direction should a billiard ball be shot from A in order that it arrive at B after having bounced off each of the given lines successively? Show that the path followed by the ball in this case is the shortest broken line going from A to B and having successive vertices on the given lines.[2]

Special Case. The given lines are the four sides of rectangle, taken in their natural order; the point B coincides with A and is inside the rectangle. Show that, in this case, the path traveled by the ball is equal to the sum of the diagonals of the rectangle.

Exercise 41. The diagonals of the two rectangles of exercise 26 are situated on the same two lines, parallel to the sides of the given parallelogram (analogous to 54). One of these diagonals is half the difference, and the other half the sum, of the sides of the parallelogram.

Exercise 42. In an isosceles triangle, the sum of the distances from a point on the base to the other sides is constant. What happens if the point is taken on the extension of the base?

In an equilateral triangle, the sum of the distances from a point inside the triangle to the three sides is constant. What happens when the point is outside the triangle?

Exercise 43. In triangle ABC, we draw a perpendicular through the midpoint D of BC to the bisector of angle A. This line cuts off segments on the sides AB, AC equal to, respectively, $\frac{1}{2}(AB + AC)$ and $\frac{1}{2}(AB - AC)$.

Exercise 44. Let $ABCD$, $DEFG$ be two squares placed side by side, so that sides DC, DE have the same direction, and sides AD, DG are extensions of each other. On AD and on the extension of DC, we take two segments AH, CK equal to DG. Show that quadrilateral $HBKF$ is also a square.

Exercise 45. On the sides AB, AC of a triangle, and outside the triangle, we construct squares $ABDE$, $ACGF$, with D and F being the vertices opposite A. Show that:

1°. EG is perpendicular to the median from A, and equal to twice this median;

2°. The fourth vertex I of the parallelogram with vertices EAG (with E and G opposite vertices) lies on the altitude from A in the original triangle;

---

[1] For similar statements concerning the altitudes of a triangle, see Exercises 19, 20, and for angle bisectors see exercises 362, 362b at the end of this volume.

[2] In the case where there is only one line, the problem reduces to the subject of Exercises 13–14. Once these exercises are solved, one tries to find a way to use the solution for the case of one line to treat the case for two lines; then to extend it to three lines, and so on.

3. CD, BF are equal to and perpendicular to BI, CI respectively, and their intersection point is also on the altitude from A.

Exercise 46. We are given a right angle AOB, and two perpendicular lines through a point P, the first intersecting the sides of the angle in A, B, and the second intersecting the same sides in C, D. Show that the perpendiculars from the points D, O, C to the line OP intercept on AB segments equal to AP, PB, respectively, but having the opposite sense.

Book II
On the Circle

CHAPTER I

Intersection of a Line with a Circle

57. Theorem. Through three non-collinear points we can always draw one and only one circle.

In other words, a circle is determined by three points not on a straight line.

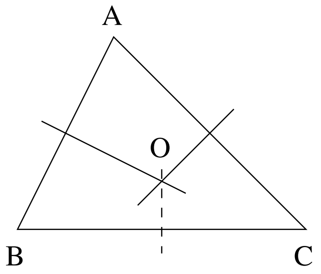

Figure 54

Indeed, assume that points A, B, C (Fig. 54) are not collinear. We proved earlier (52) that the perpendicular bisectors of segments BC, CA, AB pass through the same point O, equidistant from A, B, C. The circle with center O and radius OA passes through the three given points. It is the only circle with this property, because the center of a circle passing through A, B, C must necessarily belong to the three perpendicular bisectors just mentioned.

Corollary. We see that a circle cannot have two different centers nor, consequently, two different radii.

58. Theorem. A line cannot intersect a circle in more than two points.

If the distance from the center to the line is greater than the radius, the line does not intersect the circle.

If this distance is less than the radius, the line intersects the circle in two points.

Finally, if the distance to the line is equal to the radius, the line and the circle have only one common point.

In the last case we say that the line is tangent to the circle.

Assume that we are given a circle with center O and a line D. We drop (Fig. 55) perpendicular OH to the line.

1 . The circle cannot have more than two common points with line D. This amounts to saying that there are at most two oblique line segments equal in length to the radius R from O to D (31, Corollary).

2 . If OH is greater than the radius, the same is true a forteriori of all the oblique segments to D from O (29); thus all the points of D are outside the circle.

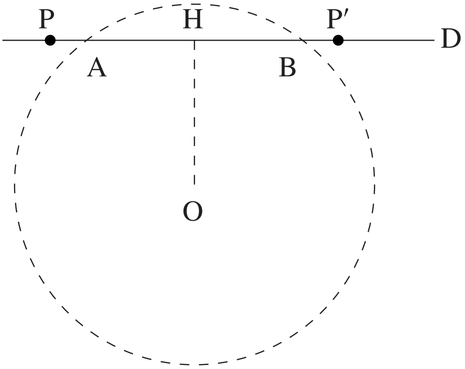

Figure 55

3 . If, on the contrary, OH (Fig. 55) is less than the radius, then point H is inside the circle; but on the two rays determined by H, there exist points outside the circle. To obtain such points, it is enough to construct points P, P on these rays such that HP, HP are equal to the radius: the distances OP, OP must then be greater than the radius. Therefore there will be an intersection point between H and P, and another between H and P ; further, these are the only points of intersection (1).

4 . Finally, if OH is equal to the radius (Fig. 56), the point H is on the circle but, as in 2 , we see that all the other points of the line are outside the circle.

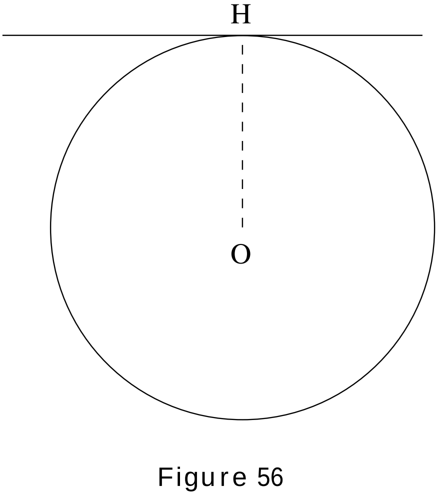

Figure 56

Corollary. Through a point on a circle we can draw one, and only one, tangent to the circle; namely, the perpendicular to the radius which ends at that point.

59. The definition just given for the tangent to a circle is not appropriate for an arbitrary curve.

Definition. A tangent to an arbitrary curve (Fig. 57) at a point M of this curve is the limiting position of line MM' as the point M' on the curve approaches the point M.

In other words,[1] line MT will be said to be tangent at M if, for any angle ε, we can find, on the two sides of M, arcs $\overset{\frown}{MM_1}$, $\overset{\frown}{MM_2}$ such that for any point M' on these arcs, line MM' makes an angle less than ε with line[2] MT.

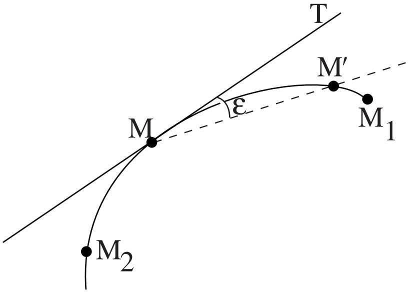

Figure 57

In the case of a circle, we will see that this definition is equivalent to the one we gave earlier.

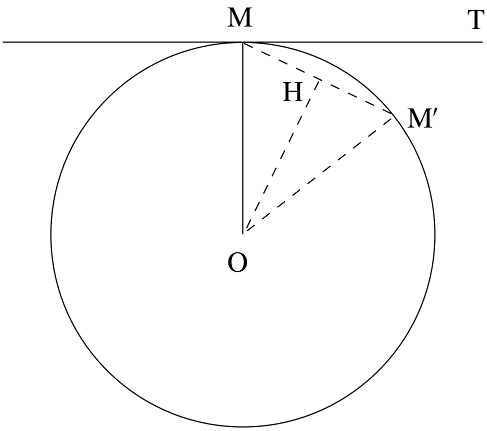

Figure 56b

From a point M on the circle we draw perpendicular MT to radius OM (Fig. 56b), and from O we drop a perpendicular OH to chord MM'. This perpendicular is both an altitude of the isosceles triangle OMM', and also the bisector of the angle at O. Angle TMM' is equal to MOH (they have pairs of perpendicular sides), and thus is half of MOM. But this angle can be made arbitrarily small by taking the point M sufficiently close to M.

---

[1] See the definition of the word limit in Leçons d'Arithmetique by J. Tannery (Paris, Librarie Armand Colin, 1894), chap. VII, n° 237, and chap. XII.

[2] One can show, as it is shown in arithmetic (Leçons de J. Tannery, n° 239), that if the line MT exists, then it is unique.

60. The line perpendicular to the tangent at its point of contact with a curve is called the normal to the curve at that point. The normal to a circle at any point is simply the radius ending at that point.

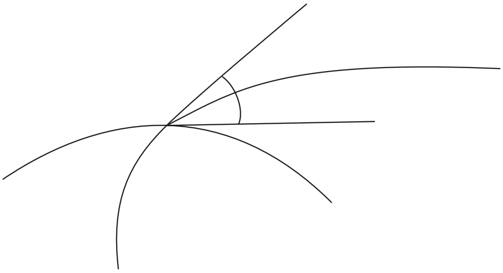

Figure 57b

On an arbitrary circle, there exist two points (and only two) such that the normals at these points pass through a given point P on the plane (different from the center): these are the endpoints of the diameter passing through P.

60b. The angle between two curves at one of their intersection points is the angle formed by the tangents to the curves at this point (Fig. 57b). The angle at which two circles intersect is therefore equal to the angle between the two radii ending at a common point, or to its supplement.

Exercises

Exercise 47. Through every point on a circle, we draw segments equal and parallel to a given segment. What is the locus of the endpoints of these segments?

Exercise 48. Find the locus of the midpoints of the segments joining a fixed point with each point on a circle.

Exercise 49. Consider a diameter AB of a circle O, a point C on the extension of the diameter, and a secant CDE passing through C which cuts the circle in D, E. If the exterior segment CD of the secant is equal to the radius, show that angle EOB is triple DOA.

CHAPTER II

Diameters and Chords

61. Using the definition of 19b, the remarks in 9 can be stated as follows:

Theorem. Every diameter is a line of symmetry for the interior of its circle, and also for its circumference.

We see that a circle has infinitely many lines of symmetry.

62. A line segments whose endpoints are the endpoints of an arc of a circle is called a chord. The arc is said to be subtended by the chord. We note that every chord subtends two different arcs, one larger than, the other smaller than, a semicircle (or both equal to a semicircle if the chord is a diameter).

63. Theorem. The diameter perpendicular to a chord cuts this chord, and its two subtended arcs, into equal parts.

Indeed, the diameter of a circle O perpendicular to a chord AB is a line of symmetry for the circle and at the same time a line of symmetry for the isosceles triangle OAB. Therefore this diameter is a line of symmetry for the whole figure formed by the circle and the chord.

Corollary. The same line is determined by any two of the following conditions:

1 . It is perpendicular to a chord;

2 . It passes through the center of the circle;

3 . It passes through the midpoint of the chord;

4 , 5 . It passes through the midpoint of one of the subtended arcs.

Corollary. The locus of the midpoints of a series of parallel chords is the diameter perpendicular to these chords.

Corollary. A tangent is parallel to any chord bisected by the diameter through the point of contact.

Theorem. Two parallel lines intercept equal arcs between them.

Indeed (Fig. 58), these arcs are symmetric with respect to the diameter which is perpendicular to these lines.

64. Theorem. On any circle, the closest and furthest point from a given point P of the plane are the feet of the normals (60) passing through P.

If A is the one of these points on ray OP, and B the point on the opposite ray (Figures 59 and 60), the distance PA is the difference between OP and the radius, and PB is the sum of the same segments. An arbitrary point M of the circle is

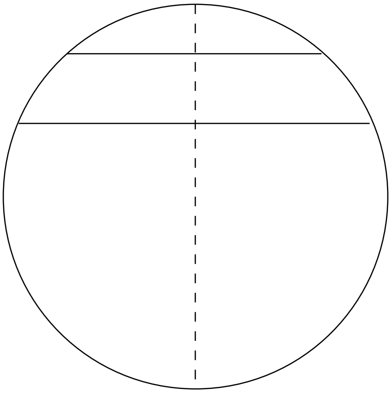

Figure 58

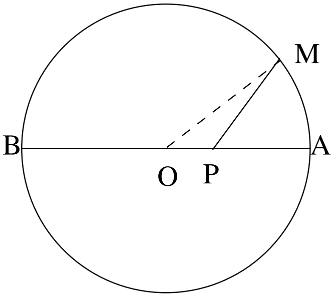

Figure 59

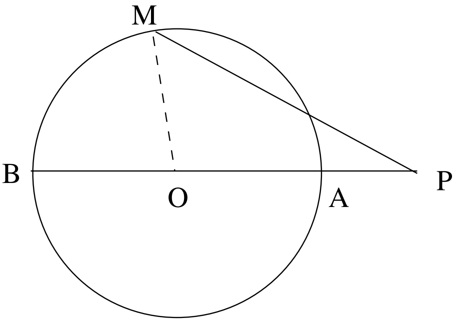

Figure 60

therefore at a distance from P greater than PA and smaller than PB, since PM is the third side of triangle OPM.

The distance PM increases as the point M moves along the circle from A to B, because, in triangle OPM, it is opposite to an angle which increases, but is contained between two constant sides.

Corollary. The diameter is the longest chord of a circle.

Indeed, if we take point P to coincide with A, we see that chord PM is smaller than the diameter PB.

65. Theorem. In the same circle, or in equal circles we have:

1 . Equal chords correspond to equal arcs, and conversely;

2 . For two unequal arcs, both less than a semicircle, the greater arc corresponds to the greater chord.

1 . If we superimpose the two equal arcs, their endpoints will coincide, and so will the corresponding chords. Conversely, if the chords are equal, the angles at the center corresponding to these chords are also equal, by the third case of congruence for triangles (SSS). Therefore the corresponding arcs are equal as well.

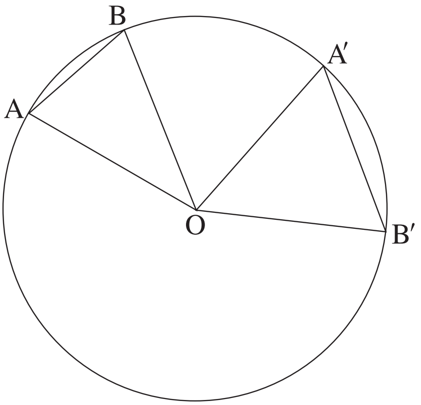

Figure 61

2°. If arc $\widehat{AB}$ is less than $\widehat{A'B'}$ (Fig. 61), and therefore the angle AOB is less than $A'OB'$, then chord AB will be less than $A'B'$ by the theorem of 28 applied to triangles OAB, $OA'B'$.

66. Theorem. In the same circle, or in equal circles:

1°. Two equal chords are equidistant from the center, and conversely;

2°. Of two unequal chords, the longer is closer to the center.

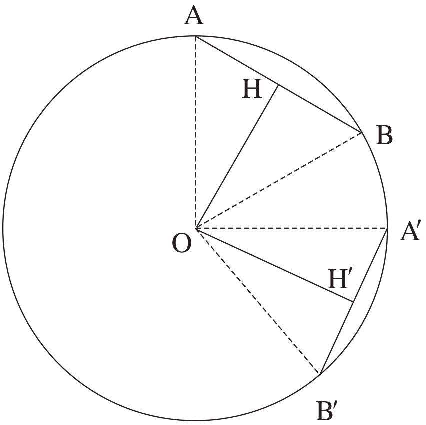

Figure 62

1°. Two equal chords of the same circle correspond to equal arcs. It suffices to superimpose the two arcs to see that the midpoints of the two chords are equidistant from the center.

Conversely, if two chords AB, $A'B'$ (Fig. 62) of circle O are equidistant from the center, then right triangles OHA, $OH'A'$ have equal hypotenuses and an equal pair of sides $OH = OH'$; thus $HA = H'A'$ and $AB = A'B'$.

2°. Suppose that chord AB is greater than $A'B'$ (Fig. 63). It follows that angle AOB is greater than $A'OB'$ and, dropping perpendiculars OH, OH', we see that

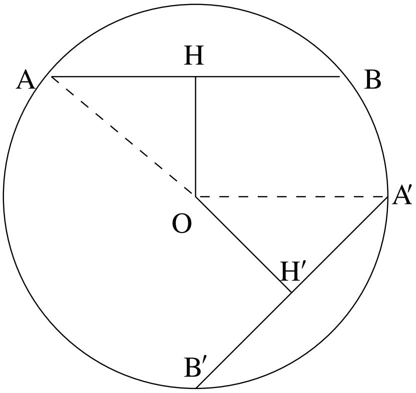

Figure 63

AOH is greater than $A'OH'$. Angle OAH, the complement of the first angle, is less than $OA'H'$, the complement of the second. Thus right triangles OHA, $OH'A'$ have equal hypotenuses, and a pair of unequal angles, from which we deduce (35) that $OH < OH'$.

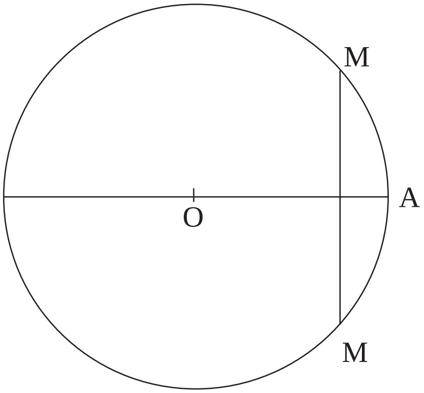

Figure 64

67. Consider a chord MM' (Fig. 64) whose distance to the center, at first less than the radius, increases until it equals the radius. Assume, to be definite, that this chord moves while remaining perpendicular to a fixed diameter OA. According to the preceding theorem, the length MM' decreases as this chord approaches the tangent at A, and we can take point M so close to point A (that is, the chord so close to the tangent), as to make this length as small as we wish, since $MM' < 2MA$. We see thus that the points M, M' approach each other and tend to coincide with the point A; this is expressed informally by saying that the tangent has a double point in common with the circle. We will see that this manner of speaking allows us to simplify the statements of certain theorems.

Exercises

Exercise 50. A circle passes through two fixed points A, B. Let C be one of the points where this circle meets a fixed line perpendicular to AB. Find the locus of the point diametrically opposite to C as the circle varies while passing through A and B.

Exercise 51. By dividing a chord into three equal parts and joining the division points to the center, we do not obtain three equal angles. Which is the greatest of the three angles? (Exercise 7.) Generalize to more than three equal parts.

Exercise 52. If two chords of a circle are equal, and we extend them (if necessary) to their point of intersection, the segments joining this intersection point with the endpoints of the two chords form two equal pairs.

Exercise 53. What is the locus of the midpoints of the chords of a given length of a circle?

Exercise 54. What is the shortest chord which passes through a given point inside a circle?

CHAPTER III

The Intersection of Two Circles

68. According to the theorem in 57, two circles cannot have more than two points in common.

Theorem. When two circles intersect, the line joining their centers is perpendicular to their common chord and divides it into equal parts. When there is only one common point, this point is on the line joining the centers. Conversely, if there is a common point on the line of their centers, the circles have only one point in common.

Indeed, the line of the centers is a common line of symmetry of the two circles. If the two circles meet at a point not on this line, they must meet again at the symmetric point. If there is only one intersection point, then it must belong to the line of the centers.

Conversely, if there is a common point on the line of the centers, then this is the only common point. Otherwise, the second common point is either on the line of the centers, in which case the circles would have a common diameter, or outside this line, in which case there would be a third common point. Under either of these circumstances, the two circles must coincide.

69. **Definition.** We say that two curves are tangent if they have the same tangent line at a common point.

According to the preceding theorem, in the case of two circles this definition becomes: Two circles are tangent when they have exactly one common point, because the tangents at this common point must be the same (58. Corollary).

70. Consider two circles with centers O, O' and radii R, R' and suppose, to be definite, that $R \geq R'$. Five cases are possible:

1°. $OO' > R + R'$ (Fig. 65). Let M be a point inside or on circle O', so that $O'M \leq R'$. We will have (26, Corollary)

$$OM \geq OO' - O'M > R + R' - O'M \geq R.$$

Therefore, every point in the second circle is exterior to the first, and every point on the first is exterior to the second. The two circles are said to be exterior to each other.

2°. $OO' = R + R'$. In this case the segment OO' can be viewed as the sum of two segments OA, $O'A$ (Fig. 66) equal to R, R', respectively. The point A is common to the two circles, and for all other points the preceding reasoning applies. The two circles are then tangent externally.

3°. $R + R' > OO' > R - R'$. In this case, R' is contained between the sum and the difference of the two lengths OO' and R.

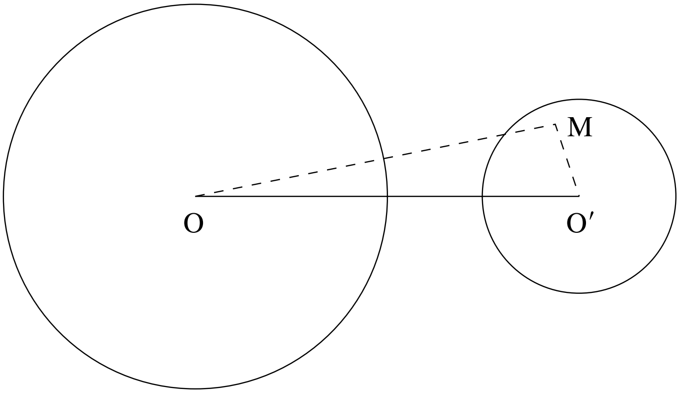

Figure 65

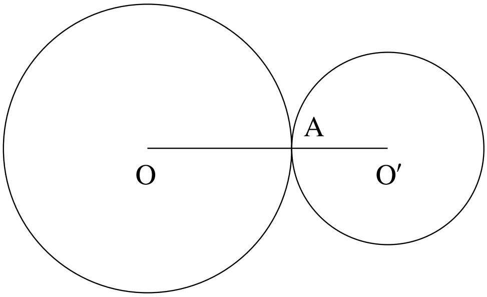

Figure 66

Therefore, of the two points A, B where circle O intersects the line of the centers, one is interior and the other exterior to circle O′ (Fig. 67). It follows that circle O, which is a curve joining A and B, meets circle O′ in a point different from either A or B, and therefore not on the line of the centers.

The circles have two common points, and are said to be intersecting.

4°. $OO' = R - R'$. In this case, OO' can be viewed as the difference of two segments OA, O′A (Fig. 68) equal to R, R′, respectively. Point A on the line of the centers is common to both circles, so the two circles are tangent.

Let M′ be any point on or inside the circle O′. We have

$$OM' \le OO' + O'M' \le OO' + R';$$

in other words, $OM' \le R$.

The entire circle O′, except for point A, is therefore interior to O. The two circles are said to be tangent internally.

5°. $OO' < R - R'$ (Fig. 69). Consider again a point M′ on or inside circle O′. We obtain

$$OM' \le OO' + O'M' \le OO' + R' < R.$$

Thus circle O′ is entirely inside O. The circle O′ is said to be interior to O.

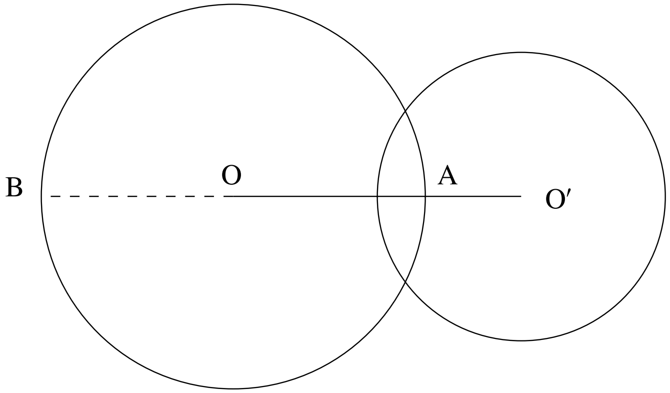

Figure 67

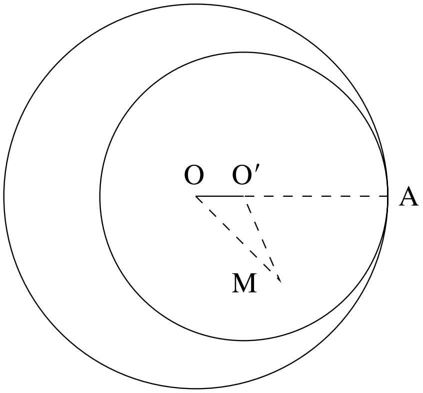

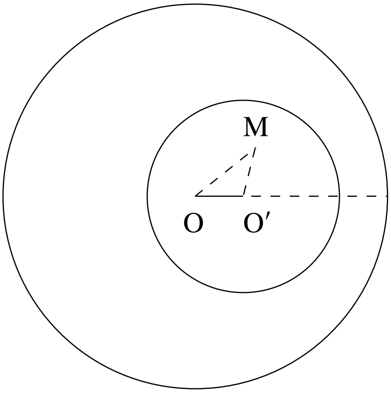

Figure 68

Figure 69

71. The preceding list exhausts the possibilities. It follows that the converses of the conclusions are also true. For example, if two circles intersect, the distance between the centers is contained between the sum and the difference of their radii: if this distance were greater than the sum of the radii, the circles would be exterior; if this distance were equal to the sum, the circles would be tangent externally, etc.

In any case, all of these converses are easily proved directly. Thus, in the case of intersecting circles, the point of intersection forms a triangle with the two centers, and the theorems of 26 yields the preceding conclusion.

We can therefore state the following theorem.

Theorem. 1 . If two circles are exterior, the distance between their centers is greater than the sum of the radii, and conversely.

2 . If two circles are tangent externally, the distance between their centers is equal to the sum of the radii, and conversely.

3 . If two circles intersect, the distance between their centers is less than the sum of the radii and greater than their difference, and conversely.

4 . If the circles are tangent internally, the distance between their centers is equal to the difference of the radii, and conversely.

5°. If one circle is interior to another, the distance between their centers is less than the difference of the radii, and conversely.

One can also say: Two circles are exterior, interior, intersecting, or tangent according as whether the segments they determine on the line of the centers are exterior to each other, are interior to each other, are extensions of each other, or overlap with a common endpoint.

72. If two circles, at first intersecting, vary so as to become tangent at A, their common points approach the point A indefinitely (see Exercise 55). One can informally say, as before (67), that two tangent circles have two common points which coincide, or a double common point.

Exercises

Exercise 55. Consider a circle O of radius R, and a circle O' of radius R' intersecting the first. Let A be one of the points where the line OO' intersects the circle O, and let B be another point on the same circle chosen arbitrarily, with particular interest when it is close to A.

Show that the two circles have one of their common points on the little arc $\overset{\frown}{AB}$:

When the point O' is on the extension of OA past A, if the difference $R + R' - OO'$ is less than $OB + O'B - OO'$;

When O' is between O and A, if the difference $OO' - (R - R')$ is less than $OO' - (OB - O'B)$;

When O is between O' and A, if the difference $OO' - (R' - R)$ is less than $OO' - (O'B - OB)$.

Exercise 56. What are the shortest and longest segments one can draw joining two circles?

Exercise 57. What is the locus of the centers of circles of fixed radius which are tangent to a fixed circle?

Exercise 58. If a line passing through the common point of two tangent circles intersects these circles again in two other points, then the radii ending at these points are parallel.

Exercise 59. Two circles which are tangent internally remain tangent if their radii are increased or decreased by the same quantity, without changing their centers. Two circles which are tangent externally remain tangent if, without changing their centers, one radius is increased by some quantity and the other is decreased by the same quantity.

CHAPTER IV

Property of the Inscribed Angle

73. An angle is said to be inscribed in a circle if it is formed by two chords AB, AC with a common endpoint. Thus an inscribed angle has its vertex on the circle.

Theorem. The measure of an angle inscribed in a circle equals one half the arc contained between its sides. (The endpoints B, C determine two arcs on the circle. The arc $\overset{\frown}{BC}$ which concerns us is the one which does not contain A.)

An inscribed angle equals half the central angle which subtends the same arc.[1]

N.B. The first part of the above statement assumes the convention of 17 (corollary).

We distinguish three cases.

First Case. One of the sides of the inscribed angle passes through the center.

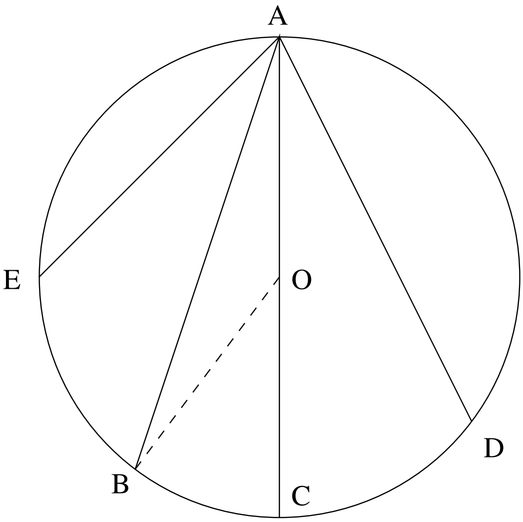

Figure 70

Consider inscribed angle BAC (Fig. 70) whose side AC passes through the center O. We join BO. Thus we form an isosceles triangle OAB whose angles A and B are equal. The exterior angle BOC, equal to the sum A + B, is therefore twice A. Since the measure of BOC is precisely that of arc $\widehat{BC}$, the measure of BAC is one half of this arc.

---

[1] The intercepted arc thus can be either minor arc $\overset{\frown}{BC}$ (20b) or major arc $\overset{\frown}{BC}$. In the last case, the corresponding central angle will be greater than two right angles, and the inscribed angle will be obtuse.

Second Case. The center is inside the inscribed angle.

Consider inscribed angle BAD (Fig. 70). Joining AO, which intersects the circle in C, we decompose the inscribed angle into two parts BAC, CAD for which the theorem has already been proved (first case). We have therefore (with the convention of 18)

$$BAC = \frac{1}{2}\text{arc } \widehat{BC}, \quad CAD = \frac{1}{2}\text{arc } \widehat{CD},$$

and adding,

$$BAD = \frac{1}{2}\text{arc } \widehat{BD}\ .$$

Third Case. The center is outside the inscribed angle.

Consider inscribed angle BAE (Fig. 70). We again construct diameter AC, and we can write

$$BAC = \frac{1}{2}\text{arc } \widehat{BC}, \quad EAC = \frac{1}{2}\text{arc } \widehat{EC},$$

and subtracting,

$$BAE = \frac{1}{2}\text{arc } \widehat{BE}\ .$$

Corollaries. I. All the angles inscribed in the same arc of a circle are equal, because they have the same measure.

II. An angle inscribed in a semicircle is a right angle, because its measure is a quarter of a circle.

74. Theorem. The angle formed by a tangent and a chord ending at the point of contact is equal to one half the arc it intercepts on the circle.

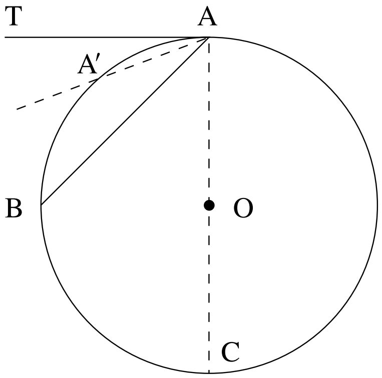

Figure 71

Angle BAT, formed by tangent AT and chord AB (Fig. 71) can in effect be considered as the limit of the angle formed by AB with chord AA when point A becomes infinitely close to A.

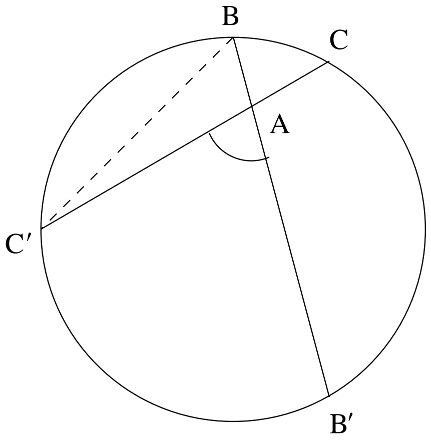

Figure 72

Alternatively, the proof given for the third case above can also be applied here; the equality $EAC = \frac{1}{2}$arc $\overset{\frown}{EC}$ must simply be replaced by

$$TAC = \frac{1}{2}\text{arc } \overset{\frown}{AC},$$

which follows from the fact that angle TAC is a right angle and arc $\overset{\frown}{AC}$ is a semicircle.

75. **Theorem.** The angle formed by two secants which intersect inside a circle is equal to one half the sum of two intercepted arcs: one which is between its sides and the other which is between the extensions of its sides.

Consider angle BAC (Fig. 72) whose sides intersect the circle again in B and C, and join BC. Angles C and B are one half the arcs $\overset{\frown}{BC}$, $\overset{\frown}{B\ C}$. But these two angles have a sum equal to A, an exterior angle for triangle ABC.

76. **Theorem.** The angle formed by two secants which meet outside a circle is equal to the half the difference of the two arcs contained between its sides.

Consider angle BAC formed by secants $AB\ B$, $AC\ C$. Angle $BC\ C$, exterior to triangle ABC, is equal to the sum $A + B$. Thus we can measure angle A as the difference $BC\ C \quad B$. This proves the theorem, since inscribed angle $BC\ C$ intercepts arc $\overset{\frown}{BC}$, and B intercepts $\overset{\frown}{B\ C}$.

Remark. If one of the secants, say $AB\ B$, is replaced by the tangent AT (Fig. 74), the theorem and its proof hold without change, if we let T play the roles of both B and B; in other words, by using the fact that the tangent meets the circle in two points coinciding at T, following the convention of 67.

77. **Theorem.** The locus of points situated on one side of a line, from which a given segment of the line subtends a given angle, is a circular arc ending at the endpoints of the given segment.

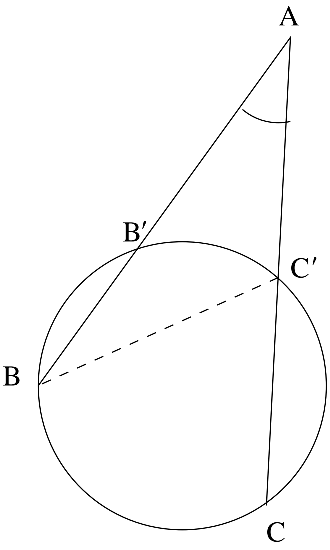

Figure 73

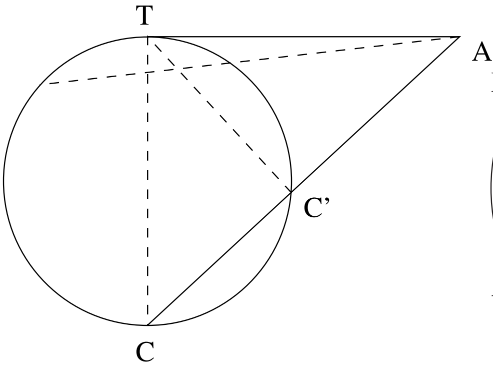

Figure 74

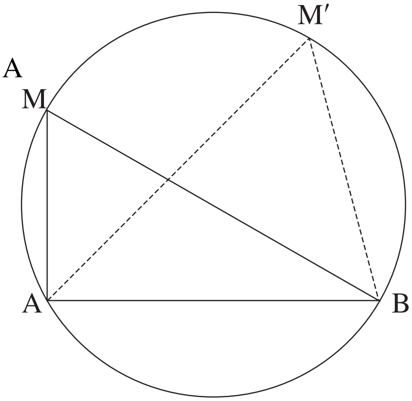

Figure 75

Indeed, let the given segment be AB, and let M be a point on the locus;[2] in other words, such that the angle AMB is equal to the given angle (Fig. 75). If we draw an arc of a circle through A, M, and B, with endpoints at A and B, any point on this arc will belong to the locus, because AM′B = AMB (by 73). On the other hand, any point N of the plane, situated on the same side of AB but not on the arc, is either outside or inside this circle. In the first case, angle ANB will be smaller than the given angle (76); in the second it will be larger (75), and therefore N will not belong to the locus. QED

---

[2] Such points certainly exist. One of them is obtained by constructing, through A and B, parallels to any angle equal to the given one and choosing, among the vertices of the parallelogram thus formed, the one which is on the required side of the line AB.

The circular arc described above is called the arc capable of the given angle relative to AB.[3]

If we do not require the points on the locus to be on one side of the line AB, then the locus will consist of two circular arcs, symmetric witih respect to AB.

78. When the given angle is a right angle, the preceding result combined with Corollary II in 73 shows that the locus of points where a given segment subtends a right angle is the circle having the segment as diameter.

This also follows from the two corollaries in 48.

79. Four randomly chosen points will not generally belong to the same circle, since any three of them determine a circle which, in general, will not pass through the fourth.

A necessary condition for four points to belong to a circle is given in the following result.

Theorem. In any convex quadrilateral inscribed in a circle, the opposite angles are supplementary.

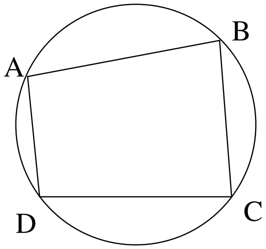

Figure 76

In quadrilateral ABCD inscribed in a circle (Fig. 76):

Angle A is equal to half arc $\overset{\frown}{DCB}$;

Angle C is equal to half arc $\overset{\frown}{DAB}$.

The sum of these two arcs is the whole circle, so that the sum A + C is equal to a central angle corresponding to a semicircle; that is, to two right angles.[4]

80. Converse. If two opposite angles of a convex quadrilateral are supplementary, then the quadrilateral is cyclic.

Suppose the quadrilateral is ABCD (Fig. 76) in which angles A and C are supplementary. The arc of the circle joining D, A, B, extended beyond BD, is the locus of the points from which BD subtends a constant angle (77), which is (79) supplementary to angle A. This arc therefore passes through point C.

81. Remark. In any quadrilateral ABCD one can consider the four angles A, B, C, D, and also, by drawing the diagonals AC, BD, the eight angles numbered 1 to 8 in Figure 77. If the quadrilateral is cyclic, then:

---

[3] The term in French is simply the word capable, which has the same ordinary meaning as in English. But it is not used in English in this mathematical sense. We will not use it in this edition. Transl.

[4] Hadamard uses the term inscribable (inscriptible), but without defining it, for a quadrilateral whose vertices lie on a circle. From this point on, we will use the standard term cyclic. Transl.

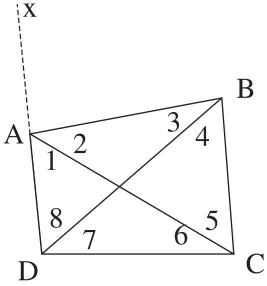

Figure 77

1 . A and C are supplementary;

2 . B and D are supplementary;

3 . 1 and 4 are equal;

4 . 5 and 8 are equal;

5 . 2 and 7 are equal;

6 . 3 and 6 are equal.

Conversely, if any one of these conditions holds, the quadrilateral is cyclic (77, 80).

Thus, any one of the conditions 1 , 2 , 3 , 4 , 5 , 6 implies the others.

82. Conditions 1 and 2 in the preceding remark can be rephrased in a form closer to 3 6 .

We note first that since points A, B (Fig. 77) are on the same side of CD, triangles CDA, CDB have the same sense of rotation, so that the equal angles DAC, DBC have the same sense. The same is true of angles ACB, ADB, etc. On the other hand, angles DAB, DCB have the opposite sense, since A and C are on different sides of BD. So we extend DA beyond point A along Ax, to form an angle xAB with the same sense as DCB: we see that these angles are equal if the angles DAB, DCB are supplementary, and we arrive at the following conclusion:

If four points A, B, C, D are on the same circle, the angle of the same sense formed by AC, AD on the one hand, and BC, BD on the other, are equal; and any statement that can be derived from this one by permuting the letters A, B, C, D is also true.

Conversely, if any one of the above six conditions holds, then the quadrilateral is cyclic. Therefore, each of the conditions 1 , 2 , 3 , 4 , 5 , 6 implies all the others.

82b. The statement of 77 can also be replaced by the following: The locus of vertices of all angles of a given size, whose sides (extended, if necessary) pass through two given points, is a circle passing through these two points.

Since every circle can be obtained in this manner, this statement can be considered as a new definition of a circle, equivalent to the first, and which can replace it if necessary.

Exercises

Exercise 60. Find the locus of the midpoints of the chords of a circle passing through a fixed point.

Exercise 61. On each radius of a circle we lay off, starting from the center, a length equal to the distance from the endpoint of the radius to a fixed diameter. Find the locus of the endpoints of the segments thus obtained.

Exercise 62. Given a fixed circle, and a fixed chord AB in this circle. Let CD be a variable chord, whose length stays fixed.

1°. Find the locus of the intersection I of the lines AC, BD.

2°. Find the locus of the intersection K of the lines AD, BC.

3°. Find the locus of the centers of the circles circumscribing the two triangles ICD, KCD. Show that these are respectively congruent to the two loci found above.

Exercise 63. Points A and B are fixed on a circle, and M is a variable point on the same circle. We extend segment MA by a length MN = MB. Find the locus of point N.

Exercise 64. Points A, B, C are three points on a circle. We join the midpoints of the arcs $\overset{\frown}{AB}$, $\overset{\frown}{AC}$. Show that this line intercepts equal segments (starting from A) on chords AB, AC.

Exercise 65. If we draw two arbitrary secants through the common points A, B of two circles, the chords joining the new intersections of these lines with the two circles are parallel.

Exercise 66. The bisectors of the angles of an arbitrary quadrilateral form a cyclic quadrilateral. The same is true for the bisectors of the exterior angles.

Exercise 67. Through the midpoint C of arc $\overset{\frown}{AB}$ of a circle, we draw two arbitrary lines which meet the circle in D, E, and chord AB in F, G. Show that DEFG is cyclic.

Exercise 68. We are given a circle, a fixed point P on this circle, and also a line, and a fixed point Q on this line. Through points P, Q we draw a variable circle which cuts the given circle again at R, and the given line at S. Show that line RS intersects the given circle in a fixed point.

Exercise 69. Two circles intersect at A and B. Through A we pass a variable line which cuts the circles again in C, C'. Show that the segment CC' subtends a constant angle at B, equal to the angle of the two radii ending in C, C'.

Through point A we draw a second secant, cutting the circles in D and D'. Show that the angle between the chords CD, $C'D'$ is equal to the angle found earlier, or to its supplement.

What becomes of the last statement when the two secants coincide?

Exercise 70. In any triangle, the points which are symmetric to the intersection of the altitudes with respect to the three sides lie on the circumscribed circle.

Exercise 71. Show that the altitudes of a triangle are the bisectors of the triangle formed by their feet.

We can apply the method of 82 to the quadrilaterals formed by two altitudes and two sides, show that these quadrilaterals are cyclic, and use the resulting angle properties.

The same method applies in a number of situations, such as the one in the following problem.[5]

Exercise 72. The feet of the perpendiculars, dropped from a point of the circumscribed circle onto the three sides of a triangle, are on the same line (the Simson Line).

Conversely, if the feet of the perpendiculars, dropped from a point in the plane onto the three sides of a triangle, are on the same line, this point must be on the circumscribed circle.

---

[5] This kind of reasoning is also useful in many of the problems proposed at the end of Book II.

CHAPTER V

Constructions

83. Since ancient times, it has been the practice to reserve the name geometric constructions for those constructions done with straightedge and compass. These constructions, theoretically, have absolute precision. In practice, they are effectively very precise, but nonetheless, as with any such process, offer some opportunity for error (such as the width of the marks left by a pencil).

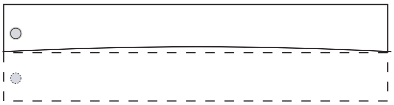

Figure 78

The straightedge is an instrument designed to draw straight lines. The accuracy of a straightedge, that is, the fact that its edge is really straight, depends on the care taken in its manufacture. To verify that this condition is satisfied, we use the actual definition of a straight line. We trace a first line along the edge of the straightedge (Fig. 78); then we turn the instrument around, placing it on the other side of the drawing. We should be able, in this new position, to trace along the edge of the straightedge a second line coinciding with the first.

The compass is composed of two pointed, articulated rods. The opening of the compass is the distance which separates the points of the two rods, and this instrument allows one to transfer distances, or to draw a circle with radius equal to this opening, with any center. This instrument is accurate if the opening does not change while the compass is moved.

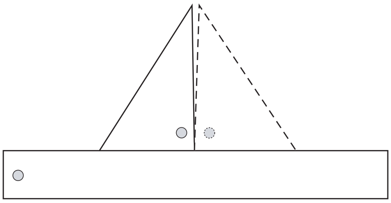

Figure 79

84. Besides the instruments just discussed, there are others which are used in practice, such as the set-square and the protractor. The set-square is a flat piece of wood (or other material) in the shape of a right triangle. A good set-square must satisfy two conditions:

1 . the sides must be straight;

2 . the angle must be a right angle.

The first of these is verified as in the case of the straightedege; it is usually satisfied in common set-squares. To verify the second one, we place the set-square on the edge of a straightedege (Fig. 79) and we trace a straight line along the side which should be perpendicular. Then, placing the set-square in the opposite sense, we should be able to draw a straight line coinciding with the first. Often, this condition is found to be only approximately satisfied, and one cannot rely on it for exact geometric constructions.

Finally, the protractor is an instrument for measuring angles. It is usually in the shape of a semicircle made of horn or copper, and divided into 180 parts. Since this division can only be done approximately, the protractor, while useful in practice, is not a geometric instrument.

85. Construction 1. (First fundamental construction). Construct the perpendicular bisector of a given segment.

This perpendicular is the locus of points equidistant from the endpoints A, B of a segment (33). So if we draw arcs, with centers A and B, which are sufficiently large that they intersect, the intersection points will belong to the perpendicular bisector; it remains simply to join these points.

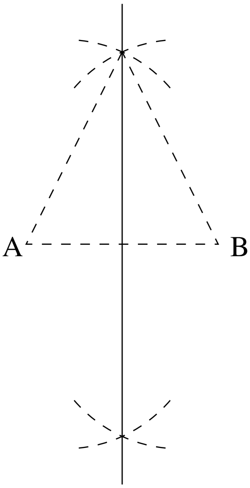

Figure 80

The following two constructions reduce to this one.

Construction 2. Drop a perpendicular from a point to a line.

With the given point O (Fig. 81 or 81b) as center, we draw a circle which intersects the line in points A, B. The perpendicular bisector of AB passes through O because OA = OB; it is therefore the desired perpendicular.

If point O is not on the line, we can take the distance OA as the common radius of the circles from construction 1 (used to find the perpendicular bisector of AB): thus we need not change the opening of the compass. These two circles will intersect at O and again at a point O′, symmetric to the first with respect to

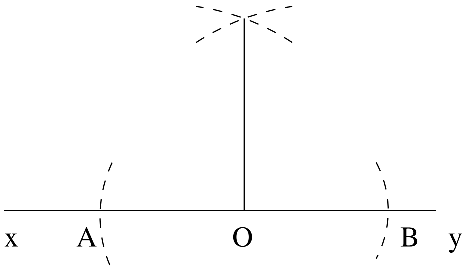

Figure 81

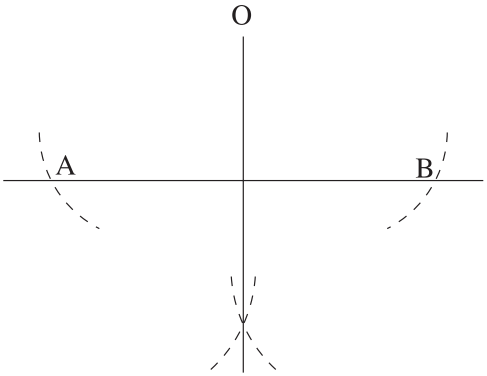

Figure 81b

AB. This simplification is not possible when O is on the line, because in that case O = O. Even when O is very close to the line it is preferable to use a different radius, as the proximity of O and O will not allow for a good determination of the line between them.

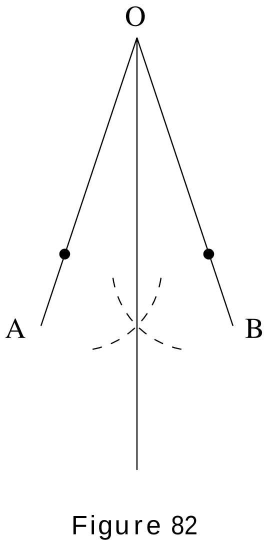

Figure 82

Construction 3. Construct the bisector of a given angle AOB (Fig. 82).

We lay off two equal segments OA, OB on the sides of the angle, so as to form an isosceles triangle. The perpendicular bisector of AB is the desired angle bisector (23).

The same simplification as before applies to the radii of the circles.

86. Construction 4. (Second fundamental construction.) Construct a triangle, knowing its three sides.

Taking segment BC equal to the first side (Fig. 83), we draw circles centered at B, C with radii equal to the other two sides; their intersection A gives the third vertex of the triangle. Thus there are two possible choices for this third vertex, since two circles have two points in common, but the two resulting triangles are symmetric with respect to BC, and so are congruent.

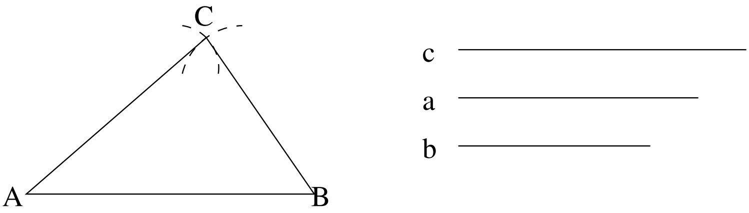

Figure 83

Condition for this construction to be possible. In order for the two circles to intersect, it is necessary and sufficient (70, 71) that the first side be less than then sum of the others, and greater than their difference or (26, Corollary), that each side be less than the sum of the other two.

If the order of the lengths of the three sides is known, it is enough to write that the longest side is smaller than the sum of the other two.

Construction 5. Through a point on a line, construct another line, forming with the first an angle equal to a given angle.

On the sides of the given angle O, we take two arbitrary points A, B. We then construct a triangle congruent to OAB, starting with a side equal to OA on the given line, and with an endpoint at the given point.

In practice, the triangle OAB is taken to be isosceles, so that we only need two different settings for the opening of the compass.

Construction 6. Knowing two angles of a triangle, find the third.

We construct two adjacent angles equal respectively to the two known angles. By extending one of the exterior sides we forms an angle supplementary to the sum of the first two. This is the required angle.

Condition for this construction to be possible. The sum of the two given angles must be less than two right angles.

Construction 7. Construct a triangle knowing two sides and the angle they contain.

On the sides of an angle equal to the given one, we lay off segments, starting from the vertex, equal to the given sides.

Construction 8. Construct a triangle knowing one side and two angles.

First, knowing two angles, we can find the third. In particular, we know the two angles adjacent to the given side; we place these angles at the endpoints of this side (Construction 5).

The conditions for this construction to be possible are the same as those for Construction 6.

87. Construction 9. Construct a triangle knowing two sides, and the angle opposite one of them.

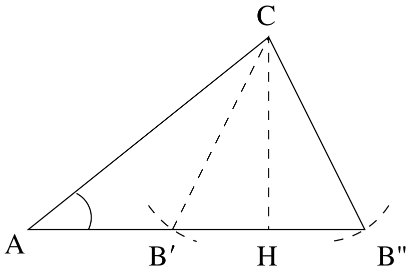

Figure 84

Let the triangle be ABC, in which we are given angle A and sides a, b, opposite A, B, respectively. After constructing an angle equal to A (Fig. 84), we lay off a segment AC equal to b on one of its sides. This determines point C, and we can then find B by drawing a circle with center C and radius a. The intersection of this circle with the second side of angle A gives us vertex B, which determines the triangle.

Discussion. We have a solution whenever the circle constructed above intersects ray Ax (Fig. 84), the second side of angle A.

We drop a perpendicular CH onto Ax.

1 . If CH > a, the circle does not intersect Ax and the construction is impossible.

2 . If CH < a, the circle intersects line Ax in two points B , B . It remains to see whether these points are on ray Ax or on its extension.

We distinguish two cases:

(a) Angle A is acute. In this case H, the midpoint of B B , is on ray Ax. At least one of the points B , B will also be on this ray, so that there always is at least one solution. There is a second solution if the second point is between A and H, which happens if and only if a < b.

(b) Angle A is obtuse. Then point H will not be on ray Ax; therefore at least one of the points B , B will not provide a solution, and thus there is at most one solution. There is one if the second point is farther from H than A is, which happens if and only if a > b.

87b. Finally, if angle A is a right angle, the problem can be restated thus: Construct a right triangle, knowing the hypotenuse and a side of the right angle. It has a solution if the hypotenuse is greater than the given side.

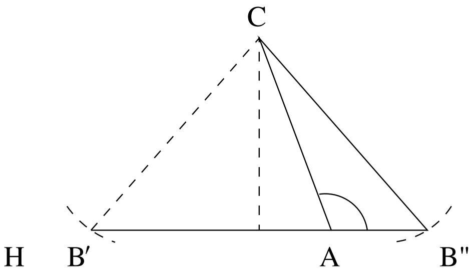

Figure 85

Remark. The following theorem is a result of the previous considerations:

Theorem. When two triangles have two sides equal in pairs, as well as the angle opposite one of them, the angles opposite the second side are either equal or supplementary. The first case (which implies the congruence of the triangles) always holds if the given equal angles are right or obtuse.

88. Construction 10. Through a point, construct a parallel to a given line.

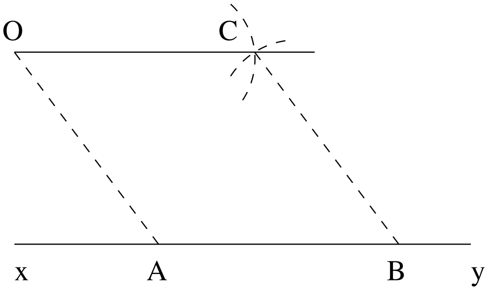

Figure 86

On the given line, we take two arbitrary points A, B (Fig. 86), then draw a circle with center O and radius AB, and a circle with center B and radius OA. These two circles will intersect (on the side of OB opposite to A) in a point C which belongs to the desired parallel. Indeed, OABC is a parallelogram because it has equal opposite sides.

It is convenient to take AB = OA so that all the circles drawn have the same radius.

89. Constructions 2 and 10 can also be performed with the set-square. To perform Construction 2 (To construct a perpendicular to a given line through a given point), we first apply the straightedge to the given line, and then slide one of the sides of the set-square along the straightedge, until its second side, perpendicular to the first, passes through the given point (Fig. 87) and thus gives the desired perpendicular.

This construction assumes the condition, usually not fully satisfied, that the angle of the set-square is a right angle, so it is not used in very precise sketches.

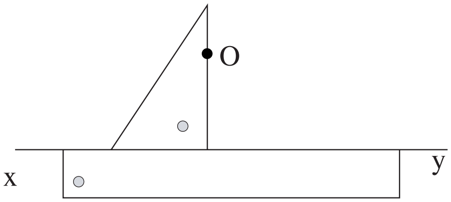

Figure 87

To perform Construction 10: Through a point, construct a parallel to a given line, we first place one side of the set-square along the given line (Fig. 88). Next, applying the straightedge to another side of the set-square and holding it in this position, we slide the set-square along the straightedge until the edge originally placed on the given line passes through the given point. The line thus obtained is parallel to the original one because it makes equal corresponding angles (A, A′ in the figure) with the same transversal (the edge of the straightedge).

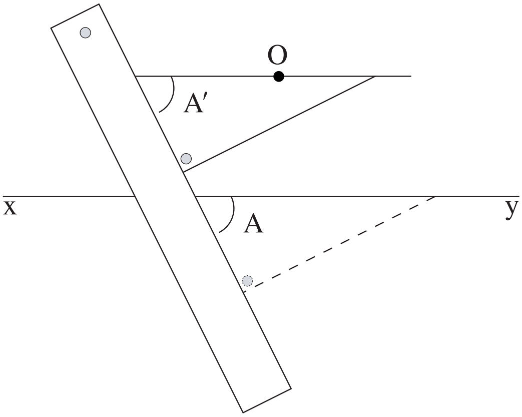

Figure 88

This construction supposes only that the edges of the straightedge and of the set-square are straight. Since it is as accurate as, and simpler than, the compass construction, it is the one that is used in practice.

90. Construction 11. Divide a circular arc into two equal parts.

We draw the perpendicular bisector of the corresponding chord (Construction 1).

Construction 12. Construct the circle passing through three given points A, B, C, not on the same line.

We construct the perpendicular bisectors of two of the segments joining the points: their intersection O is the center of the circle, and OA is its radius.

The circle thus obtained is said to be circumscribed about the triangle formed by the three points.

In general a polygon (or a broken line) is said to be inscribed in a curve, which is then said to be circumscribed about the polygon, when all the vertices of the polygon are on the curve.

Remark. If the three points A, B, C were collinear, there would not be any circle passing through them; we can consider line ABC as replacing it. A straight line can be viewed as a limiting case of a circle, whose center becomes infinitely distant. In fact, line AB is the locus of points at which segment AB subtends a constant angle; namely, an angle of zero degrees, or two right angles. One can also show directly that a circle passing through two fixed points AB, and whose center recedes indefinitely, has the line AB as its limit (one must, of course, give a precise meaning to this statement.)

Construction 13. Construct a circle knowing two of its points A, B, and the tangent AT at one of them.

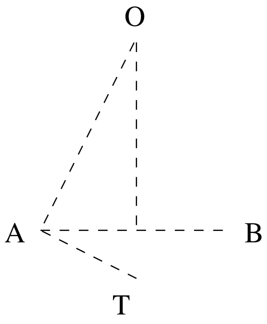

Figure 89

The center O will be the intersection of the perpendicular bisector of AB with the perpendicular to AT at the point A. The circle with center O and radius OA will indeed be tangent to AT, and will pass through B (Fig. 89).

Remark. This construction is a limiting case of the preceding one, following the general definition of tangents (59).

Construction 14. On a given segment, construct the arc of a circle from which the segment subtends a given angle.

Let AB be the given segment. Construct one point M of the locus (see footnote 2 to 77) and construct the circle AMB; or, note that the tangent at A to this circle forms with AB an angle equal to the given one (73, 74), which allows us to construct it (Construction 5), and we have reduced the problem to the preceding construction.

91. Construction 15. Construct the tangent to a given circle at a given point.

We draw a perpendicular to the radius at the point of contact.

Construction 16. Construct a tangent to a circle, parallel to a given line.

The diameter passing through the point of contact is precisely the diameter perpendicular to the given line; this diameter has two endpoints, and therefore there are two solutions.

Construction 17. Construct a tangent to a circle through a point in the plane.

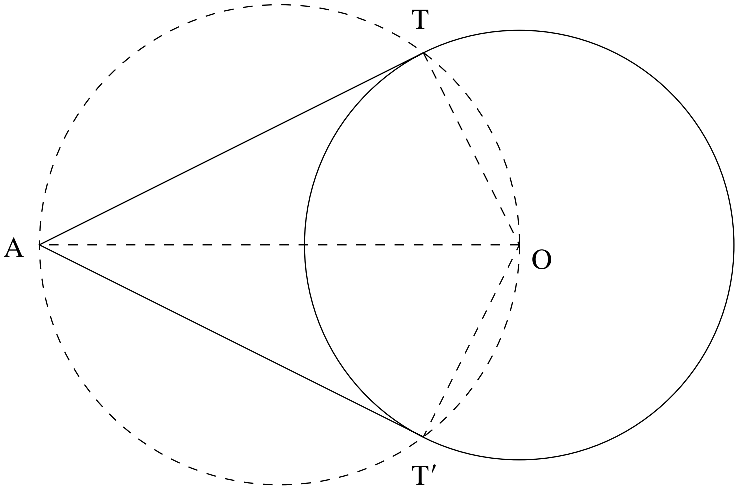

Figure 90

Let the given point be A, and the given circle have center O (Fig. 90). Assume that the problem is solved, and let T be the point of contact of a tangent passing through A. Since ATO is a right angle, point T belongs to the circle with diameter OA. Conversely, if a point T is on the given circle, and on the circle with diameter OA, then the tangent through T passes through A, because ATO is a right angle.

Therefore the points T which satisfy the conditions of the problem are the common points of the given circle and the circle with diameter OA.

Another method. Let the desired point of contact be T. Extend the segment OT beyond T by a length TO′ = OT (Fig. 91). Since TA must be perpendicular to OT, point O′ is symmetric to O with respect to AT, and therefore AO = AO′. Thus point O′ belongs to the circle with center A and radius AO. As it also belongs to a circle centered at O and with a radius twice the radius of the given circle, it is determined by the intersection of these two curves. Conversely, if point O′ is such that AO′ = AO, the midpoint T of OO′ is the point of contact of a tangent from A to the circle with center O and radius OT, because of the properties of an isosceles triangle.

Discussion. Let us start, for example, with the second construction. In order for a solution to exist, it is necessary that the two circles which determine O′ intersect; that is, (66) that the distance between their centers be less than the sum of the radii, and more than the difference. If R is the radius of the given circle,

(1) $$AO \quad 2R + AO$$

and

(2) $$AO \quad AO \quad 2R$$

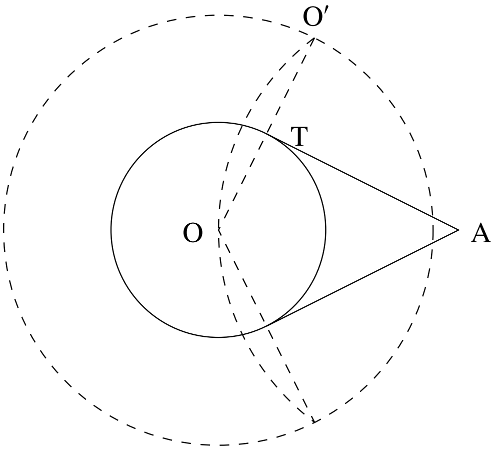

Figure 91

or

$$(3) \qquad AO \quad 2R \quad AO,$$

depending on whether AO is greater than or less than 2R. The inequalities (1) and (2) are obviously satisfied. Inequality (3) can be written 2AO 2R, or AO R. Thus the problem is impossible if A is inside the circle. On the other hand, if A is outside, there are two solutions, since the circles intersect in two points. Finally, if point A is on the circle, the two circles which determine point O are tangent, and there is only one solution, the tangent at A. Or rather, there are two identical solutions because, as we remarked (72), if the point A approaches infinitely close to the circle, the two points of contact, and therefore the two tangents, tend to coincide.

92. Theorem. The two tangents to a circle passing through a given point are equal, and they form equal angles with the diameter passing through the point. This diameter is perpendicular to the chord joining the two points of contact.

Indeed, the two points of contact are symmetric with respect to OA (Fig. 90) because they are the intersection points of two circles with centers on this line (see 68).

93. Construction 18. Draw the common tangents to two circles.

Consider two circles with centers O, O and radii R, R . The common tangents can be of two kinds: they can be external (Fig. 92), which means that both circles are on one side of the line, or internal (Fig. 93) when the two circles are on different sides of the tangent.

1 . Common external tangents. Suppose that a solution exists, and let AA be the required tangent (Fig. 92), with A, A being the points of contact, so that OA, O A are perpendicular to AA . We daw a parallel through O to AA , extended until it intersects OA in C. We will determine this point C.

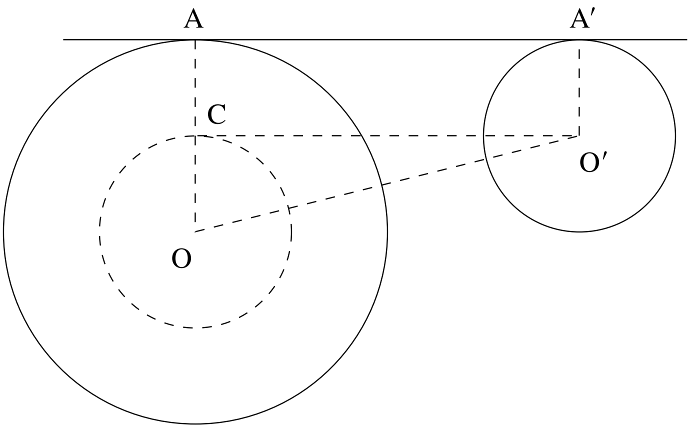

Figure 92

To this end, observe that CAA O is a rectangle, so that AC = R and therefore[1] OC = R R .

The point C therefore lies on a circle we can draw, since we have its center, O, and its radius, which is the difference between the given radii. Also, line CO is tangent to this circle, since angle OCO is a right angle. Thus we are led to Construction 17.

Once point C is determined, extending radius OC gives us point A. The tangent at A to the circle O is then the common tangent, because if we drop a perpendicular O A onto AA , the equality OC = R R gives O A = AC = OA OC = R .

The construction is possible (91) only if OO R R , in other words (70), if the two circles are external to each other, tangent externally, intersecting, or tangent internally. In the first three cases there are two solutions, since we can draw two tangents from O to circle OC; in the fourth case, there is only one solution, which can be considered two coinciding solutions, since the two tangents from O to circle OC coincide.

2 . Common internal tangents. Let BB be a common internal tangent, with points of contact at B and B (Fig. 93). As in the first case, we draw a parallel O D to BB , where D is the intersection of the parallel with line OB. Quadrilateral DBB O is a rectangle, and therefore BD = R , and D belongs to the circle centered at O with radius R + R . We can draw this circle, and draw a tangent to it from O . Once point D is determined, the intersection of OD with the first circle provides the point B. Following this reason backwards, we see that the tangent at B is a common tangent.

The construction is possible only if OO R + R , that is, if the two circles are exterior to each other, or externally tangent. In the first case there are two solutions, in the second only one (or two identical solutions).

In summary:

Two circles external to each other have two common external tangents and two common internal tangents;

---

[1] To be definite, we assume that the circle O has the greater radius. This assumption, which we have the right to make, is not essential here. In the opposite case, we will have OC = R R.

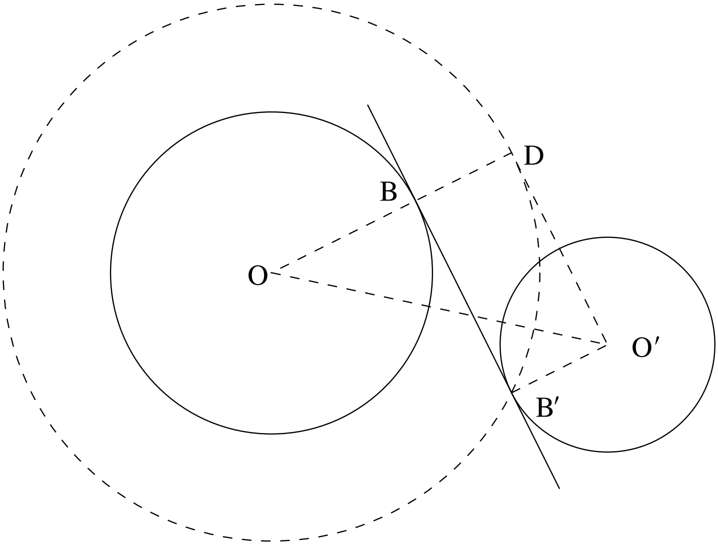

Figure 93

Two circles which are tangent externally have two common external tangents, and one common internal tangent (at their point of contact);

Two intersecting circles have two common external tangents;

Two circles which are tangent internally have one common external tangent (at their point of contact);

Two circles, one of which is interior to the other, have no common tangents.

94. Construction 19. Construct the circles tangent to three lines.

The problem amounts to this: find the points equidistant from three lines. A circle with its center at such a point, and the common distance as radius, will answer the question.

Now, the locus of points equidistant from two intersecting lines consists of the two bisectors of the angles formed by these lines.

Let us assume first that each pair of the three lines intersect, but not all three pass through the same point, so that they form a triangle (Fig. 94). In this triangle we construct the bisectors of the interior and exterior angles. We already know that: 1° the bisectors of the interior angles are concurrent; 2° the bisector of any interior angle has a point in common with the bisectors of the non-adjacent exterior angles. The four points thus defined (the intersection of the interior bisectors, and the three vertices of the triangle formed by the exterior bisectors) are therefore the desired points, and there are no others.

The first of the circles with centers at these points is inside the triangle. It is called the inscribed circle: in general, a curve is inscribed in a polygon when it is tangent to all of its sides. The three other circles, also tangent to the three sides, but outside the triangle, are said to be escribed: each one of them is situated inside one of the angles of the triangle, but separated from its vertex by the opposite side, as indicated in the figure.

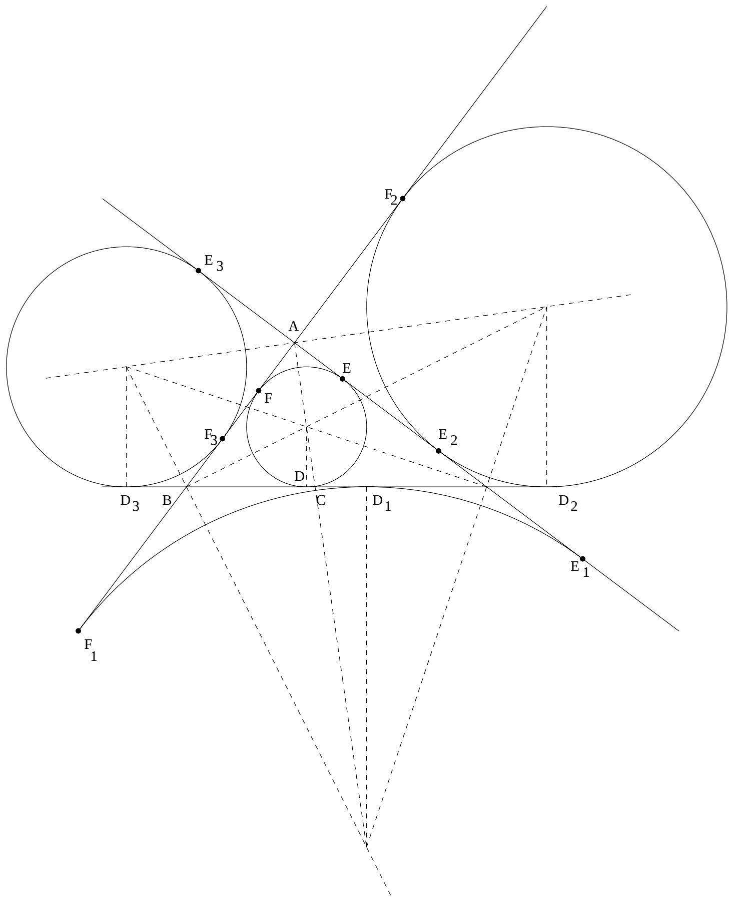

Figure 94

If the three given lines pass through the same point, there is no solution properly speaking, because one can draw only two tangents from a point to a circle. The preceding construction gives a circle reduced to one point; namely the, common point of the three lines.

If two of the lines are parallel, and the third is a transversal (Fig. 95), the bisectors of the angles formed by the transversal with the other two lines form two parallel pairs. Therefore we obtain only two circles, on either side of the transversal.

Finally, if the three lines are parallel, there is no solution, because a circle has only two tangents with a given direction.

Exercises

Exercise 73. Construct a circle of given radius:

(i) which passes through two given points;

(ii) which passes through a given point and is tangent to a given line;

(iii) which is tangent to two given lines;

(iv) which is tangent to a given line and a given circle.

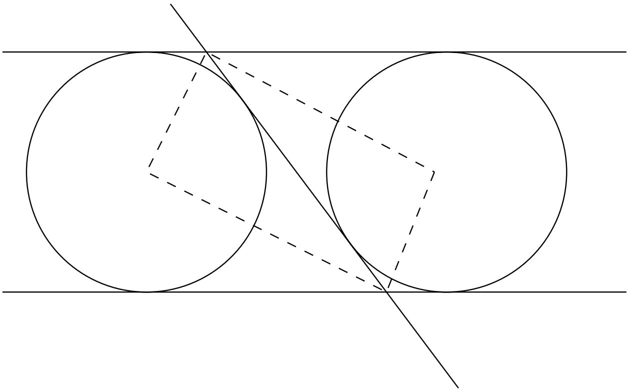

Figure 95

Exercise 74. Construct a circle tangent to a given line at a given point and also tangent to a given circle.

Exercise 75. Between two given lines (or circles), construct a segment of given length and direction.

Exercise 76. Construct a tangent to a given circle, on which a given line determines a segment of a given length.

Exercise 77. Construct a triangle knowing a side, the opposite angle, and an altitude (distinguish two cases, according as the given altitude corresponds to the given side or not).

Exercise 78. Divide a segment into three equal parts using the theorem of no. 56 on the medians of a triangle.

Exercise 79. Construct a triangle knowing:

(i) two sides and a median (distinguish two cases, according as the given median falls on one of the given sides or is contained between them);

(ii) one side and two medians (two cases);

(iii) the three medians.

Exercise 80. Construct a triangle knowing a side, an altitude, and a median (five cases).

Exercise 81. Construct a triangle knowing an angle, an altitude, and a median (five cases).

Exercise 82. Construct a triangle knowing one side, the opposite angle, and the sum or the difference of the other sides.

Exercise 83. Same problem, but the angle is adjacent to the given side.

Exercise 84. Construct a triangle knowing an angle, an altitude, and the perimeter (two cases).

Exercise 85. Construct a triangle knowing one side, the difference of the adjacent angles, and the sum or difference of the other sides.

Exercise 86. Construct the bisector of the angle formed by two lines which cannot be extended to their intersection.

Theorems on Tangents (see 92).

Exercise 87. In a quadrilateral circumscribed about a circle (and containing the circle in its interior), the sum of two opposite sides is equal to the sum of the other two opposite sides. Conversely, a convex quadrilateral in which the sums of the opposite sides are equal can be circumscribed about a circle.

While we cannot be sure that a quadrilateral circumscribed about a circle contains the circle in its interior, we can nonetheless always say that the sum of two side of the quadrilateral, appropriately chosen, is equal to the sum of the two others, and conversely.

Exercise 88. A circle tangent to three sides of a convex quadrilateral is on the same side as the interior of the quadrilateral, relative to these three sides. Show that this circle intersects or does not intersect the fourth side according as the sum of this side and the opposite side is greater than or less than the sum of the other sides.

Exercise 88b. If two points are outside a circle, the line joining them is exterior to or secant to this circle according as this segment between the two points is or is not contained between the sum and the difference of the tangents from these points to the circle.

Exercise 89. The segment intercepted by two fixed tangents of a circle on a variable tangent subtends a constant angle at the center. Special case: the fixed tangents are parallel.

Exercise 90. If a variable tangent to a circle intersects two fixed tangents, and the point of contact of the variable tangent is on the smaller arc determined by the point of contact of the fixed tangents, the triangle formed by the three tangents has a constant perimeter.

What can we say about this situation if the point of contact of the variable tangent lies on the larger arc determined by the fixed tangents?

Exercise 90b. Denote by a, b, c the three sides of a triangle ABC, and let p be the semiperimeter of the triangle (so that $2p = a + b + c$). Let D, E, F be the points of contact of the inscribed circle, and D_1, E_1, F_1, D_2, E_2, F_2, D_3, E_3, F_3 be the points of contact of the escribed circles in angles A, B, C, respectively. Then the segments intercepted by these points have the following values:

$$AE = AF = CD_2 = CE_2 = BD_3 = BF_3 = p - a;$$

$$BF = BD = AE_3 = AF_3 = CE_1 = CD_1 = p - b;$$

$$CD = CE = BF_1 = BD_1 = AF_2 = AE_2 = p - c;$$

$$AE_1 = AF_1 = BF_2 = BD_2 = CD_3 = CE_3 = p.$$

Exercise 91. Construct three pairwise tangent circles with centers at the three vertices of a given triangle.

CHAPTER VI

On the Motion of Figures

95. We have defined (20) the notion of congruent figures with the same orientation. We know (50) that if two points of a figure coincide with the corresponding points in a congrent figure, then the two figures coincide completely. In other words, there is only one way to place a figure F congruent to a given figure F with the same orientation[1] in such a way that two points of this figure (the points corresponding to two given points A, B of F) have a given position.

In fact, with this information (knowledge of the homologues A , B of A, B), we can determine the point C corresponding to another point C of F.

Indeed, it suffices to construct the triangle A B C congruent to A, B, C (Construction 4) then choose, from the two possibilities for the third vertex, the one which corresponds to the same orientation.

Since this can be done for every point of F , we see that we can solve (at least for figures composed of finitely many points and lines) the following:

Problem. Construct a plane figure F congruent to a given figure F (and with same orientation), knowing the points corresponding to two given points.

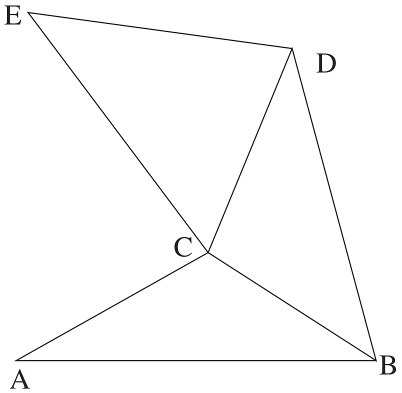

Figure 96

We should note that in constructing each point F , we are not obliged to start directly from the given points A , B .

---

[1] It is clear that without this restriction, nothing prevents us from replacing the figure F with the figure symmetric to it, with respect to the line joining the two points.

On the contrary, we can obtain the point corresponding to any point using the triangle formed, not with the original points, but with two other points already constructed.[2]

In this way we can construct a figure ABCDE (Fig. 96) by constructing successively three triangles congruent to ABC, BCD, CDE.

96. The operation called translation transforms every figure into a congruent figure with the same orientation. This motion can be thought of as a continuous sliding of the figure in its plane. It suffices to make the translation vary continuously from the value zero (for which the transformed figure coincides with the original one) to the final value of the translation.

In this parallel motion, the points move along parallel lines, in the same direction.

97. A rotation is the name given to a motion in which each point of the figure turns around a fixed point, called the center of the rotation, in a determined sense, through an angle which defines the magnitude of the rotation. In other words, a point A of the original figure F being given, we find the corresponding point A' of F' by joining A to the center O of rotation, forming an angle AOA' equal to the angle of rotation (and with the same orientation) then taking, on the second side of this angle, a length OA' equal to OA (Fig. 97).

We see that a rotation is determined by its center, its magnitude, and its sense.

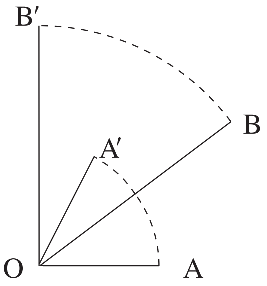

Figure 97

The figure F' obtained from F by an arbitrary rotation is congruent to F. To see this, take any two points A, B of F (Fig. 97) and consider the homologues A', B'. Angle $A'OB'$ is equal to AOB (and has the same orientation). Suppose, to be definite, that AOB has the same orientation as the rotation.[3] Replacing OB by OB', we increase this angle by a quantity equal to the angle of rotation, but then replacing OA by OA' diminishes the angle by the same quantity.

We conclude that the triangles AOB, $A'OB'$ are congruent, with same orientation, because they have an equal angle contained between equal sides. ($OA = OA'$, $OB = OB'$). Since this holds for all points B, the congruence of the figures is established.

---

[2] We will see how we can proceed in just the same manner in drawing maps (see Solid Geometry, Book X, 565).

[3] Recall (20) that angle AOB is taken to be drawn in the sense going from AO towards OB. We can make the assumption of the text by taking, as side AO, the first side we encounter, as we rotate in the given sense.

A rotation can also be obtained as a sliding of the figure in the plane, making the angle of rotation vary continously from zero to its final value. In this motion, each point moves along a circular arc with its center at the center of rotation. These arcs correspond to equal central angles.

98. Theorem. In two equal figures, derived from each other by a rotation around a point O (Fig. 98):

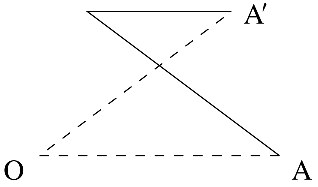

Figure 98

1°. Two corresponding lines, taken in the corresponding sense, form an angle equal to the angle of rotation, and in the same sense;

2°. The center of rotation, two arbitrary corresponding points A, A', and the intersection I of two corresponding lines passing through A and A', respectively, belong to the same circle.

1°. The first part of the theorem is true, by definition, for two corresponding lines passing through the center of rotation. It is therefore true for arbitrary corresponding lines, because each one can be replaced by a parallel line passing through the center of rotation.

2°. The four points A, A', O, I are on the same circle; namely, the locus of the vertices of angles, equal to the angle of rotation, whose sides pass through points A, A'.

99. Rotations through an angle equal to two right angles, or 180°, are of particular interest. The point A' corresponding to a point A can be constructed by joining OA, and extending this segment by a length $OA' = OA$. The point A' thus obtained is called the point symmetric to A with respect to the point O. Thus, in plane geometry, symmetry with respect to a point, and rotation about the same point by 180°, are two identical operations.

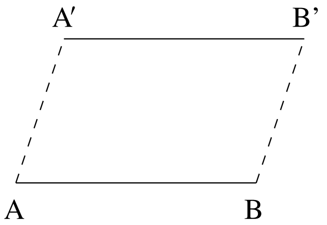

Figure 99

100. If, in two equal figures with the same orientation, two corresponding segments AB, $A'B'$ (Fig. 99) are parallel and have the same sense, the two figures

can be superimposed by a translation. Indeed, the quadrilateral $ABA'B'$ is a parallelogram, and therefore AA' is also parallel to BB', equal to it, and in the same sense: the translation AA' moves the points A, B to their respective homologues, which implies that this translation will make the two figures coincide completely.

If, in two equal figures with the same orientation, a point O coincides with its homologue, the two figures can be superimposed by a rotation around this point.

Indeed, if A, A' are two other corresponding points, the rotation with angle AOA' around O brings the point A to A', while the point O remains its own homologue.

101. We have seen (20) that two congruent figures with different orientations cannot be superimposed without one of them leaving the plane. On the other hand, two congruent figures with the same orientation can always be superimposed by a motion in the plane; namely, by a translation followed by a rotation. Indeed, if A, A' are two corresponding points, the translation AA' applied to the first figure will make these two points coincide, after which a rotation about the point A' will suffice to make the figures coincide (by the preceding section).

Observing that a translation does not change the directions of lines, we deduce that two arbitrary corresponding lines of two congruent figures with same orientation form a constant angle: thus we can talk of the angles between the two figures.

102. However, of the two preceding operation (translation and rotation), we can show that one only is necessary. Indeed, we have the following theorem:

Theorem. Two congruent figures with the same orientation can be superimposed either by a translation, or by a rotation about a properly chosen point.

This point is called the center of rotation.

Proof. Consider two points A, B of the first figure, and their homologues A', B' in the second figure. We will have superimposed the two figures if we make the segements AB and $A'B'$ coincide.

1°. If the segments AB, $A'B'$ are parallel in the same sense (Fig. 99), the figures can be superimposed by a translation;

2°. Assume that this is not the case. Let us see if these figures can be superimposed by a rotation. We know the angle of this rotation, which is equal to the angle between these figures, for instance the angle between AB and $A'B'$ (Fig. 100). We must therefore find a point O such that the rotation around O with this angle takes A to A'. This amounts to finding the center of a circular arc ending at A, A' and subtended by an angle equal to half the angle of rotation, and in the same sense (since the angle at the center equals twice the inscribed angle intercepting the same arc).

The point O will therefore be on the perpendicular bisector of the segment AA'; on the other hand, it will also be on the perpendicular to the tangent to the circle, constructed as indicated in 90 (Construction 14).

Conversely, point O being thus determined, the rotation with this center and with an angle equal to the angle of the two figures, will take A onto A'; it will also take the segment AB to a new position, parallel to $A'B'$ and with same direction. Since the two segments have the endpoint A' in common, this new position must be $A'B'$ itself. Thus the figures are superimposed. QED

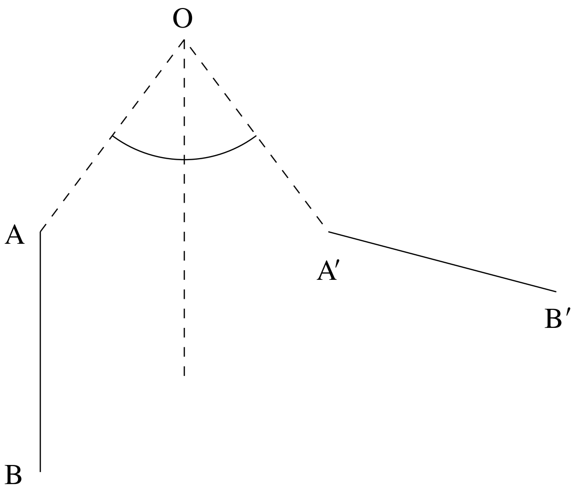

Figure 100

Remark. We can also prove this theorem by finding point O as the intersection of the perpendicular bisectors of AA' and BB' or (98) as the intersection of the circumscribed circles of triangles IAA', IBB', where point I is the intersection of AB and $A'B'$. With either of these constructions, one would establish that the triangles OAB and $OA'B'$ are congruent.

102b. The preceding theorem can also be proved by decomposing rotations and translations into two successive symmetries.

Lemma. Successive reflection in two lines D_1, D_2 is equivalent to:

1°. a translation perpendicular to the common direction of the lines, and twice the translation which would bring the first line onto the second, when the lines are parallel;

2°. a rotation around their intersection point and double the one which would bring the first line onto the second, when the lines intersect.

Proof. Let F be a figure, let F' be its reflection in D_1, and let F'' be the reflection of F' in D_2.

1°. Suppose that D_1 and D_2 are parallel (Fig. 101). If M is a point on F, we can find its reflection M' in D_1, by extending the perpendicular MH_1 from M to D_1 by its own length. We can then find the reflection M'' of M' in D_2 by extending the perpendicular $M'H_2$ from M' to D_2 by its own length. We see immediately that the three points M, M', M'' are on the same common perpendicular to D_1 and D_2. To be definite, we assume that M' is between D_1 and D_2. In this case the segment MM'', equal to the sum of MM' and $M'M''$ (Fig. 101), is twice the segment H_1H_2 which is the sum of $M'H_1$ and $M'H_2$.

This conclusion remains true if the point M' is exterior to the two parallel lines: in that case segment MM'' is the difference of MM' and $M'M''$, and H_1H_2 is the difference of $M'H_1$ and $M'H_2$. Thus the translation represented by a segment perpendicular to the two lines and double in length to H_1H_2 in fact does take any point of F onto the corresponding point of F''.

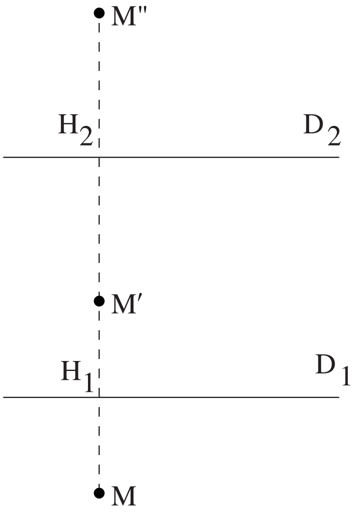

Figure 101

2°. Assume that the two lines of symmetry meet at O (Fig. 102), and let M, M', M'' be corresponding points of F, F', F'', so that M, M' are symmetric with respect to D_1 and M', M'' are symmetric with respect to D_2. Points M, M', M'' are clearly on the same circle with center O. Moreover, angle MOM'' is equal to the sum or difference of MOM' and $M'OM''$, and therefore is twice the angle between D_1 and D_2, and can be thought of as the sum or the difference of the angles made by OM' with D_1 and D_2. Therefore the rotation defined in the statement of the lemma moves each point M onto its corresponding point M''. QED

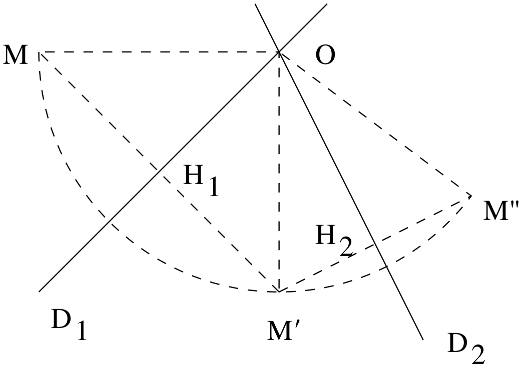

Figure 102

Remark. Two successive reflections in the same line cancel each other, since each point returns to its original position.

Corollary. Conversely, every translation can be replaced by two successive line reflections, in lines perpendicular to the direction of the translation, one of which can be chosen arbitrarily;

Every rotation can be replaced by two successive reflections in lines passing through the center of the rotation, and one of these can be chosen arbitrarily.

Indeed, in the case of a translation, it is enough to take the line that is not arbitrarily chosen to be at a distance from the arbitrary line equal to half that of the translation; and, in the case of a rotation, to take it so as to make, with the arbitrarily chosen line, an angle half that of the rotation.

103. Theorem. Any number of successive translations or rotations can be replaced with a single translation or a single rotation.

This process called composition of displacements: the final motion is called the result of the given displacements.

It suffices to know how to compose two displacements; if we have three, we begin by composing the first two, and then compose the result with the third; one would continue in an analogous fashion if there were more than three displacements.

Two successive translations replace a line with a parallel one, in the same sense, and therefore the result is a translation (100).

We need therefore consider only a translation followed or preceded by a rotation, or two rotations.

In the first case, we assume, to be definite, that the translation is performed first. This translation can be decomposed into two reflections in the lines D_1, D_2, and the rotation can also be decomposed into reflections in the lines D_1, D_2, so that we must perform four reflections altogether, in lines D_1, D_2, D_1, D_2. Now the line D_2 can be chosen arbitrarily from among those perpendicular to the direction of the translation, and the line D_1 can be chosen arbitrarily from among those passing through the center of the rotation. So we can choose both to coincide with the line through the center of rotation and perpendicular to the direction of translation.

With this choice, the reflections in these two lines will cancel, and we are left with two reflections, in lines D_1, D_2 which will yield (by the preceding numbered paragraph) a translation or a rotation.

If we had to compose two rotations, we would have taken $D_2 = D_1$ to be the line joining the two centers of rotation. This proves the theorem in all cases.

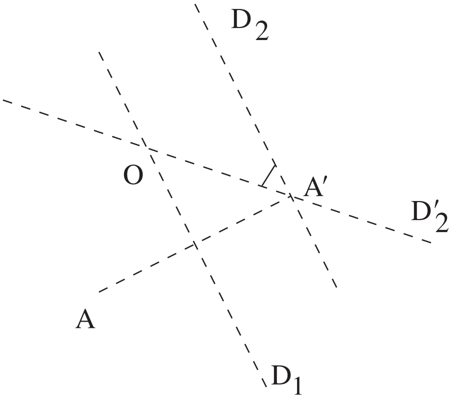

Figure 103

The theorem in 102 can now be regarded as a corollary of the one we just proved. An arbitrary motion of a figure in the plane is a translation followed by a rotation, namely (if A, A' are two corresponding points of the original figure and of the displaced figure) the translation AA' followed by a rotation with center A' through an angle equal to the angle of the two figures (Fig. 103). Lines D_2, D_1 will coincide with the perpendicular from A' to AA'; line D_1 will then be the perpendicular bisector of AA', and D_2 will be obtained by rotating D_2 about A' through half the angle of rotation. The intersection point of D_1, D_2 gives the center of rotation. We see that the construction is entirely in agreement with the one given earlier, because in constructing (Construction 14) the tangent to the circular arc on AA' which subtends half the angle of rotation, we are actually constructing a perpendicular to D_2.

104. **Theorem.** When a figure moves in the plane, without change shape, at each instant the normals (60) to the trajectories of the various points (if they are not all parallel) will be concurrent at a point which we call the instantaneous center of rotation.

Leaving aside the case where all normals to the moving points $M, N, P, \ldots$ are parallel, we assume that two of these normals, the normals at M, N for instance, intersect in a point O (Fig. 104).

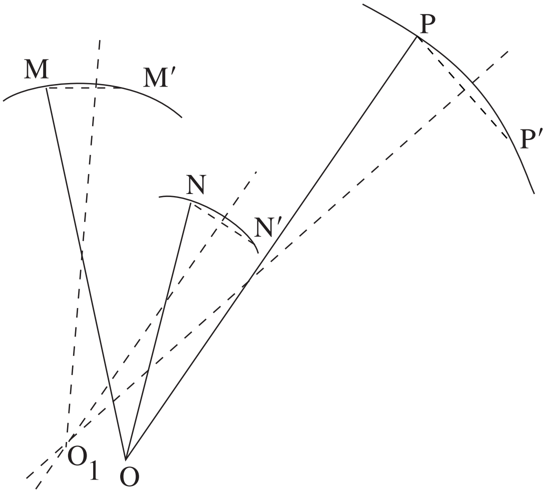

Figure 104

Consider a second position of the moving figure, close to the first, where the new positions of M, N, $P, \ldots$ are M', N', P' … The perpendicular bisectors of MM', NN', PP', … pass through the same point O_1, the center of the rotation which brings the first position of the figure onto the second. If we now imagine the second position coming arbitrarily close to the first, the midpoint of MM' will approach M, the line MM' will approach the tangent at M to the trajectory of this point, and the perpendicular bisector of MM' will approach the normal to this trajectory. In the same way, the perpendicular bisector to NN' approaches the normal to the trajectory of N. The point O_1 will then approach the point O, so that the normals to the trajectories of P ..., which are the limiting positions of the perpendicular bisectors of PP ,..., will also pass through O.[4]

Corollary. If we know the tangents to the trajectories of two points of a moving figure which does not change shape, we can find the tangent to the trajectory of any other point of the figure.

Indeed, the perpendicular to the known tangents determine the instantaneous center of rotation and, therefore, allow us to draw the normal to the trajectory at any point.

Exercises

Exercise 92. If a figure moves, without changing shape, in such a way that two of its lines each pass through a fixed point, then there exist infinitely many lines in the figure which, during the motion, also pass through a fixed point. Every other line remains tangent to a fixed circle. The instantaneous center of rotation for any two positions of the figure remains on a certain fixed circle.

Exercise 93. Given three figures F_1, F_2, F_3, all congruent and with the same orientation, we determine the three centers of the rotations which would superimpose one of these figures on another. Show that the angles of the triangle formed by these centers of rotation are equal or supplementary to half the angles between pairs of these figures.

Exercise 94. Compose two rotations with the same magnitude but opposite sense, and with different centers of rotation.

Exercise 95. Two congruent figures with opposite orientation can be superimposed:

1 . In infinitely many ways, by three successive line reflections;

2 . In infinitely many ways, by a translation followed by a line reflection;

3 . In only one way, by a translation preceded or followed by a reflection in a line parallel to the translation.

Exercise 96. Construct an equilateral triangle with vertices on three given parallel lines, or on three given concentric circles.

Exercise 97. On a given circle, find an arc, equal to a given arc, such that the lines joining the endpoints to two given points are parallel.

---

[4] We assume here, as axioms, propositions such as these: If a variable point M_1 has a limit position M, and a variable direction D_1 has a limit position D, the parallel through M_1 to D_1 has as limiting position the parallel through M to D. If two lines D_1, D_1 have limiting positions D, D , then the intersection point of D_1, D_1 has limiting position the intersection of D, D . In reality, these propositions are theorems which should be proved; we omit the proofs because they could not be performed with the desired simplicity, without assuming a knowledge of limits relying on notions of differential calculus.

Problems for Book II

Exercise 98. We join a point M on a circle with the points of contact A, B of the tangents passing through a point P in the plane. We then draw a parallel through P to the tangent at M. Show that lines MA, MB intercept on this parallel a segment whose length is independent of M, and which is divided by P into two equal parts.

Exercise 99. Let ABC be an equilateral triangle inscribed in a circle, and let M be a point on arc $\overset{\frown}{BC}$. Show that $MA = MB + MC$.

Exercise 100. Through the three vertices of an equilateral triangle, draw lines such that the bisectors of the angles they form with the altitudes from the same vertex are parallel. Show that these three lines intersect on the circumscribed circle.

Exercise 101. The midpoints of the sides of a triangle, the feet of the altitudes, and the midpoints of the segments, on each altitude, between the vertex and their intersection, are nine points on the same circle (the nine point circle). The center of this circle is the midpoint of the segment which joins the intersection of the altitudes to the center of the circumscribed circle; its radius is half that of the circumscribed circle. Deduce from this the result of Problem 70.

Exercise 101b. In any triangle, the circle passing through the centers of the three escribed circles has its center at the intersection of the radii of these three circles to the points of contact with the corresponding sides; also, its center is symmetric to the center of the inscribed circle with respect to the center of the circumscribed circle. Its radius is twice that of the circumscribed circle.

Exercise 102. In any triangle, the six feet of the perpendiculars dropped from the foot of each altitude onto the other sides lie on the same circle.

Exercise 103. In triangle ABC, the perpendicular bisector of BC and the angle bisector of A intersect on the circumscribed circle. Their point of intersection is equidistant from B, C, from the center of the inscribed circle, and from the center of the escribed circle contained in the angle A.

Exercise 103b. Construct a triangle knowing the lengths of the altitude, the median, and the bisector from the same vertex.

Exercise 104. Two tangents to a circle and the chord joining their points of contact divide into equal parts the perpendicular dropped from an arbitrary point on this chord to the line which joins it with the center.

Exercise 105. On the three sides of the triangle ABC, and outside the triangle, we construct equilateral triangles BCA , CAB , ABC , and join AA , BB , and CC . Show that:

1 . These three line segments are equal;

2 . They pass through the same point, at which the three sides of the original triangle subtend equal angles;

3 . If this point is inside the triangle, the sum of its distances to the three vertices is equal to the common length of AA , BB , CC (Problem 99).

Exercise 106. Lines ABE, CDE,BCF, ADF intersect in pairs, and form four triangles. Show that the circles circumscribing these triangles all pass through the same point I.

The centers of these four circles lie on another circle G, which also passes through point I (use Problem 69).[5]

A necessary and sufficient condition for quadrilateral $ABCD$ to be cyclic is that line EF, which connects the intersections of opposite sides of the quadrilateral, contain point I. This line is then the bisector of the angles AIC, BID subtended by the diagonals of the quadrilateral at point I, or of their supplements (the angle formed by IA and the extension of IC, or by IB and the extension of ID).[6]

The circumcenter O of quadrilateral $ABCD$ lies on circle G. This circumcenter also lies on the circles AIC and BID. Conclude from this that I is the foot of the perpendicular from O to EF.

Exercise 107. The bisectors of the angles formed by the (extensions of) the opposite sides of a cyclic quadrilateral are perpendicular. They are parallel to the bisectors of the angles formed by the diagonals of the quadrilateral, and conversely.

Exercise 107b. If any two lines intersect two given circles, the chords joining any pairs of points of intersection of the lines with the first circle intersect the chords joining any pairs of points of the intersection of these lines with the second circle in four concyclic points.

Exercise 108. Given triangle ABC, find the locus of points M such that the three perpendiculars erected from A, B, C to AM, BM, CM respectively are concurrent.

Exercise 109. Find the locus of the vertices of the rectangles considered in Exercise 41, if the given parallelogram is articulated (46b) while one of its sides is held fixed.

Exercise 110. On two consecutive segments AB, BC of the same line, we draw two variable circles with the same radius. These circles intersect at B, and at one additional point, whose locus is required.

Exercise 111. Let OA, OB be two variable perpendicular radii of a circle O. Through A, B construct two lines, each parallel to one of two fixed perpendicular directions. Find the locus of the intersection of these lines, as the right angle AOB turns around the center.

Exercise 112. Two circles, each of which touches a fixed line at a fixed point, vary while remaining tangent to each other. Find the locus of their point of contact.

Exercise 113. Find the locus of the vertex of the right angle of a right triangle which does not change shape, as the two other vertices slide along two perpendicular lines.

Exercise 114. Draw a line along which two given circles intercept given lengths.

---

[5] The reference to Problem 69 is probably an error in the original text. We give a proof using Problem 72. transl.

[6] The second case is the one that always holds. [This footnote, in the original, is the author s correction of an error in an earlier edition. transl.]

Exercise 115. In a given circle, inscribe a triangle whose sides are parallel to three given lines; or two of whose sides are parallel to given lines, and whose third side passes through a given point.

Exercise 116. Given a line xy and two points A, B, find a point M on the line such that the angle AMx is twice BMy.

Exercise 117. Construct a pentagon (or, more generally, a polygon with an odd number of sides) knowing the midpoints of the sides. What happens when the polygon has an even number of sides?

Exercise 118. Construct a trapezoid knowing its sides. More generally, contruct a quadrilateral knowing its four sides and the angle between (the extensions of) two opposite sides.[7]

Exercise 119. Cut the sides AB, AC of a triangle with a transversal having a given direction, and intercepting equal segments on these sides, starting at B and C.

Exercise 120. Construct a segment perpendicular to two given parallel lines, which subtends a given angle at a given point.

Exercise 121. We are given a circle, points P, Q on the circle, and a line. Find a point M on the circle such that the lines MP, MQ intercept on the line a segment IK of given length.

Exercise 121b. Same problem as above, except that we are given not the length, but the midpoint, of IK.

Exercise 122. Construct a square whose sides pass through four given points. Can the problem have infinitely many solutions? In that case, what will be the locus of the centers of the squares described in the problem?

Exercise 123. In an articulated quadrilateral $ABCD$ (46b, Remark III), what conditions must the lengths of the sides satisfy if a vertex, say B, is to pivot through a complete revolution; in other words, such that the size of the angle at B can be arbitrary? Show that the vertex D is not, in general, the center of a complete revolution. What is the exceptional case?

---

[7] With relation to this problem and the following ones, see 284, Note A.

CHAPTER II

Similarity of Triangles

117. **Definition.** Two triangles are similar if they have equal angles and proportional corresponding sides.

Remarks. Two congruent triangles are similar. Two triangles similar to a third are also similar to each other. In particular, if two triangles are similar, any triangle congruent to the first is similar to the second.

Theorem. Every parallel to one side of a triangle forms a triangle with the other two sides which is similar to the first.

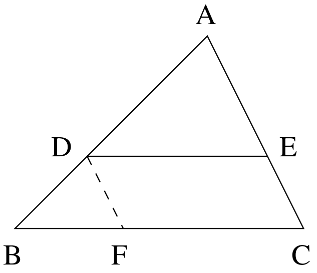

Figure 115

Consider parallel DE to side BC of triangle ABC (Fig. 115). We claim that the new triangle ADE is similar to ABC.

First, the angles of the two triangles are equal, A being common to both, and angles D, E being corresponding angles with B, C, respectively.

Second, we have (114) $\frac{AD}{AB} = \frac{AE}{AC}$, and it remains only to prove that the common value of these ratios is also equal to $\frac{DE}{BC}$.

To show this, we draw a parallel DF to AC, forming parallelogram DEFC. Line DF cuts sides BA, BC into proportional parts, so that $\frac{DE}{BC} = \frac{FC}{BC} = \frac{AD}{AB}$.

QED

Remark. Line DE can be inside (Fig. 115) or outside (Figs. 116, 117) triangle ABC without affecting the validity of the proof. However, in the case represented in figure 117, the corresponding angles of the two triangles are equal because they are alternate interior angles, rather than corresponding angles.

118. The following theorems (cases of similarity for triangles) give necessary and sufficient conditions for two triangles to be similar. They correspond to the three cases of congruence, to which they are reduced by use of the preceding theorem.

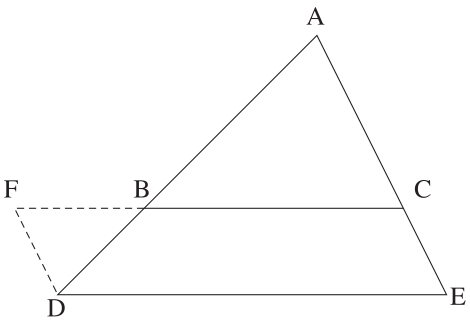

Figure 116

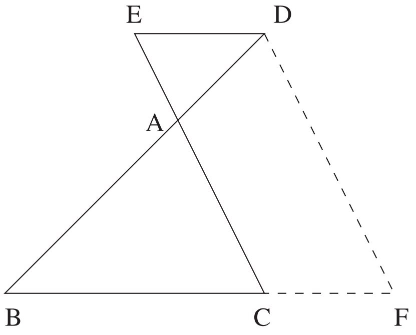

Figure 117

First case of similarity. Two triangles are similar if they have two equal corresponding angles.

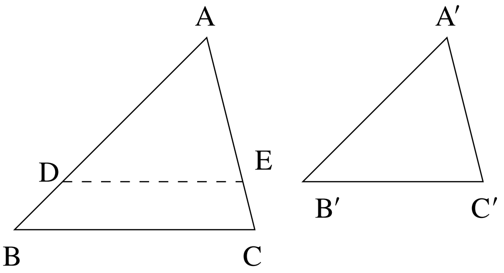

Figure 118

Consider triangles ABC, A B C in which we have A = A , B = B (Fig. 118). On AB we construct a length AD = A B and through point D we draw a parallel DE to BC. Triangle ADE is similar to ABC (by the preceding theorem) and congruent to A B C , having an equal side between two equal angles.

Second case. Two triangles are similar if they have an equal angle contained between proportional sides.

Consider triangles ABC, A B C in which we have A = A and $\frac{AB}{AC} = \frac{A\ B}{A\ C}$. On side AB we take a length AD = A B and we draw parallel DE to BC. Triangle ADE is similar to ABC and congruent to A B C . Indeed, they have an equal angle (A = A) contained between equal sides: AD = A B by construction, and the two proportions $\frac{AB}{AC} = \frac{A\ B}{A\ C}$ (given) and $\frac{AB}{AC} = \frac{AD}{AE}$, which have three common terms, give us A C = AE.

Third case. Two triangles are similar if they have three proportional sides.

Suppose the two triangles are ABC, A B C in which $\frac{AB}{A\ B} = \frac{AC}{A\ C} = \frac{BC}{B\ C}$. On side AB we take a length AD = A B and draw parallel DE to BC. Triangle ADE is similar to ABC and congruent to A B C , having three pairs of corresponding sides equal. Indeed, AD = A B by construction, and the proportions $\frac{AB}{AD} = \frac{AC}{AE}$ and $\frac{AB}{AD} = \frac{BC}{DE}$ (by the previous result) have three terms in common with the proportions $\frac{AB}{A'B'} = \frac{AC}{A'C'}$ and $\frac{AB}{A'B'} = \frac{BC}{B'C'}$ (given by hypothesis), respectively. We conclude that in fact $AE = A'C'$, $DE = B'C'$.

Remark. The definition of similar triangles consists of five conditions: three given by the equality of the angles, two by the proportionality of the sides. Corollary III of 44 (Book I) shows that one of the first three conditions can be omitted, which reduces the total to four. The cases of similarity show that, to establish similarity, we only need to prove two of these conditions, if chosen properly.

119. Theorem. Two triangles whose corresponding sides are parallel or perpendicular are similar.

Indeed, in this situation, the corresponding angles are either equal in pairs or supplementary (Book I, 43), so that if the triangles are ABC and $A'B'C'$, we have

$$A = A' \quad \text{or} \quad A + A' = 2 \text{ right angles},$$

$$B = B' \quad \text{or} \quad B + B' = 2 \text{ right angles},$$

$$C = C' \quad \text{or} \quad C + C' = 2 \text{ right angles}.$$

The three equations in the second column cannot all be satisfied simultaneously, because they would imply that the total sum of the angles in the two triangles is equal to six right angles, rather than four. Nor can even two of these equalities hold simultaneously; for instance, $A + A' = 2$ right angles and $B + B' = 2$ right angles would give a total sum for the angles of the two triangles equal to 4 right angles $+C + C'$. Therefore at least two equalities in the first column must hold, and then the triangles have angles which are equal in pairs (first case of similarity).

120. Theorem. Two right triangles are similar if the ratio of one of the sides of the right angle to the hypotenuse is the same in the two triangles.

Indeed, we can proceed as in 118 by forming a third triangle similar to the first, and having the same hypotenuse as the second. The second and third triangles will then be congruent, by the second case of congruence for right triangles.

Remark. Aside from this case of similarity, we can apply to right triangles the cases for similarity for arbitrary triangles. For instance, two right triangles will be similar if they have an equal acute angle (first case of similarity for arbitrary triangles); or if the sides of the right angle are proportional (second case of similarity).

Because of this, all right triangles ABC which have the same acute angle C have proportional sides. If we are given the angle C, we can then determine:

1°. The ratio of the opposite side AB to the hypotenuse BC (this ratio is called the sine of C and is denoted $\sin C$);

2°. The ratio of AC to the hypotenuse (called the cosine of C and denoted $\cos C$;

3°. The ratio of AB to AC (called the tangent of C and denoted $\tan C$).

These facts form the basis of trigonometry.

121. Theorem. A family of concurrent lines cuts off proportional segments on two parallel lines.

Consider, for instance, the three concurrent lines SAA', SBB', SCC' (Fig. 119) which meet two parallels ABC, $A'B'C'$. Similar triangles (117) SAB, $SA'B'$

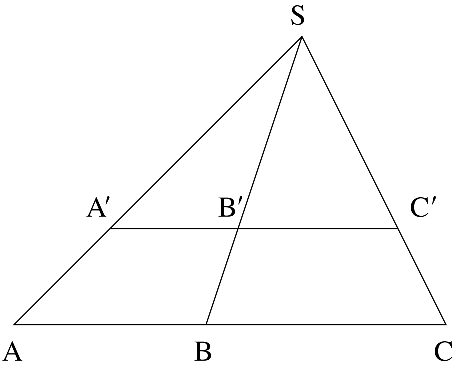

Figure 119

yield

$$\frac{A'B'}{AB} = \frac{SB'}{SB},$$

and similar triangles SBC, SB′C′ give

$$\frac{B'C'}{BC} = \frac{SB'}{SB},$$

from which it follows that A′B′, B′C′ are proportional to AB, BC.

Remark. The corresponding segments all have the same sense, or each pair has the opposite sense, according as point S is exterior or interior to the two parallels.

Converse. If three lines intercept proportional segments on two parallel lines (all in the same sense, or each pair in the opposite sense), these three lines are either concurrent or parallel.

If the corresponding segments are equal and in the same sense, the three lines are parallel (46, converse). Assume then that lines AA′, BB′, CC′ intercept proportional segments on parallel lines ABC, A′B′C′, so that

$$\frac{A'B'}{AB} = \frac{B'C'}{BC} = \frac{A'C'}{AC};$$

the value of this ratio being different from 1 if the segments are in the same sense. This last condition makes it impossible (46) for lines AA′, BB′ to be parallel; they therefore intersect at some point S.

Joining SC, we see that this line cuts the parallel A′B′C′ in a point C_1 which must coincide with the point C′ because $\frac{A'C_1}{B'C_1} = \frac{AC}{BC}$ (by the preceding theorem), which equals $\frac{A'C'}{B'C'}$ (by hypothesis).

Exercises

Exercise 129. Through the intersection of the diagonals of a trapezoid we draw a parallel to the bases. Show that this line is divided into equal segments by the non-parallel sides.

Exercise 130. Let a = AB and b = CD be the two bases of a trapezoid. We divide one of the non-parallel sides into the ratio $\frac{EA}{EC} = \frac{m}{n}$, and through point E we draw a parallel to the bases. Show that the segment of this parallel contained inside the trapezoid is equal to $\frac{m \cdot CD + n \cdot AB}{m+n}$. Special case: E is the midpoint of AC.

Exercise 131. From the vertices of a triangle, and from the intersection of its medians, we drop perpendicular segments onto a line exterior to the triangle. Show that the last of these segments is equal to the arithmetic mean of the first three. (Preceding exercise.)

Exercise 132. Through vertex A of parallelogram ABCD we draw a line which intersects diagonal BD in E, and sides BC, CD in F, G. Show that AE is the geometric mean of EF and EG.

Exercise 133. Find the locus of the points which divide the segment intercepted by the sides of an angle, on the lines parallel to a given direction, in a given ratio.

Exercise 134. Find the locus of points at which two given circles subtend the same angle.[1]

---

[1] The angle subtended by a curve at a given point is the angle formed by the tangents to the curve through that point.

CHAPTER III

Metric Relations in a Triangle

122. **Definition.** The foot of the perpendicular dropped from a point onto a line is called the orthogonal projection (or, briefly, projection) of the point onto that line. The segment whose endpoints are the projections of the endpoints of a given segment is called the projection of the segment onto the line.

123. Let ABC (Fig. 120) be a triangle with a right angle at A. From this vertex A, drop altitude AD onto the hypotenuse. We will discover certain relations among the elements of this figure.

Theorem. In a right triangle, each side of the right angle is the geometric mean between the whole hypotenuse and its projection onto the hypotenuse.

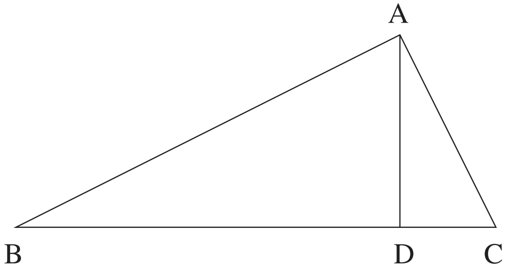

Figure 120

For instance, AB is the geometric mean between BD and BC. Indeed, right triangles ABD, ABC, having angle B in common, are similar (120, Remark). The sides corresponding to AB, BD in the first are sides BC, AB in the second, so that

$$\frac{BD}{AB} = \frac{AB}{BC}, \quad \text{or} \quad AB^2 = BD \cdot BC.$$

QED

Corollary. Any chord in a circle is the geometric mean between a diameter and its projection on the diameter passing through one of its endpoints (Fig. 121).

This is true because the diameter and the chord are the hypotenuse and a side of a right triangle (73, Corollary II).

Remark. Similar triangles ABD, ABC (Figures 120, 121) also give

$$\frac{AB}{BC} = \frac{AD}{AC} \quad \text{or} \quad AB \cdot AC = BC \cdot AD.$$

Thus, the product of the sides of the right angle in a right triangle, is equal to the product of the hypotenuse and the corresponding altitude.

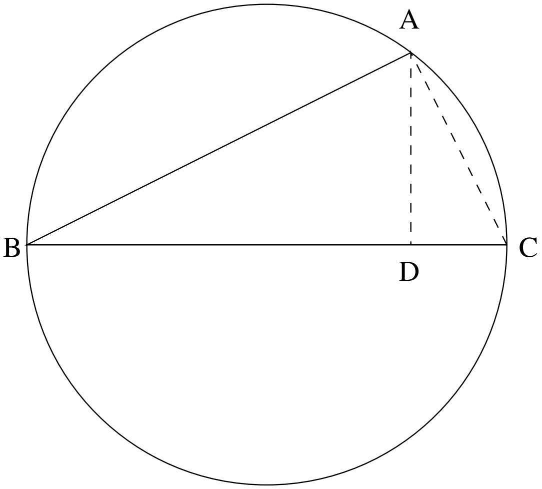

Figure 121

124. Theorem of Pythagoras. In a right triangle, the square of the hypotenuse is equal to the sum of the squares of the other two sides.

We have just seen that

$$AB^2 = BC \cdot BD.$$

The same theorem applied to the side AC gives

$$AC^2 = BC \cdot CD.$$

Adding these equalities we obtain

$$AB^2 + AC^2 = BC(BD + CD) = BC^2.$$

QED

This theorem can be used to calculate any side of a right triangle when we know the other two sides. Thus, let us calculate the hypotenuse of a right triangle in which the legs are 3 and 4 meters. If the unit is the meter, the square of the number representing the measure of the hypotenuse will be the sum of the squares of the numbers 3 and 4. This sum is $3^2 + 4^2 = 25$, whose square root is 5; thus the hypotenuse will equal 5 meters.

Let us now calculate one leg of a right triangle, knowing that the hypotenuse is equal to 10 meters and the other leg is 7 meters. The square of the required side, added to $49 (= 7^2)$ must give $100 (= 10^2)$; this square is therefore equal to $100 - 49 = 51$. The square root of 51, (which is 7.14, correct to the nearest centimeter) will give the measure, in meters, of the desired side.

125. Theorem. In a right triangle, the altitude from the right angle is the geometric mean between the two segments which it determines on the hypotenuse.

Indeed, triangles ABD, ACD (Fig. 120) are similar because they have perpendicular sides. Segments BD, AD are therefore proportional to AD, DC.

Corollary. The perpendicular from any point on a circle to a diameter is the geometric mean between the two segments it determines on the diameter.

126. *Theorem.* The difference of the squares of two sides of a triangle is equal to the difference of the squares of their projections on the third side.

In triangle ABC (Fig. 123), we project vertex B to point H on AB. The equations

$$AB^2 = AH^2 + BH^2,$$

$$BC^2 = CH^2 + AH^2$$

yield, by subtraction, $BC^2 - AB^2 = CH^2 - AH^2$.

Theorem. In any triangle:

1. The square of the side opposite an acute angle is equal to the sum of the squares of the other two sides, minus twice the product of one of these sides and the projection of the other onto it;

2. The square of the side opposite an obtuse angle is equal to the sum of the squares of the other two sides, plus twice the product of one of these sides and the projection of the other onto it.

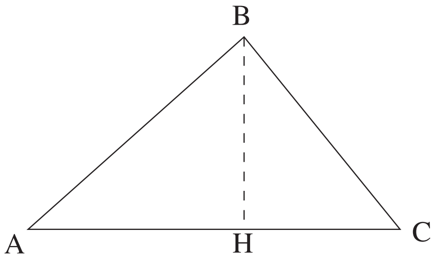

Figure 122

1. In triangle ABC, consider side BC opposite acute angle A. Drop altitude BH from B to AC. By the preceding theorem we have

$$BC^2 = AB^2 + CH^2 - AH^2.$$

Now CH is the difference between AC and AH, so that CH^2 can be replaced[1] by

$$AC^2 - 2AC \cdot AH + AH^2,$$

yielding the desired result

$$BC^2 = AB^2 + AC^2 - 2AC \cdot AH.$$

2. In triangle ABC, consider side BC opposite obtuse angle A. Drop altitude BH from B to AC. Again we have

$$BC^2 = AB^2 + CH^2 - AH^2,$$

---

[1] We assume that the formulas for the squares of the sum and the difference of two numbers are known:

$$(a + b)^2 = a^2 + 2ab + b^2,$$

$$(a - b)^2 = a^2 - 2ab + b^2.$$

See Tannery, Leçons d'Arithmetique, chap. II, n^{os} 83, 85.

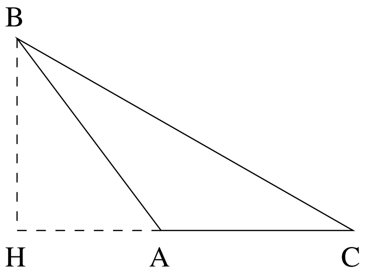

Figure 123

but CH is the sum of AC and AH, so that CH^2 can be replaced by

$$AC^2 + 2AC \cdot AH + AH^2,$$

yielding

$$BC^2 = AB^2 + AC^2 + 2AC \cdot AH.$$

Corollary. An angle of a triangle is acute, right, or obtuse, according as the square of the opposite side is less than, equal to, or greater than the sum of the squares of the two other sides.

127. Stewart's Theorem. Given triangle ABC and point D on the base between B and C, we have

$$AB^2 \cdot DC + AC^2 \cdot BD - AD^2 \cdot BC = BC \cdot DC \cdot BD.$$

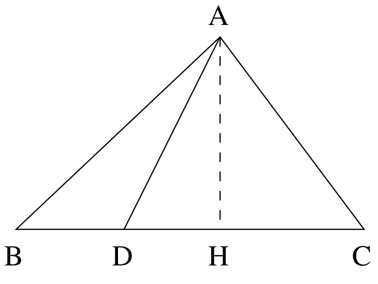

Figure 124

We drop a perpendicular AH from A to BC (Fig. 124) and suppose, to be definite, that H and C are on the same side of D. The two theorems of the preceding section apply, one to triangle ACD and the other to triangle ABD, to yield

$$AC^2 = AD^2 + DC^2 - 2CD \cdot DH,$$

$$AB^2 = AD^2 + BD^2 + 2BD \cdot DH.$$

We multiply the first equation by BD, and the second by CD, then add the resulting equations. The term $2BD \cdot CD \cdot DH$, which appears once with a + sign and once with a − sign, disappears and we have

$$AC^2 \cdot BD + AB^2 \cdot CD = AD^2(BD + CD) + DC^2 \cdot BD + BD^2 \cdot CD$$
$$= AD^2 \cdot BC + BC \cdot DC \cdot BD.$$

128. Application to the calculation of various notable lines in a triangle. Consider an arbitrary triangle ABC whose sides BC, CA, AB have known measures a, b, c, respectively. Let us calculate the lengths of the medians, bisectors, and altitudes of this triangle.

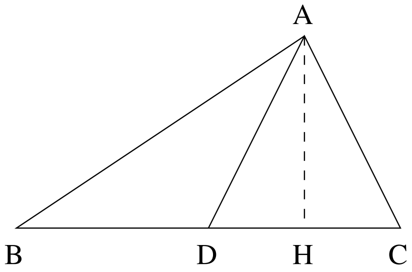

Figure 125

1 . Medians. Let AD be the median from vertex A (Fig. 125). In the equation given by the previous theorem, we replace BC, CA, AB by a, b, c, respectively; DC and BD by a/2. Dividing by a we obtain

$$\frac{b^2 + c^2}{2} = AD^2 + \left(\frac{a}{2}\right)^2,$$

and therefore

$$AD^2 = \frac{b^2 + c^2}{2} - \left(\frac{a}{2}\right)^2.$$

Thus, the sum of the squares of two sides of a triangle equals twice the square of half the third side, plus twice the square of the corresponding median.

128b. On the other hand, if, in the equalities

$$AC^2 = AD^2 + DC^2 - 2CD \cdot DH,$$
$$AB^2 = AD^2 + BD^2 + 2BD \cdot DH$$

we replace BC, CA, AB by a, b, c and DC and BD by a/2, then substracting them term by term, we get

$$c^2 - b^2 = 2a \cdot DH.$$

Thus the difference between two sides of a triangle is equal to twice the product of the third side and the projection of the median onto this side.

Corollary. The locus of points C, such that the difference of the distances from C to two fixed points A and B is constant, is a line perpendicular to AB.

The reason is that the difference $AB^2 - AC^2$ is constant, so the projection H of C onto AB is a fixed point.

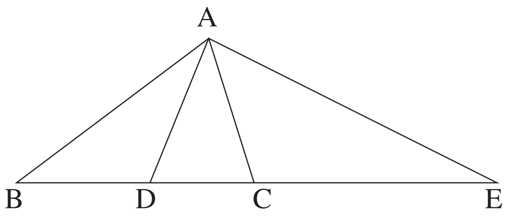

Figure 126

129. 2 . Bisectors. We now denote by AD the bisector of A (Fig. 126). Point D divides side BC into segments proportional to AB and AC, so that

$$\frac{BD}{c} = \frac{CD}{b} = \frac{BC}{b+c} = \frac{a}{b+c},$$

or

$$BD = \frac{ac}{b+c}, \quad CD = \frac{ab}{c+b}.$$

In the result of the theorem in 127, we replace BD and CD with these values, and BC, CA, AB with their values. Dividing by a, we obtain

$$\frac{c^2b}{b+c} + \frac{b^2c}{b+c} - AD^2 = \frac{ab}{b+c} \cdot \frac{ac}{b+c},$$

so that

$$AD^2 = \frac{c^2b + b^2c}{b+c} - \frac{a^2bc}{(b+c)^2} = bc\frac{(b+c)^2 - a^2}{(b+c)^2}.$$

Now we consider bisector AE of the exterior angle at A (Fig. 126) and, to be definite, we assume that AB is greater than AC, so that point E, which divides segment BC externally into parts proportional to AB and AC, is on the extension of BC past C. We then have

$$\frac{BE}{c} = \frac{CE}{b} = \frac{BC}{c-b} = \frac{a}{c-b},$$

and therefore

$$BE = \frac{ac}{c-b}, \quad CE = \frac{ab}{c-b}.$$

We apply the theorem of 127 to triangle ABE with point C on base BE. Replacing BC, CA, AB, BE, CE by their values, and dividing by a, we have

$$\frac{c^2b}{c-b} + EA^2 - \frac{b^2c}{c-b} = \frac{ac}{c-b} \cdot \frac{ab}{c-b},$$

so that

$$AE^2 = \frac{a^2bc}{(c-b)^2} - \frac{c^2b - b^2c}{c-b} = bc\frac{a^2 - (c-b)^2}{(c-b)^2}.$$

130. 3 . Altitudes. We drop altitude AH from A (Fig. 127). Of the two angles B, C, at least one is acute. We assume, to be definite, that B is acute, and apply the theorem of 126 to the side AC = b opposite this angle to obtain

$$b^2 = a^2 + c^2 - 2a \cdot BH,$$

or

$$BH = \frac{a^2 + c^2 - b^2}{2a}.$$

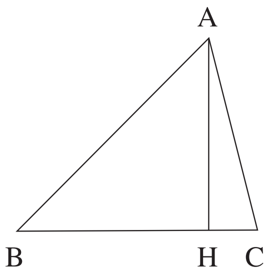

Figure 127

Now in right triangle AHB we have

$$AH^2 = c^2 - BH^2 = c^2 - \frac{(a^2 + c^2 - b^2)^2}{4a^2}.$$

This equation, whose right-hand member is a difference of two squares, can be written as[2]

$$\begin{aligned} AH^2 &= \left(c - \frac{a^2 + c^2 - b^2}{2a}\right)\left(c + \frac{a^2 + c^2 - b^2}{2a}\right) \\ &= \frac{(2ac - a^2 - c^2 + b^2)(2ac + a^2 + c^2 - b^2)}{4a^2} = \frac{[b^2 - (a - c)^2][(a + c)^2 - b^2]}{4a^2}. \end{aligned}$$

But each of the factors appearing in the numerator of the right-hand member of this equation is also a difference of two squares. Thus this last formula can be written as

$$AH^2 = \frac{(b - a + c)(b + a - c)(a + c - b)(a + b + c)}{4a^2}.$$

If we denote by p the semi-perimeter of the triangle, so that $a + b + c = 2p$, the quantities $b + c - a$, $c + a - b$, $a + b - c$ are equal to $2p - 2a$, $2p - 2b$, $2p - 2c$, respectively, so that

$$AH^2 = \frac{4p(p - a)(p - b)(p - c)}{a^2}.$$

On the other hand, if we want to use the product $[(a + c)^2 - b^2][b^2 - (a - c)^2]$, we can write the the following formula:

$$AH^2 = \frac{1}{4a^2}[4b^2c^2 - (b^2 + c^2 - a^2)^2] = \frac{1}{4a^2}(2b^2c^2 + 2c^2a^2 + 2a^2b^2 - a^4 - b^4 - c^4).$$

130b. 4°. **Radius of the circumscribed circle.** The product of two sides of a triangle is equal to the altitude drawn to the third side, multiplied by the diameter of the circumscribed circle.

In triangle ABC (Fig. 128), let AH be the altitude from A, and let AA' be the diameter of the circumscribed circle. Triangles AHC, ABA' have right angles at H and B, respectively. They have an equal acute angle ($A' = C$ since they intercept the same arc $\overset{\frown}{AB}$). They are therefore similar, so that $\frac{AH}{AC} = \frac{AB}{AA'}$, or $AB \cdot AC = AH \cdot AA'$. QED

---

[2] See Leçons d'Arithmétique, by J. Tannery, chap. II, n° 87.

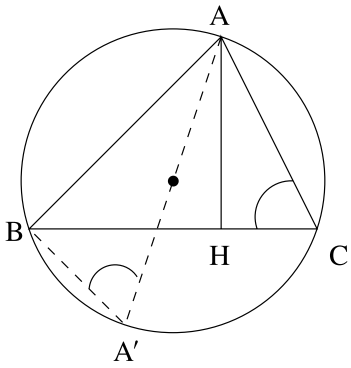

Figure 128

Using the value just found for AH, this theorem gives the following formula for the radius R of the circumscribed triangle:

$$R = \frac{AA'}{2} = \frac{bc}{2AH} = \frac{abc}{4\sqrt{p(p-a)(p-b)(p-c)}}.$$

Exercises

Exercise 135. The product of the segments intercepted by a variable tangent of a circle on two parallel tangents is constant.

Exercise 136. The inverse of the square of the altitude of a right triangle is equal to the sum of the inverses of the squares of the sides of the right angle.

Exercise 137. What is the ratio of the sum of the squares of the medians to the sum of the squares of the sides of a triangle?

Exercise 138. The sum of the squares of the distances from an arbitrary point in the plane to two opposite vertices of a parallelogram differs by a constant quantity from the sum of the squares of the distances from the same point to the other two vertices. Special case: the rectangle.

Exercise 139. The sum of the squares of the four sides of a quadrilateral is equal to the sum of the squares of its diagonals plus four times the square of the segment joining their midpoints.

Exercise 140. If ABC is a triangle, G the intersection of its medians, and M an arbitrary point in the plane, we have $MA^2 + MB^2 + MC^2 = GA^2 + GB^2 + GC^2 + 3MG^2$.

Exercise 141. Find the locus of points such that the squares of their distances to two fixed points, multiplied by two given numbers, have a given sum or difference. Use this to find a new proof of the theorem in 116.

Exercise 142. Find the locus of points such that the squares of their distances to three points in the plane, multiplied by three given numbers, has a given constant sum. Same problem with an arbitrary number of points.

Exercise 143. The square of the bisector of an angle of a triangle is equal to the product of the sides which contain it, diminished by the product of the segments it intercepts on the opposite side. State and prove an analogous statement for the bisector of the exterior angle.

Exercise 144. Deduce the inequalities indicated in Exercises 11 and 18 from the formulas found for the medians and bisectors.

Exercise 145. If the median of a triangle is the geometric mean between the sides which contain it, then the square with side $b \quad c$ has a diagonal equal to the third side of the triangle.

Exercise 146. The altitudes of a triangle are inversely proportional to the sides to which they are drawn.

Exercise 147. The product of the distances from a point on a circle to two opposite sides of an inscribed quadrilateral is equal to the product of the distances of the same point to the other sides, or to the diagonals. What happens to this statement when the two opposite sides become tangents?

CHAPTER IV

Proportional Segments in a Circle. Radical Axis

131. Theorem. If a variable secant to a circle is drawn from a point A in the plane of the circle, the product of the distances from A to the two intersection points with the circle is constant.

We distinguish two cases.

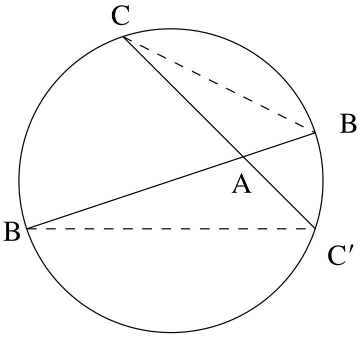

Figure 129

1 . Point A is inside the circle (Fig. 129). Consider two secants ABB', ACC', and join BC', CB'. Triangles ABC', ACB' are similar, since they have equal angles. Indeed, the angles at A are equal because they are vertical angles, and B = C because both have measure equal to one half arc $\overset{\frown}{B'C'}$. The proportionality of the sides then gives $\frac{AB}{AC} = \frac{AC'}{AB'}$, and the equality of the products of the means and the extremes gives $AB \cdot AB' = AC \cdot AC'$. QED

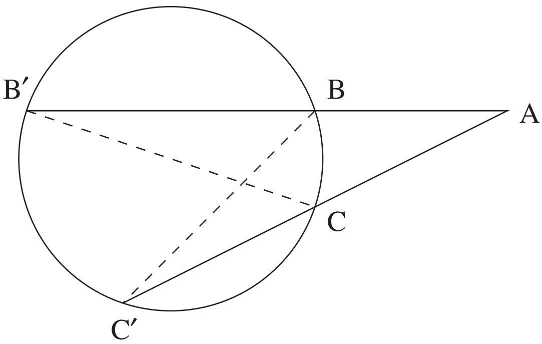

Figure 129b

2 . Point A is outside the circle (Fig. 129b). Consider two secants ABB , ACC , and join BC , CB . Triangles ABC , ACB are again similar, having equal angles: the angle at A in common, and B = C intercept the same arc. The conclusion follows as before.

131b. Converse. If, on two lines ABB , ACC through a point A (Fig. 130) we take four points A, A , B, B (the point A being either exterior to both segments BB , CC , or interior to both) such that AB • AB = AC • AC , then these four points are on the same circle.

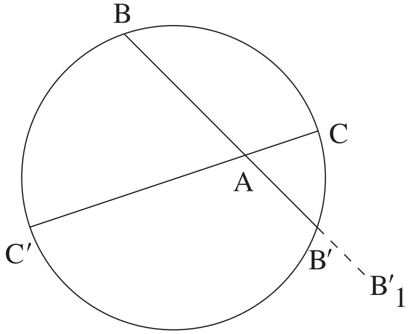

Figure 130

Indeed, the three points B, C, C determine a circle, and this circle intersects ABB in a point B_1 such that $AB \cdot AB_1$ = AC • AC . This equality, combined with the one in the hypothesis, shows that AB_1 = AB , and therefore the point B_1 coincides with B .

132. Theorem. If, through a point exterior to a circle, we draw a tangent and a secant to the circle, the tangent is geometric mean between the entire secant and its external segment.

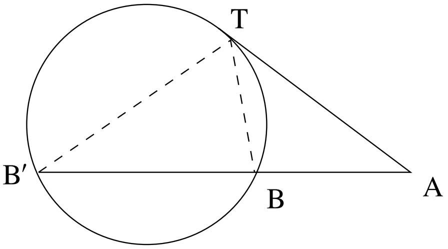

Figure 131

Indeed, consider secant ABB and tangent AT (Fig. 130). We repeat the proof of 131 (2) with no modification except replacing both letters C, C by the letter T.

The preceding argument is another example of the fact (Book II, 67) that the tangent should be thought of as having a double intersection with the circle at the point of contact.

Conversely, If we take points B, B' on line ABB', both on the same side of A, and on another line AT we take point T such that AT is geometric mean between AB and AB', then the three points B, B', T are on a circle tangent to AT at T.

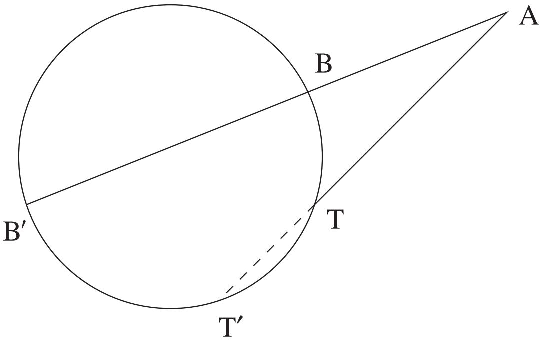

Figure 132

Indeed, circle $BB'T$ has the common point T with line AT (Fig. 132); if it had another common point T', then (131) $AB \cdot AB' = AT \cdot AT'$. This equation, compared with the hypothesis $AB \cdot AB' = AT^2$, shows that point T' must coincide with T.

133. Definition. For any point A, the product of the segments from A to the points of intersection of a secant with a given circle passing through the point is called the power of point A with respect to the given circle. According to 131, this product is independent of the secant. The product is preceded by a + sign if the point A is outside the circle, and by a − sign if A is inside. When the point is exterior to the circle, the power is equal to the square of the tangent from this point.

134. The power of the point A with respect to a circle of center O is equal to the difference of the square of OA and the square of the radius.

Indeed, let us take line OA as our secant (in place of ABB'). The segments AB, AB' represent the sum and the difference between OA and the radius of the circle; their product is therefore the difference of the squares of these quantities.

If one takes into account the sign of the power, this is always equal to $d^2 - R^2$ (where d is the distance OA and R is the radius).

135. When two circles meet at a right angle, the square of the radius of each one is equal to the power of its center with respect to the other, and conversely.

If circles O, O' (Fig. 133) intersect in A at a right angle, the tangent to circle O' at this point is precisely OA, and the power of point O with respect to circle O' is indeed OA^2.

Conversely, if the power of point O with respect to circle O' is OA^2, then OA is tangent to this circle, and therefore the two circles are orthogonal.

136. Theorem. The locus of points which have the same power with respect to two given circles is a line perpendicular to the line of the centers.

This line is called the radical axis of the two circles.

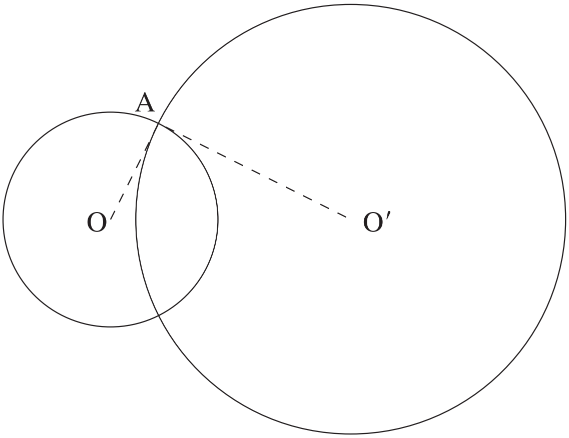

Figure 133

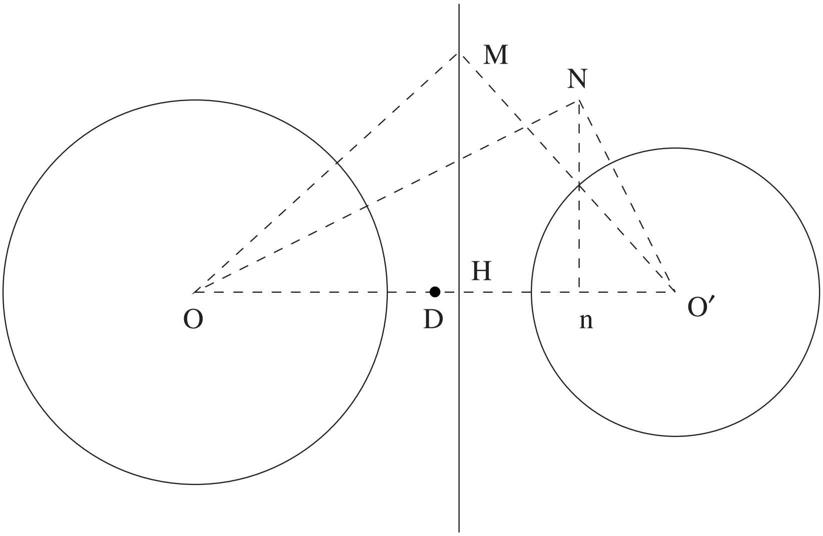

Figure 134

Consider two circles with centers O, O' (Fig. 134) and radii r, r'. If the point M has the same power with respect to the two circles, we have $OM^2 - r^2 = O'M^2 - r'^2$, which can be rewritten as $OM^2 - O'M^2 = r^2 - r'^2$ and gives us the desired conclusion (128b).

According to the results of 128b, the distance between the intersection H of the radical axis with the line of the centers, and the midpoint D of this segment, is given by the formula $2DH \cdot OO' = r^2 - r'^2$.

Remarks. I. The preceding proof remains valid if one of the circles has a radius equal to zero, and so reduces to its center. Thus, the locus of points such that their power with respect to a given circle is equal to the square of their distance to a given point is a line perpendicular to the line joining the given point to the center of the circle. We can call this line the radical axis of the circle and the point.

II. Two concentric circles do not have a radical axis.

III. The difference between the powers of an arbitrary point with respect to two circles is equal to twice the product of the distance of this point to the radical axis and the distance between the centers (Fig. 134).

Indeed, let N be the point in question, and suppose n is its projection onto OO'. The difference of the powers of this point with respect to the two circles will be

$$ON^2 - r^2 - (O'N^2 - r'^2) = ON^2 - O'N^2 - (r^2 - r'^2).$$

Since $ON^2 - O'N^2 = 2Dn \cdot OO'$ and $r^2 - r'^2 = 2DH \cdot OO'$, we obtain

$$ON^2 - O'N^2 - (r^2 - r'^2) = 2Hn \cdot OO'.$$

137. If two circles intersect, their radical axis is their common chord.

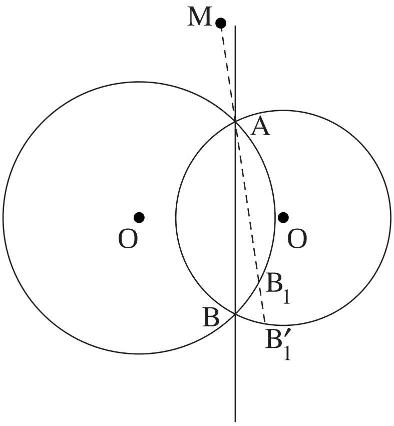

Figure 135

Indeed, it is clear that every point of the common chord AB (Fig. 135) belongs to the locus. It follows that, conversely, every point of the radical axis belongs to this chord. This can be seen directly by drawing MA: if this line intersects the two circles in two distinct new points B_1, B_1', the two powers $MA \cdot MB_1$ and $MA \cdot MB_1'$ will be different.

In the same way, if two circles are tangent, their radical axis is their common tangent.

138. The radical axis of two circles (or at least the part of the axis which is exterior to the two circles) is the locus of the centers of circles cutting the first two at right angles.

This is true because the center of such a circle has the same power with respect to the given circles; namely, the square of the radius.

The radical axis divides a common tangent into two equal parts.

139. Theorem. Given three circles, the three radical axes determined by pairs of them are either parallel or concurrent.

This is true because the point of intersection of two of the radical axes will have same power with respect to the three axes, and will therefore belong to the third radical axis as well. This point is called the radical center of the three circles; if it is exterior, it is the center of a circle cutting all three of them at right angles.

Remark. If two of the radical axes coincide, the preceding argument shows that the third must coincide with the first two. The three circles then have the same radical axis. Every circle orthogonal to the first two will be orthogonal to the third as well.

Exercises

Exercise 148. We are given a circle and two points A, B in its plane. Through A we draw a variable secant AMN which cuts the circle in M, N. Show that the circle passing through M, N, B also passes through another fixed point.

Exercise 149. The locus of points such that the ratio of their powers with respect to two given circles is equal to a given number is a circle which has the same radical axis with the first two.

Exercise 150. The preceding exercise is equivalent to exercise 128 if the two given circles intersect in two points.

Exercise 151. Consider a triangle ABC, points D, D' on BC, E, E' on CA, and F, F' on AB. If it is known that there is a circle passing through D, D', E, E', a circle passing through E, E', F, F', and a circle passing through F, F', D, D', it follows that all six points D, D', E, E', F, F' are on the same circle.

Exercise 152. When do all the circles orthogonal to two given circles O, O' intersect line OO'? Show that if they all do, then the intersection points are always the same (the limit points of Poncelet); namely, the points that have the same radical axis with the given circles.

Exercise 153. Four points A, B, C, D are given on the same line. A variable circle passes through A, B, and another variable circle passes through C, D. Show that the common chords of these circles pass through a fixed point.

Exercise 154. If the radical center of three circles is interior to these circles, then it is the center of a circle divided into two equal parts by each of the first three circles.

CHAPTER VI

Constructions

151. Construction 1. Divide a segment into equal parts, or into parts proportional to given segments.

First method (Fig. 148). Suppose segment AB must be divided, say, into three equal parts. On an arbitrary line passing through A, and starting from this point, we construct three equal segments AC, CD, DE.

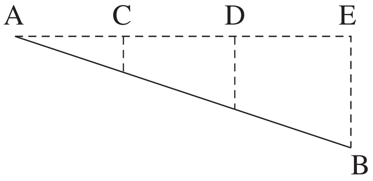

Figure 148

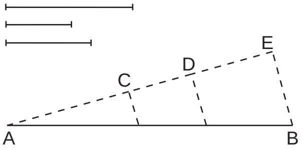

Figure 149

It suffices to draw BE, then draw parallels to this line through C and D.

These parallels will divide AB into three equal parts (113). If we need to divide AB into parts proportional to three given segments (Fig. 149), we take AC, CD, DE equal to the three segments in question.

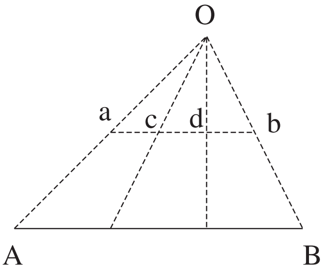

Figure 150

Second method (Fig. 150). Again, suppose segment AB must be divided into three equal parts. We draw an arbitrary parallel ab to AB, and on it take equal segments ac, cd, db. We then draw Aa, Bb, which will intersect in O. Lines Oc, Od then divide AB into three equal parts (121).

If we need to divide AB into parts proportional to three given segments (Fig. 149), we take ac, cd, db equal to the three segments in question.

Construction 2. Find the fourth proportional to three given segments.

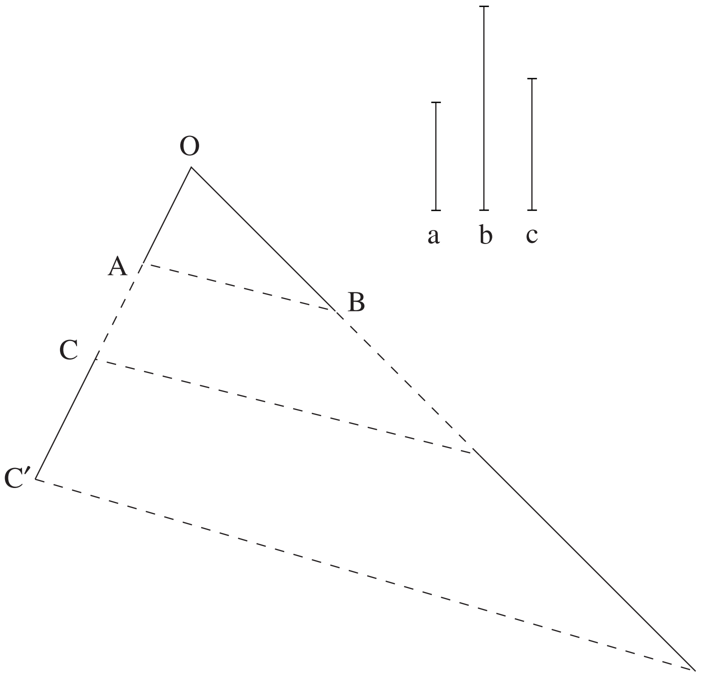

Figure 151

The constructions are similar to the preceding.

First method (Fig. 151). Consider the given segments a, b, c. We must find x such that $\frac{a}{b} = \frac{c}{x}$. On the sides of an arbitrary angle AOB, we construct segments $OA = a$ and $OB = b$. Then segment c can be placed anywhere on the side OA (in the figure, it is CC'). The lines parallel to AB through the endpoints of this segment determine on OB a segment equal to the required fourth proportional.

If we take one of the endpoints of segment c to coincide with point A or point O, we need, in general, to draw only a single parallel.

We leave it to the reader to apply the second method used in the preceding construction to this problem.

152. Construction 3. On a given segment, construct a triangle similar to a given triangle.

Suppose the given the triangle is ABC, and the given segment is A_1B_1. We find a point D on AB such that $AD = A_1B_1$, and draw a parallel DE to BC (Fig. 152), extending it to intersect AC at E. Then it remains only to construct a triangle on A_1B_1 congruent to ADE (Book II, 86, Construction 4).

This construction obviously gives a solution to the following problem:

Problem. Given two points A, B of a figure F and their corresponding points A', B' in a similar figure F', find the point corresponding to an arbitrary third point of F.

In particular, repeated application of this construction will allow us to perform

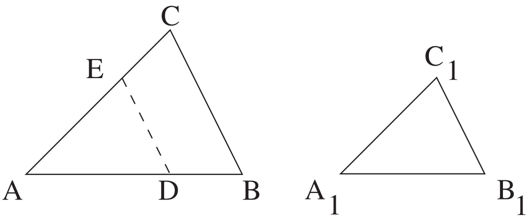

Figure 152

Construction 3b. On a given segment, construct a polygon similar to one given.

153. Construction 4. Construct the geometric mean of two segments.

We have stated three theorems leading to geometric means (123, 125, 132). Each of these theorems provides a method for solving the proposed problem.

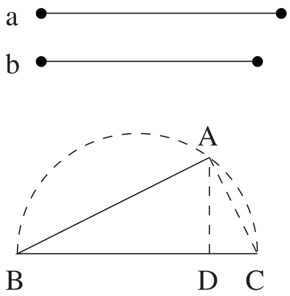

Figure 153

First method (Fig. 153). Starting from a point B on a line, we mark off, in the same sense, segments BD, BC equal to the given segments a, b (labeling the smaller of the two BD). We will construct a right triangle with hypotenuse BC, in which BD will be the projection of another side onto the hypotenuse. To do this, it suffices to place the vertex A of the right angle at the intersection of the perpendicular erected from D to BC with the circle on diameter BC. Then AB will be the required geometric mean (123).

Second method (Fig. 154). From an arbitrary point D on an arbitrary line, and in opposite senses, we construct segments DB, DC equal to the given segments a, b. We will consider them to be the projections of the legs of a right triangle on its hypotenuse. To do this it will suffice to place the vertex A of the right angle at the intersection of the perpendicular from D to BC with the circle with diameter BC. Then AD will be the geometric mean (125).

Third method (Fig. 155). Starting from a point O on a line, and in the same sense, we construct segments OA, OB equal to the given segments a, b. We draw an arbitrary circle through A and B, and draw a tangent OT to this circle. This tangent is the geometric mean (132).

154. Construction 5. Construct a segment whose square is the sum of the squares of two given segments.

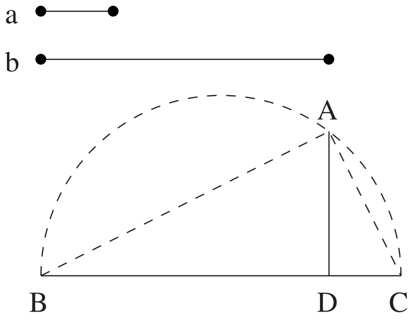

Figure 154

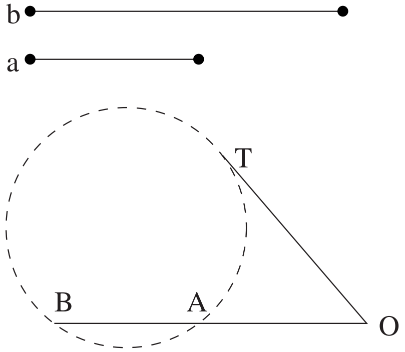

Figure 155

We construct segments equal to the given ones on the two sides of a right angle, starting from the vertex. The required segment will be the hypotenuse of the right triangle thus formed.

Construction 6. Construct a segment whose square is the difference of the squares of two given segments.

We construct (Book II, 87b, Construction 9) a right triangle having the larger of the given segments as hypotenuse, and the other as a side of the right angle. The other side of the right angle gives the required segment.

155. Construction 7. Construct two segments, knowing their sum and their product.

Supppose we must find two segments whose sum is equal to a given segment $a = BC$ and whose product is equal to the product of two given segments b, c. We may assume that these last two lengths are laid off (as BB , CC along the perpendiculars to the endpoints of BC) in the same sense (Fig. 156). Since the sum of the required segments is BC, they can be represented as BM and CM, for some point M on BC. Now, the product $BM \cdot CM$ must equal $BB \cdot CC$, and therefore

$$\frac{BB}{BM} = \frac{CM}{CC},$$

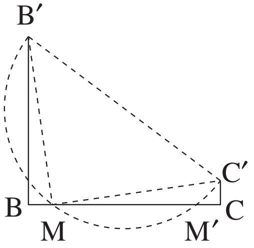

Figure 156

which shows that the right triangles $BB'M$, CMC' are similar. Thus angle BMB' is equal to the corresponding angle $MC'C$, and therefore complementary to CMC', so that angle $B'MC'$ is a right angle. Point M will be on the circle with diameter $B'C'$.

Conversely, if the circle with diameter $B'C'$ intersects BC in M, triangles $BB'M$, $CC'M$ will be similar, since they have perpendicular sides, and the equality $BM \cdot CM = BB' \cdot CC'$ follows.

Conditions for existence. We have taken lines b and c arbitrarily, but we may assume that they are equal: we may replace them, without changing their product, by their geometric mean. Assume thus that $BB' = CC'$, so that $BB'CC'$ is a rectangle. The midpoint of $B'C'$ is then at a distance from BC equal to BB', and the radius of the circle is one half $B'C'$, which is the same as one half BC. Therefore the circle will intersect BC if BB' is at least equal to half of BC; in other words, if the given product is at most equal to the square of half of BC.

If M is a point satisfying the conditions of the problem, then, turning the segment BC around on itself or taking the symmetric figure with respect to the midpoint of BC (which is the same thing), we obtain a point M' which will have the same property as the first, since $BM' = CM$, $BM = CM'$. We see thus that the intersections M, M' of BC with the circle with diameter $B'C'$ are symmetric with respect to the midpoint of BC, which can also be verified directly with the help of 62.

If the given product is equal to the square of half of BC (which, as we have just shown, is the greatest value it can take), the circle with diameter $B'C'$ is tangent to BC; the points M, M' coincide with each other and with the midpoint of BC, so that $BM = CM$. We thus see that the product of two segments whose sum is constant is maximal when these two segments are equal.

Remark. Let x denote segment BM. We have $CM = a - x$, and the equality $BM \cdot CM = BB' \cdot CC'$ can be written $x(a - x) = bc$, or

$$x^2 - ax + bc = 0.$$

The preceding construction allows us to find a segment x satisfying

$$x^2 - ax + q = 0,$$

where a is a given segment, and q is the product of two given segments.

Construction 8. Construct two segments, knowing their difference and their product.

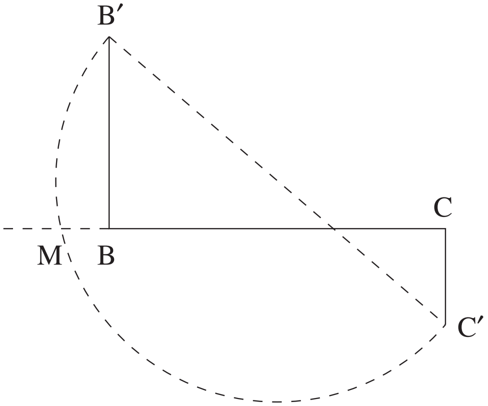

Figure 157

Suppose we wish to find two segments whose difference is equal to a given segment $a = BC$, and whose product is equal to the product of two given segments b, c. We may assume that these last two lengths are laid off as BB', CC', perpendicular to the endpoints of BC in opposite senses (Fig. 157). Since the difference of the required segments is BC, they can can be represented as BM, CM, where M is a point on an extension of BC (in one of two directions) satisfying $BM \cdot CM = BB' \cdot CC'$. As in the preceding construction, we conclude that point M must belong to the circle with diameter $B'C'$ and, conversely, a point of intersection of this circle with an extension of BC satisfies the conditions of the problem.

Since the points B', C' are on different sides of BC, the circle always intersects the line, and therefore a solution is always possible.

Remark. Let x be the smaller of the segments found above; the other can be represented as $y = a + x$, and the equality $xy = bc$ becomes either

$$x(a + x) = bc, \quad x^2 + ax - bc = 0,$$

or

$$(y - a)y = bc, \quad y^2 - ay - bc = 0.$$

We can therefore find segments satisfying either of the following two conditions

$$x^2 + ax - q = 0,$$

$$y^2 - ay - q = 0,$$

where a is a given segment, and q is the product of two given segments.

156. We say that a line is divided into extreme and mean ratio if the greater segment is geometric mean between the whole segment and the smaller part.

Construction 9. Divide a segment into extreme and mean ratio.

Let the given line segment be BC (Fig. 158), on which we need to find a point D such that $\frac{BC}{BD} = \frac{BD}{CD}$. In this proportion, let us add the numerators and denominators. We obtain

$$\frac{BC}{BD} = \frac{BC + BD}{BC}.$$

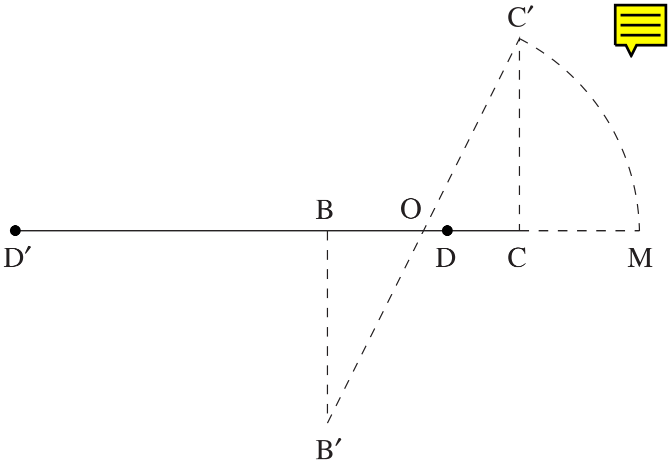

Figure 158

Thus the two segments BD and BC + BD, whose difference is equal to BC, have a product equal to BC^2. This observation leads us to the preceding construction. We must construct perpendicular segments BB′, CC′ on the two endpoints of BC, and in opposite senses, both equal to BC. The circle with diameter B′C′ will intersect the extension past C of BC in a point M. Then if we construct BD = CM, point D is the required point of division.

Starting from B, and in the sense opposite to BC, we construct a segment BD′ = BM. The point D′ thus constructed has a property analogous to that of D: its distance to B is the geometric mean between its distance to C and the segment BC. Indeed, we have BD′ = BC + BD, so that the proportion $\frac{BC}{BD} = \frac{BC+BD}{BC}$ can be rewritten as $\frac{BC}{BD} = \frac{BD'}{BC} = \frac{CD'}{BD'}$.

The point D′ is said to divide the segment BC into mean and extreme ratio externally.[1]

Note that in order to have this property, the point D′ must be chosen as described, because the proportion $\frac{BD'}{BC} = \frac{CD'}{BD'}$ gives, conversely, $\frac{BD'}{BC} = \frac{BC}{BD'-BC}$ (by taking the difference of the numerators and denominators), so that BD′ is one of the segments whose difference is BC and whose product is BC^2.

Let BD = a: we propose to calculate BD and BD′. We remark first that since BB′ and CC′ are equal, the circle with diameter B′C′ has as its center the midpoint O of BC, so that $OC = \frac{a}{2}$. The theorem about the hypotenuse of right triangle, applied to triangle OCC′, tells us that:

$$OC' = OM = \sqrt{\left(\frac{a}{2}\right)^2 + a^2} = \sqrt{\frac{5}{4}a^2} = \frac{a\sqrt{5}}{2}.$$

We therefore have

$$CM = BD = a\frac{\sqrt{5}-1}{2}, \quad BM = BD' = a\frac{\sqrt{5}+1}{2}.$$

---

[1] The points D and D′ are not conjugate with respect to AB (see Exercise 173).

157. Problem. Find the locus of points with the property that the ratio of their distances to two given lines is equal to a given ratio.

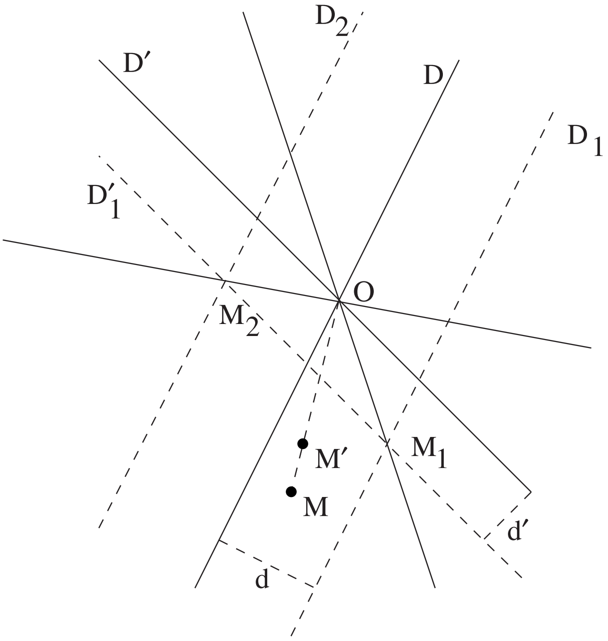

Figure 159

Let D, D' be the given lines, and assume that they meet at point O (Fig. 159). We are looking for points whose distances to these lines are in the ratio $d : d'$ of two given segments. If M is a point on this locus, every point M' on line OM will also be on the locus, because the perpendicular segments from M to D, D', and the corresponding perpendicular segments from M', obviously form two homothetic figures with center of homothecy O. It follows that the locus consists of lines passing through O. We can obtain some points on this locus by finding points whose distances to D, D' are equal to d, d', respectively. We know that the locus of points at a distance d from D consists of two lines D_1, D_2 parallel to D. Likewise, the locus of points at a distance d' from D' consists of two lines D'_1, D'_2 parallel to D'. Let M_1, M_2 be the intersections of D_1, D_2 with D'_1. The lines OM_1, OM_2 are part of our locus. They are in fact the entire locus. Indeed, if M is a point on the locus, then line OM intersects D'_1 in a point M' which, being at distance d' from D', must be at distance d from D, and must therefore coincide with M_1 or with M_2.

If the two lines D, D' are parallel, there would be two points of the locus on any arbitrary common perpendicular:[2] these would be the two conjugate points which divide this perpendicular in the given ratio. The locus consists of parallels to the original lines through these two points.

---

[2] Except when the given ratio is one. In this case there is only one point, the midpoint of the common perpendicular, the other point being thrown to infinity.

Construction 10. Find all points whose distances to three given lines have given ratios.

We first construct the two lines which are the loci of points whose distances to the first two lines are in the given ratio; we then do the same for the second and third given line. In this way we obtain two new lines which will intersect the first two parallels in four points which satisfy the conditions of the problem.

158. Construction 11. Construct the common tangents to two circles.

We have solved this problem in Book II, 93. The preceding theorems allow us to give an entirely different solution. It suffices to draw two parallel radii, so as to determine the centers of similarity (143), and to draw from either of these centers a tangent to one of the circles: this line will be tangent to the second as well because of the homothecy of the two figures.

Construction 12. Find the radical axis of two circles.

If the two circles are secant or tangent, we need only draw the common chord or the common tangent.

If not, we draw an arbitrary third circle which intersects the two circles. The intersection of its two common chords with the given circles will belong (139) to the required radical axis. It suffices then to drop a perpendicular from this point to the line of the centers. Alternatively, we can repeat the construction with another circle in order to determine a second point.

Remark. This construction can be applied to a circle and a line, which leads us to state that the radical axis of a circle and a line is the line itself.

The construction can also be applied in the limiting case when one of the circles is reduced to one point. The auxilliary circle must then pass through this point.

The preceding construction also allows us to find the radical center of three given circles, and therefore (139) to solve the following problem:

Construction 13. Construct the circle orthogonal to three given circles. In particular, construct:

a circle passing thorough a given point and orthogonal to two given circles; or

a circle passing through two points and orthogonal to a given circle.

159. Construction 14. Construct a circle passing through two given points and tangent to a given line.

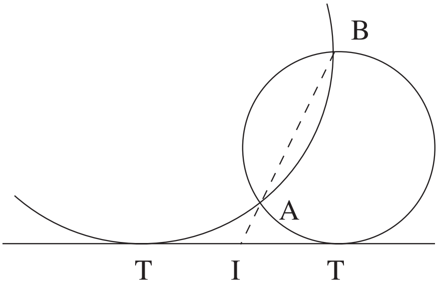

Figure 160

Consider points A, B (Fig. 160) and line xy; let T be the point of contact of the required circle with xy. Extend AB to its intersection I with xy. The segment IT is known: it is the geometric mean of IA and IB.

Conversely, if point T verifies this condition, there exists (132) a circle passing through A, B and tangent to xy at T: it is determined by construction 13 of Book II, 90.

Since the geometric mean of IA, IB can be placed on either side of point I on xy, there are two solutions to the problem.

The solution is clearly possible only when A, B are on the same side of line xy.

Remarks. I. The preceding method does not apply when AB is parallel to xy. In this case the problem has only one solution, the point of contact being the intersection of xy with the perpendicular bisector of AB.

II. On the other hand, this method does apply when A and B coincide on the line IA intersecting xy at I; that is, when we are required to find a circle tangent to IA at A and also tangent to xy. The point of contact T can be found by laying off, in either sense, the segment IT = IA.

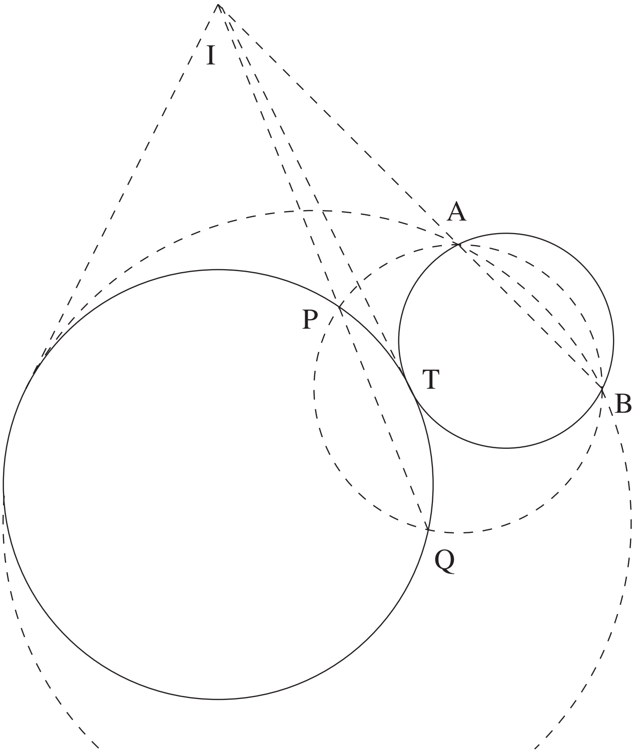

Figure 161

Construction 15. Construct a circle passing through two given points and tangent to a given circle.

Consider two points A, B (Fig. 161) and circle C. We are looking for the point of contact T with the required circle.

To find this point, let I be the point of intersection of AB with the tangent at T. Take an arbitrary circle passing through A, B, and intersecting C in P, Q. Point I will be on line PQ (139).

Since the intersection of AB with PQ gives us point I, it suffices to construct tangents to C through this point. The problem thus has two solutions.

Condition for existence. The point I must be exterior to circle C. For this to happen, it is necessary and sufficient that this point lie on the extention in one direction or the other of segment PQ; that is, outside the auxiliary circle. This will happen when points A, B are both on the same arc determined on the auxilliary circle by P, Q; that is, when A and B are both inside or both outside the given circle.

The remarks of the preceding construction apply here, with respect to the case when A and B are two identical points on a given line.

Exercises

Exercise 163. Find a segment whose ratio to a given segment is equal to the ratio of the squares of two given segments.

Exercise 164. Find a segment such that the ratio of its square to the square of a given segment is equal to the ratio of two given segments.

Exercise 165. Draw a segment through a given point which is divided into a given ratio by two given lines.[3]

Exercise 166. Through a point exterior to a circle, draw a secant which is divided into mean and extreme ratio by the circle.

Exercise 167. Given three consecutive segments AB, BC, CD on a line, find a point at which they subtend the same angle.

Exercise 168. Through two points on the same diameter of a circle, draw two equal chords which intersect on the circle.

Exercise 169. Construct a triangle knowing two sides and the bisector of the angle they include.

Exercise 170. Construct a triangle knowing a side, the corresponding altitude, and the product of the other two sides.

Exercise 171. Construct a triangle knowing the angles and the perimeter; or the angles and the sum of the medians; or the angles and the sum of the altitudes, etc.

Exercise 172. Construct a triangle knowing its three altitudes (Exercise 146).

Exercise 173. The harmonic conjugate of point B with respect to segment DD (Fig. 158, 156) is obtained by extending segment BC by its own length. The harmonic conjugate of D with respect to BC is the point symmetric to D with respect to the midpoint of BC. Also show that the circle with diameter DD passes through the vertices (other than B, C) of the square with diagonal BC.

---

[3] See solution for a note on this problem statement. transl.

Exercise 174. Given a line and two points A, B, find a point on the line at which AB subtends the greatest possible angle.

This problem can be treated indirectly, by first seeking points on the line at which AB subtends a given angle, then finding the greatest angle for which the construction is possible.

The next two problems can be approached in the same way.

Exercise 175. Draw a common perpendicular to two given parallel lines which subtends the greatest possible angle at a given point.

Exercise 176. Find a circle passing through two given points, and intercepting a chord of given length on a given line. Find the minimum possible length when the two points are on different sides of the line.

Exercise 177. Construct a circle passing through a given point and having the same radical axis as two given circles.

CHAPTER VII

Regular Polygons

160. A regular polygon is a convex polygon all of whose sides are equal, and all of whose angles are equal. A regular broken line is a broken line all of whose sides are equal, and all of whose angles are equal and have the same orientation.

161. Theorem. If a circle is divided into an arbitrary number n of equal parts, then:

1 . The division points are the vertices of a regular polygon;

2 . The tangents at these points are the sides of a second regular polygon.

1 . Two consecutive sides of the polygon with vertices at the points of division are obviously symmetric with respect to the radius ending at their common endpoint; two consecutive angles of this polygon are symmetric with respect to the radius perpendicular to their common side.

2 . Two consecutive angles of the polygon formed by the tangents at the points of division are obviously symmetric with respect to the radius perpendicular to their common side; two consecutive sides of this polygon are symmetric with respect to the radius perpendicular to the chord joining their points of contact.

162. Theorem. Conversely, every regular polygon and, more generally, every regular broken line, can be inscribed in a circle and circumscribed about another circle.

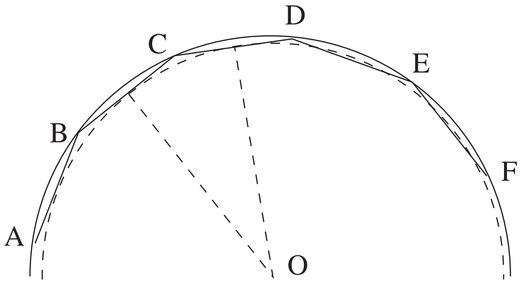

Figure 162

Consider, for instance, the regular broken line ABCDEF (Fig. 162). We draw the circle cirumscribing triangle ABC, whose center O is on the perpendicular bisector of BC. We claim that this circle passes through the point D. To see this, it suffices to observe that the sides BA, CD are symmetric with respect to the perpendicular bisector of BC; indeed, the segment symmetric to BA coincides with CD in direction (because of the equality of the angles at B and C) and length (because $BA = CD$). Thus we have $OA = OD$. Likewise, we see that this same circle, circumscribed about BCD passes through E, and so on.

Now, chords AB, BC, etc., are equal chords of the circumscribed circle, and they are therefore equally distant from the center O. Therefore the sides of the broken line are tangent to a second circle with center O.

The radius of this second circle, or the distance from an arbitrary side to the center, is called the apothem of the regular broken line (or of the regular polygon).

Remark. Every regular polygon with n sides can be superimposed on itself by certain rotations (namely the rotations whose angle is a number of times the n^{th} part of the circle) and by certain line reflections (reflections in the perpendicular bisectors of the sides or the bisectors of the angles).

The number of axes of symmetry is always n. If $n = 2p$ is even, the vertices form diametrically opposite pairs, and this gives p axes of symmetry, each of which is the common bisector of a pair of opposite angles. Likewise, the sides give p axes of symmetry, each perpendicular to two opposite sides.

If $n = 2p + 1$ is odd, each axis of symmetry bisects an angle, and is at the same time the perpendicular bisector of the opposite side.

163. Thus there are infinitely many regular polygons with the same number n of sides, but all of them are similar.

Theorem. Two regular polygons with the same number of sides are similar.

Indeed, two regular polygons with the same number of sides inscribed in congruent circles are obviously congruent: they will coincide if we superimpose their circumscribed circles and one vertex.

If we now are given two regular polygons P, P' inscribed in circles C, C', we can draw a circle concentric to C and congruent to C'. If we look at the intersections of this circle with the radii of C drawn to the vertices of P, we will find a regular polygon which is homothetic to P with respect to the center of C, and congruent to P'.

Remark. In particular, all regular polygons with the same number n of sides have the same angle. It is easy to calculate this angle. Since the sum of the angles of one of these polygons is $2n - 4$ right angles, each one will be the nth part of this measure; that is, $2 - \frac{4}{n}$ right angles.

164. Having divided a circle into n equal parts, let us join the points of division separated by p equal arcs, starting from one division point, until we visit some vertex for the second time. If P is the first vertex which is visited twice, this vertex can only be the one where we started, because if it were the endpoint of a side NP, already traversed in the sense NP, it is clear that we would have visited N first before returning to P.

The figure thus obtained is (21, Remark) an improper polygon, and is called a regular star polygon. For instance, Fig. 163 represents the star pentagon obtained by dividing the circle into five equal parts at the points A, B, C, D, E and joining them in the order $ACEBDA$ ($n = 5$, $p = 2$).

We may assume that n and p are relatively prime. Indeed, if they had a common divisor $d > 1$, we would obtain the same construction replacing n, p by $\frac{n}{d}$, $\frac{p}{d}$.

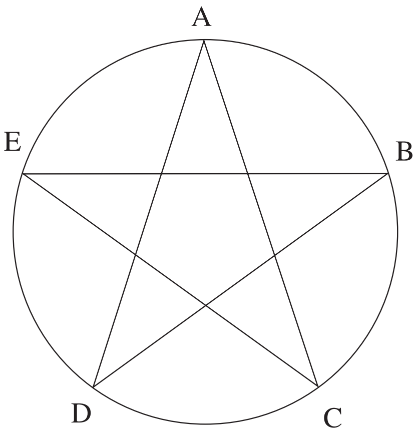

Figure 163

If n and p are relatively prime, the star polygon will have precisely n sides. Indeed, since each side spans p parts of the circle, tracing k sides we will have spanned kp parts. We will have returned to the starting point after traveling a whole number of circles, that is if kp is a multiple of n. It is shown in arithmetic[1] that this happens for some value $k < n$ if p and n are not relatively prime; but if, on the other hand, p is relatively prime to n, this happens for the first time when $k = n$.

We can thus form star polygons with n sides by dividing the circle into n equal parts, and joining every p^{th} division point, where p is any number less than, and relatively prime to, n. Every star polygon is obtained in two ways by this construction, because if its side is the chord corresponding to an arc equal to p divisions, it is also the chord corresponding to $n - p$ divisions. For instance, the star polygon in Figure 163 can be obtained either by joining every second point, or by joining every third point. Thus one half of the values of p must be discarded if we want to find each polygon once. The value $p = 1$ (and therefore $p = n - 1$) corresponds to the usual regular polygon.

Example. Consider $n = 15$. Besides 1 and 14, the numbers less than 15 and relatively prime to it are 2, 4, 7, 8, 11, 13. We need not consider the values $p = 8$, 11, 13, which give the same polygons as 7, 4, 2. Thus there is one proper regular pentadecagon, and three star pentadecagons.

165. Construction of inscribed regular polygons. If we know how to inscribe a regular polygon, we also know how to circumscribe the regular polygon with the same number of sides.

This last is formed by the tangents to the circle through the vertices of the first.

If we know how to inscribe a regular polygon, we also know how to inscribe a regular polygon with double the number of sides.

It suffices to divide the arc intercepted by the first polygon into two equal parts.

---

[1] See Tannery, Leçons d'Arithmetique, chap. IV.

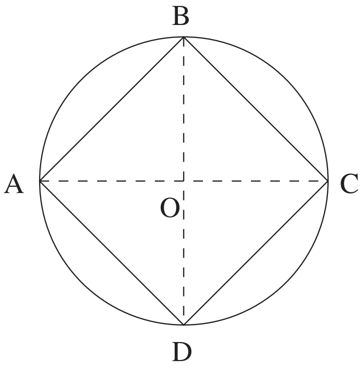

Figure 164

166. The Square. To inscribe a square in a circle O (Fig. 164), it suffices to draw two perpendicular diameters AC, BD: they will divide the circle into four equal parts.

The preceding remark allows us to construct the inscribed regular octagon, then the regular polygons with 16, 32, . . . and, generally, 2^n sides.

The side of the square inscribed in a circle of radius R is $c_4 = R\sqrt{2}$.

This is true because in right triangle AOB (Fig. 164), we have

$$AB^2 = AO^2 + BO^2 = 2R^2.$$

The apothem of an inscribed regular polygon can be calculated by the following rule: the square of the apothem equals the square of the radius of the circumscribed circle minus the square of half a side. This follows from the fact that the apothem, radius, and half a side form a right triangle.

Thus, the apothem a of a polygon with side c inscribed in a circle of radius R is $a = \sqrt{R^2 - \frac{c^2}{4}}$.

For the square, this apothem is

$$a_4 = \sqrt{R^2 - \frac{c_4^2}{4}} = \sqrt{R^2 - \frac{2R^2}{4}} = \frac{R\sqrt{2}}{2}.$$

It is equal to half the side, which was evident a priori.

167. The Hexagon.

Theorem. The side of a regular hexagon is equal to the radius of its circumscribed circle.

Let AB (Fig. 165) be the side of a regular hexagon inscribed in a circle with center O. We claim that triangle OAB is equilateral. We see right away that it is isosceles. Also, the angle at O intercepts a sixth of the circle, so it is equal to $\frac{4}{6} = \frac{2}{3}$ of a right angle. There remain $2 - \frac{2}{3} = \frac{4}{3}$ of a right angle for the sum of the angles at A and B. Since these two angles are equal, both are $\frac{2}{3}$ of a right angle. The triangle is equiangular, and so equilateral.

The apothem of the regular hexagon is

$$a_6 = \sqrt{R^2 - \frac{R^2}{4}} = \frac{R\sqrt{3}}{2}.$$

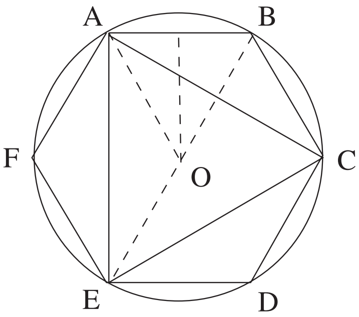

Figure 165

The Equilateral triangle. Joining every other vertex of our hexagon, we form inscribed equilateral triangle ACE (Fig. 165).

Side AC of this triangle, being perpendicular to radius OB, is equal to twice the altitude of triangle AOB; that is (since the three altitudes of an equilateral triangle are equal), twice the apothem of the hexagon: $c_3 = R\sqrt{3}$.

This can also be seen by observing that B and E are diametrically opposite (since the arc between them is $\frac{3}{6}$ of the circle). Triangle ABE thus has a right angle at A, and side AE is twice the length of the perpendicular from the midpoint O of BE to AB.

The apothem of the inscribed equilateral triangle is $a_3 = \frac{R}{2}$.

Knowing the construction for the inscribed hexagon, we can derive the construction of inscribed polygons with $12, 24, \ldots, 3 \times 2^n$ sides.

168. The Decagon.

Theorem. The side of the inscribed regular decagon is equal to the greater segment of the two that divide the radius into mean and extreme ratio.

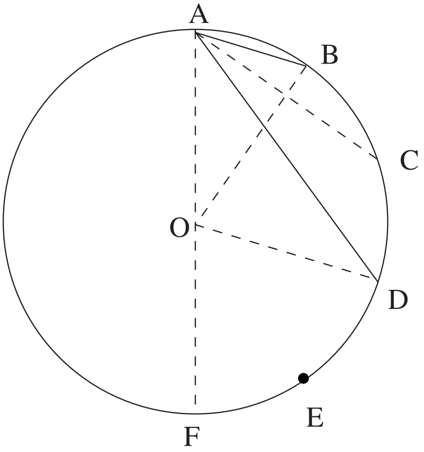

Figure 166

Let AB (fig. 166) be the side of the regular decagon inscribed in a circle with center O. The angle at O is $\frac{4}{10} = \frac{2}{5}$ of a right angle. The sum of the angles OAB, OBA is therefore $2 - \frac{2}{5} = \frac{8}{5}$ of a right angle, so each of them is $\frac{4}{5}$ of a right angle. We construct the bisector AI of OAB (with I on OB), which forms, with OA and AB, angles equal to $\frac{2}{5}$ of a right angle. Angle AIB, exterior to triangle AIO is equal to the sum of the two remote interior angles, which is here $\frac{4}{5}$ of a right angle. It follows that triangles AIB, AIO are isosceles and that AB = AI = IO. The property of the angle bisector (115), $\frac{OI}{IB} = \frac{OA}{AB}$, can thus be rewritten as

$$\frac{OI}{IB} = \frac{OB}{OI}.$$

QED

The side of the regular inscribed decagon can then be determined by Construction 9 in 156. This side is:

$$c_{10} = R\frac{\sqrt{5} - 1}{2},$$

and the apothem is:

$$a_{10} = \sqrt{R^2 - R^2\left(\frac{\sqrt{5} - 1}{4}\right)^2} = \frac{R}{4}\sqrt{10 + 2\sqrt{5}}.$$

169. Aside from the ordinary regular decagon, there is also a star regular decagon, obtained by joining every third vertex of the vertices of the ordinary one.

We can find the side of the ordinary decagon, and the side of the star decagon, from the following result:

Theorem. The difference of the sides of the two regular inscribed decagons is equal to the radius, and their product is the square of the radius.

Once again, we let AB (Fig. 166) be the side of the ordinary regular decagon, so that semicircle $\overset{\frown}{AF}$ is divided into five equal parts by the points B, C, D, E. Then AD is the side of the star decagon, and line AD coincides with the bisector AI of angle OAB, since the inscribed angles FAD, DAB intercept equal arcs on the circle. Radius OD is parallel to AB because alternate interior angles ODA, DAB are both equal to OAD. Thus triangles AIB, DOI are similar; they are also isosceles, as we have seen in the preceding section. We then have AD − AB = AD − AI = ID = OD.

As for the relation $AB \cdot AD = AI \cdot AD = OA^2$, this follows from the similarity of triangles AIO, AOD which have equal angles.

We observe that the sides of the two regular decagons correspond to the two divisions (interior and exterior) of the radius into mean and extreme ratio, obtained in Construction 9.

The side of the star decagon is $c_{10} = R\frac{\sqrt{5}+1}{2}$, and its apothem is:

$$a_{10} = \sqrt{R^2 - R^2\left(\frac{\sqrt{5} + 1}{4}\right)^2} = \frac{R}{4}\sqrt{10 - 2\sqrt{5}}.$$

170. The Pentagon. Joining every other vertex of a regular decagon we obtain the ordinary regular pentagon. Joining every other vertex of the pentagon,

which amounts to joining every fourth vertex of the decagon, we obtain the regular star pentagon.

Side AC of the ordinary regular pentagon is twice the altitude from A in triangle AOB (Fig. 166). Thus we can compute it, knowing the side of the decagon, since we can compute the altitudes of a triangle, given its sides. But, more simply, the side of the ordinary regular pentagon is twice the apothem of the star decagon. This can be seen either from triangle AIO whose altitudes (namely, half the side of the pentagon, and the apothem of the star decagon) are equal, or in right triangle ADF, where side DF is equal to the side of the pentagon, and the parallel through O to this side is equal to the apothem of the star decagon. The side and apothem of the ordinary regular pentagon are therefore

$$c_5 = 2a_{10} = \frac{R}{2}\sqrt{10 - 2\sqrt{5}}, \quad a_5 = \frac{R}{4}(\sqrt{5} + 1).$$

In the same way, by considering right triangle ABF, we see that the side of the star pentagon is twice the apothem of the ordinary decagon, and therefore

$$c_5 = \frac{R}{2}\sqrt{10 + 2\sqrt{5}}, \quad a_5 = \frac{R}{4}(\sqrt{5} - 1).$$

Remark. In general, the same reasoning shows that the calculation of the side and apothem of a polygon (ordinary or star) obtained by dividing the circle into 2n + 1 equal parts, and joining every p^th^ point of division, amounts to the calculation of the polygon obtained by dividing the circle into 4n + 2 equal parts and joining every q^th^ point of division, where q is derived from p by the relation[2]

$$\frac{p}{2n+1} + \frac{q}{4n+2} = \frac{1}{2}, \quad \text{or} \quad 2p + q = 2n + 1.$$

171. The Pentadecagon. Next we consider inscribing a proper regular pentadecagon in a circle. We will know how to do this, once we have constructed the hexagon and decagon, from the following result.

Theorem. The arc intercepted by the side of the regular inscribed pentadecagon is the difference of the arcs intercepted by the side of the hexagon and the side of the decagon.

Indeed, this arc is a 15th of the circle, and the ratio $\frac{1}{15}$ is equal to the difference $\frac{1}{6} - \frac{1}{10}$.

Thus we can start from point A (Fig. 167), and lay off two openings of the compass AB, AC, on the circle, one equal to the side of the regular hexagon, the other to the side of the decagon. Segment BC will be the required side.

Aside from the ordinary regular pentadecagon, there exist three star pentadecagons (164) whose sides intercept $\frac{2}{15}$, $\frac{4}{15}$, and $\frac{7}{15}$ of the circle. These arcs can be easily deduced from the first, and can also be obtained by constructions analogous to the one used for the ordinary pentedecagon.

---

[2] Conversely, this remark allows to reduce the calculations for a polygon with 4n + 2 sides to calculations for a polygon with 2n + 1 sides. This is true because a polygon with 4n + 2 sides corresponds to an odd number q (see 164); 2n + 1 − q will then be even and the relation 2p = 2n + 1 − q will yield an integer p, relatively prime to 2n + 1 and corresponding to a polygon with 2n + 1 sides, for which it will suffice to calculate the side and the apothem. In this way, the calculations done for the pentadecagon (174,175) can be used to find the corresponding results for polygons with 30 sides.

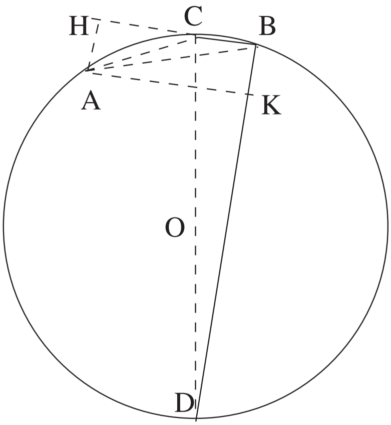

Figure 167

The arc intercepted by the side of the first star pentadecagon is the difference of the arcs intercepted by the sides of the star decagon and that of the hexagon.

The arc intercepted by the side of the second star pentadecagon is the sum of the arcs intercepted by the sides of the proper decagon and that of the hexagon.

The arc intercepted by the side of the third star pentadecagon is the sum of the arcs intercepted by the sides of the star decagon and that of the hexagon.

Indeed, we have:

$$\frac{2}{15} = \frac{3}{10} - \frac{1}{6},$$
$$\frac{4}{15} = \frac{1}{10} + \frac{1}{6},$$
$$\frac{7}{15} = \frac{3}{10} + \frac{1}{6}.$$

172. More generally, if we know how to inscribe regular polygons with m sides and n sides, with m, n relatively prime, we also know how to inscribe a regular polygon with mn sides.

Indeed, the sides of the two known polygons intercept an m^{th} and an n^{th} of the circle. By adding p times the first arc, and subtracting q times the second, we obtain the arc intercepted by the new polygon if

$$\frac{p}{m} - \frac{q}{n} = \frac{1}{mn}, \quad \text{or} \quad np - mq = 1.$$

It is shown in arithmetic[3] that this relation is not possible if m and n have a common factor (different from one), but that it is possible if m and n are relatively prime.

For instance, the regular dodecagons can be inscribed using the constructions for the square and the triangle, because $\frac{1}{12} = \frac{1}{3} - \frac{1}{4}$, $\frac{5}{12} = \frac{2}{3} - \frac{1}{4}$.

The remark of 170 is a special case of this one, corresponding to $m = 2$ and n odd.

---

[3] Tannery, Leçons d Arithmetique, chap. XIV, n 511

173. The geometer Gauss proved that we can inscribe, with straightedge and compass, any regular polygon whose number of sides is of the form $2^n + 1$. Thus we were able to inscribe the regular triangle $(2 + 1 = 3)$ and pentagon $(2^2 + 1 = 5)$. Next come the polygons with $17(= 2^4 + 1)$, $257(= 2^8 + 1)$, etc., sides.[4]

Combining this proposition with those already obtained, we see that we can inscribe, with straightedge and compass, a regular polygon with N sides if the prime factorization of N contains only: 1°. prime factors of the form $2^n + 1$, all distinct; 2° the factor 2 to an arbitrary power.

Conversely, we can prove that the construction cannot be done by straightedge and compass if the number N is not of the type just described.

Thus, the regular polygon with $170(= 2 \times 5 \times 17)$ can be inscribed, but not the polygon with 9 sides, because the number 9 is a power of 2 plus one, but is not prime; alternatively, its factors $(9 = 3 \times 3)$ are certainly of the form $2^n + 1$, but are equal.

174. To calculate the side of the ordinary regular pentadecagon inscribed in a circle of radius R, we again consider sides AB, AC (Fig. 167) of the inscribed decagon and hexagon, so that BC is the required side. If we drop a perpendicular AH onto BC, we will have $BC = BH - CH$.

Now angle ABH, as an inscribed angle, intercepts arc $\overset{\frown}{AC}$, and is therefore equal to half the central angle corresponding to a side of the decagon, so that BH is the apothem of the regular decagon inscribed in a circle with radius AB. Thus

$$BH = \frac{AB}{4}\sqrt{10 + 2\sqrt{5}} = \frac{R}{4}\sqrt{10 + 2\sqrt{5}},$$

since $AB = R$.

Similarly, angle ACH is equal to the inscribed angle intercepting arc $\overset{\frown}{ACB}$ (since both these angles are supplementary to ACB), so it is equal to half the central angle corresponding to the side of the regular hexagon. Thus CH is the apothem of the regular hexagon inscribed in the circle with radius AC, or:

$$CH = \frac{AC\sqrt{3}}{2} = R\frac{\sqrt{5} - 1}{2} \cdot \frac{\sqrt{3}}{2},$$

and consequently

$$BC = \frac{R}{4}\left(\sqrt{10 + 2\sqrt{5}} - \sqrt{3}(\sqrt{5} - 1)\right).$$

It is clear that the preceding method applies whenever we must solve problems of the following type: knowing the chords of two arcs in a circle of given radius, find the chord of the difference of the two arcs.

In particular, to calculate the side of the first star pentadecagon, we use the same reasoning, replacing the side and apothem of the ordinary decagon with the side and apothem of the star decagon. The required side will be

$$R\frac{\sqrt{5} + 1}{2}\frac{\sqrt{3}}{2} - \frac{R}{4}\sqrt{10 - 2\sqrt{5}} = \frac{R}{4}\left((\sqrt{5} + 1)\sqrt{3} - \sqrt{10 - 2\sqrt{5}}\right).$$

---

[4] It is easily proved (it is enough to apply n° 48 and n° 49, application III, of Bourbet, Leçons d'Algébre) that for $2^n + 1$ to be prime it is necessary that n itself be a power of 2; this condition is not sufficient.

Next let us calculate the side of the second star pentadecagon. We again consider the sides AB, AC′ of the hexagon and ordinary decagon, but we draw them in opposite senses along the circle, so that BC′ is the required segment (Fig. 167b).

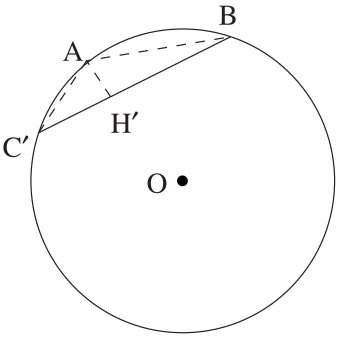

Figure 167b

We drop perpendicular AH′ onto BC′. The two segments BH′, C′H′ will again be equal, the first to the apothem of the ordinary decagon inscribed in the circle with radius AB, the second to the apothem of the hexagon inscribed in the circle with radius AC′. Their sum BC′ will then be

$$BC' = \frac{R}{4}\left(\sqrt{10+2\sqrt{5}}+\sqrt{3}(\sqrt{5}-1)\right).$$

Clearly we can operate the same way whenever we find ourselves in the position of knowing the chords of two arcs inscribed in a circle of given radius, and seeking the chord of the sum of the two arcs.

In particular, for the side of the third star pentadecagon we find the value

$$\frac{R}{4}\left((\sqrt{5}+1)\sqrt{3}+\sqrt{10-2\sqrt{5}}\right).$$

175. We could deduce the apothem of the pentadecagon from the value found for its side, but this would require the extraction of an additional square root. We can instead compute the apothem (without requiring an additional square root), using a method similar to the one used for the side.

In Fig. 167, we construct diameter CD from point C. Triangle BCD shows that BD is again twice the required apothem. We now drop perpendicular AK from A to BD. Angle ADB (as an inscribed angle) is equal to half the central angle corresponding to a side of the hexagon; the segment DK is equal to the apothem of the hexagon inscribed in the circle of radius AD; and thus

$$DK = AD\frac{\sqrt{3}}{2} = \frac{R}{2}\sqrt{10+2\sqrt{5}}\,\frac{\sqrt{3}}{2},$$

because AD is twice the apothem of the regular decagon inscribed in the given circle.

On the other hand, angle ABD is equal to ACD; that is, to the complement of half the central angle corresponding to the regular decagon; angle KAB is equal to half this central angle; and BK is half the side of the decagon inscribed in the circle with radius AB, so:

$$BK = AB\frac{\sqrt{5}-1}{4} = R\frac{\sqrt{5}-1}{4}.$$

The required apothem is thus

$$\frac{BD}{2} = \frac{BK+DK}{2} = \frac{R}{8}\left(\sqrt{3}\sqrt{10+2\sqrt{5}}+\sqrt{5}-1\right).$$

Analogous reasoning gives the following value for the apothems of the first star pentadecagon:

$$\frac{R}{8}\left(\sqrt{3}\sqrt{10-2\sqrt{5}}+\sqrt{5}+1\right).$$

For the second star pentadecagon, we get:

$$\frac{R}{8}\left(\sqrt{3}\sqrt{10+2\sqrt{5}}-(\sqrt{5}-1)\right).$$

For the third star pentadecagon, we get:

$$\frac{R}{8}\left(\sqrt{3}\sqrt{10-2\sqrt{5}}-(\sqrt{5}+1)\right).$$

176. Measurement of the circumference of a circle.

Theorem. Let P be the perimeter of a regular circumscribed polygon, and let p be the perimeter of the inscribed polygon with the same number of sides. If we keep doubling the number of sides indefinitely, then P and p tend to a common limit L.

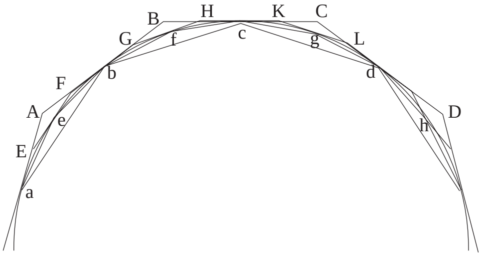

Figure 168

Consider inscribed polygon $abcd\cdots$ (see Fig. 168) and circumscribed polygon $ABCD\cdots$ whose sides have, as points of contact, the vertices of the first. Let us double the number of sides of these polygons, dividing each of the arcs $\overset{\frown}{ab}$, $\overset{\frown}{bc}$, $\overset{\frown}{cd}, \ldots$ into two equal parts, so as to form the new regular inscribed polygon $aebfcg\cdots$ and the corresponding new circumscribed polygon $EFGHKL\cdots$ (Fig. 168). We operate in the same way on the new polygons, and so on, indefinitely. We claim that the perimeters p of the inscribed polygons and the perimeters P of the circumscribed polygons tend to a common value.

We will prove this with the help of the following remarks.

1 . The perimeters p increase as we double the number of sides; for instance, polygon $aebfcg\cdots$ has a greater perimeter than polygon $abcd\ldots$, since this last polygon is inside it;

2 . The perimeters P decrease as we double the number of sides; for example polygon $EFGHKL\cdots$ has a smaller perimeter than polygon $ABC\cdots$, which contains it in its interior;

3 . Any perimeter p is smaller than any perimeter P, because each inscribed polygon is inside each circumscribed polygon.

The quantity p, which increases while always remaining less than a fixed quantity (namely, any value of P) tends to a limit (Leçons d Arithmetique de M. Tannery, chap. XII, n 470).

Likewise, the quantity P, which decreases while always remaining greater than a fixed quantity (namely, any value of p), also tends to a limit.

These limits are equal. Indeed, the two polygons are always similar, and their perimeters are in the same ratio as their apothems. Now the apothem of the circumscribed polygon is equal to the radius R of the given circle, so that

$$\frac{P}{p} = \frac{R}{a},$$

where a denotes the apothem of the inscribed polygon. But as we keep doubling the number of sides indefinitely, the apothem a tends to R. Thus the limit of the ratio $\frac{P}{p}$, which is the ratio of the two limits referred to above (Leçons d Arithmetique chap. XII, n 466) is equal to one. QED

177. We now claim that the perimeter of any convex polygon, inscribed or circumscribed,[5] all of whose sides decrease indefinitely, tends to the limit of the preceding theorem.

In particular, this limit is independent of the initial regular polygon.

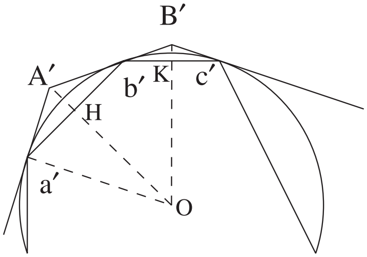

Figure 169

Indeed, consider an arbitrary inscribed polygon $a\,b\,c\cdots$ (Fig. 169), and also the convex circumscribed polygon $A\,B\cdots$ formed by the tangents at $a\,,b\,,c\,\ldots$. Let p and P be the perimeters of the two polygons. The limit L of the preceding theorem is contained between p and P because p, for instance, is smaller than any of the perimeters P considered above, which have limit L, so that p L. In the same way, we find that P L.

---

[5] It is understood that a circumscribed polygon includes the circle in its interior.

On the other hand, line OA intersects ab at its midpoint H, and

$$\frac{aA + Ab}{ab} = \frac{aA}{aH} = \frac{R}{OH},$$

since right triangles AaH, oaA are similar, having a common acute angle. Likewise,

$$\frac{bB + Bc}{bc} = \frac{R}{OK},$$

where K denotes the midpoint of bc, and so on.

Let us add the numerators and denominators of the left hand sides of these equalities. We obtain a ratio contained between the smallest and the greatest[6] of the original ratios; thus

$$\frac{P}{p} = f,$$

where f is between the smallest and largest of the quantities $\frac{R}{OH}, \frac{R}{OK}, \ldots$. Now if the polygon varies in such a way that all the sides decrease indefinitely, all the distances OH tend to R, and all the ratios $\frac{OH}{R}, \frac{OK}{R}$ tend to one. Therefore the same happens for $\frac{P}{p}$, and therefore for $\frac{L}{p}$ and $\frac{P}{L}$ which are both between 1 and $\frac{P}{p}$. Thus P and p tend to L. QED

Definition. The length L, the common limit of the inscribed and circumscribed convex polygons as the sides decrease indefinitely (a limit whose existence has just been proved), is called the circumference or length of the circle.

178. Theorem.

The ratios of the lengths of two circles is the ratio of their radii.

Consider circles C, C_1 with radii R, R_1. In these circles, we inscribe regular polygons with the same number of sides. These polygons are similar, and therefore (146, Corollary) the ratio of their perimeters P, P_1 is the ratio of their radii. As the number of sides increases indefinitely, the ratio $\frac{P}{P_1}$ tends to the ratio $\frac{C}{C_1}$ of the circumferences of the circles. This proves the theorem.

Corollary. The ratio of the length of a circle to the diameter is constant.

Indeed, the proportion $\frac{C}{C_1} = \frac{R}{R_1}$ can be rewritten $\frac{C}{R} = \frac{C_1}{R_1}$ or $\frac{C}{2R} = \frac{C_1}{2R_1}$. Thus the ratio of the circumference to the diameter is the same for any two circles.

This constant number, the ratio of the circumference to the diameter, is denoted by the Greek letter π.

Corollary. The circumference of a circle of radius R is $2\pi R$.

179. Length of an arc of a circle.

Definition. The length of an arc of a circle is the limit of the perimeters of convex broken lines inscribed in the arc, ending at the endpoints of the arc, as all the sides decrease indefinitely.

---

[6] Leçons d Arithmetique, chap. VI, n 212.

The existence of this limit is proved by the same reasoning used for the whole circle. We first consider a regular inscribed or circumscribed broken line, and we double the number of sides indefinitely. Then we pass to an arbitrary broken line.[7]

Every arc of a circle is longer than its chord, since it is the limit of broken lines longer than this chord, whose perimeters increase.

For analogous reasons, it is shorter than any broken line surrounding it, with the same endpoints.[8]

The ratio of an arc of a circle to its chord tends to one as the arc tends to zero (if the circle remains fixed). This is true because the arc $\overset{\frown}{ab}$ (Fig. 169) is contained between its chord and the broken line aAb formed by the tangents at its endpoints: as we have seen (177) the ratio of these quantities goes to one when the arc $\overset{\frown}{ab}$ decreases indefinitely.

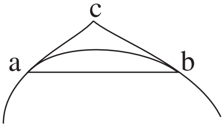
179b. Two congruent arcs have equal lengths, since the broken lines used in the definition of their lengths can be taken to be equal in pairs. The sum of two arcs has a length equal to the sum of the lengths of the two arcs, since two broken lines inscribed in the two arcs, taken together, constitute a broken line inscribed in the total arc.

Thus, according to a principle invoked several times before, the ratio of the lengths of two arcs of the same circle is equal to the ratio of the arcs (17). In particular, the ratio of these lengths is equal to the ratio of the measures of the arcs in degrees or gradients.

Since the circumference of a circle of radius R is $2\pi R$, and this circle is divided into 360 degrees, it follows that the length of each degree will be $\frac{2\pi R}{360} = \frac{\pi R}{180}$. The length of a minute will be equal to one sixtieth of this quantity, or $\frac{\pi R}{180 \times 60}$, and a second $\frac{\pi R}{180 \times 60 \times 60}$. Thus, on a circle with radius R, an arc of m degrees, n minutes,

---

[7] This method of proof can be extended to any convex curve A; that is, to a curve such that none of its arcs intersects its chord. It suffices to show that to every number $m < 1$ (but as close to 1 as we want) we can associate a length ε such that for any arc $\overset{\frown}{ab}$ contained in A whose endpoints are closer to each other than ε, the ratio of the chord ab to the sum $ac + bc$ (see figure) of the tangents at a, b (bounded by their points of intersection) is contained between m and 1. This condition is satisfied (as is proved in differential calculus) under certain assumptions which are always satisfied in the case of the curves we consider. We are then assured (as in 177), that the ratio of the perimeter of an inscribed broken line to the perimeter of the corresponding circumscribed line tends to one, as the number of sides increases and each of them tends to zero.



This can be used to prove the existence of a limit so long as the vertices of each broken line are included among the vertices of the next one (by the argument in 176). Then we pass to the general case as in 177.

Finally, a non-convex arc can often be broken into convex pieces, allowing us to define its length.

[8] These conclusions extend to any arc of a curve defined in accordance with the considerations of the preceding note. In particular, the line segment is the shortest path from one point to another. A convex arc (see previous note) is shorter than any line surrounding it (a broken line or a curve) with the same endpoints.

p seconds, has length

$$\frac{R}{180}\quad m+\frac{n}{60}+\frac{p}{60\times 60}\quad ;$$

an arc of n gradients will have length $\frac{Rn}{200}$.

180. Thus we see that we can calculate the length of any arc of a given circle, if we know the number .

Calculation of . Method of perimeters. To calculate this number, or equivalently, to calculate the length of a circle of a given radius R, we have to calculate the perimeters of regular inscribed polygons whose number of sides doubles indefinitely. Each of these perimeters will furnish an estimate from below of the required length, and this approximation gets close as the number of sides increases. If, at the same time that we calculate the perimeter of the inscribed polygon, we can calculate the perimeter of the corresponding circumscribed polygon, we will obtain an estimate from above, and the difference of these two estimates will give an upper bound to the error committed by adopting one of them.

We have learned to calculate the sides of a number of regular inscribed polygons, for instance, that of a square. To deduce from this the sides of the polygons with $4\times 2, 4\times 2^2, \ldots, 4\times 2^n$ sides, it will suffice to solve the following problem:

Problem. Knowing the side c of a regular polygon inscribed in a circle with given radius R, calculate the side of the polygon inscribed in the same circle, with twice the number of sides.

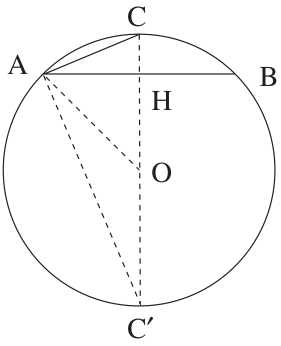


Figure 170

Let AB = c (Fig. 170) be the side of the first polygon inscribed in a circle with radius OA = R. Dividing arc $\widehat{AB}$ into two equal parts with radius OC, perpendicular to the midpoint H of AB, we obtain side AC of the inscribed polygon with twice the number of sides. Now in triangle OAC we have:

$$AC^2 = OA^2 + OC^2 \quad 2OC\bullet OH = 2R^2 \quad 2R\bullet OH = 2R(R \quad OH),$$

where OH equals $\overline{R^2 \quad \frac{c^2}{4}}$. Thus the required side c_1 will be

$$c_1 = \overline{2R \quad R \quad \overline{R^2 \quad \frac{c^2}{4}}}\ .$$

Thus, since the side of the square is $R\sqrt{2}$ and its perimeter $R \times 4\sqrt{2}$, the side of the octagon and its perimeter will be

$$R\sqrt{2-\sqrt{2}}, \quad R \times 8\sqrt{2-\sqrt{2}}.$$

The side and perimeter of the regular inscribed polygon with sixteen sides will be

$$R\sqrt{2-\sqrt{2+\sqrt{2}}}, \quad R \times 16\sqrt{2-\sqrt{2+\sqrt{2}}},$$

and so on.

180b. In order to get an upper estimate for the length of the circle, we need to calculate the perimeter of a circumscribed regular polygon, and we must therefore solve the following problem:

Problem. Knowing the side c of a regular polygon inscribed in a circle of radius R, calculate the side of the regular polygon with the same number of sides circumscribed about the same circle.

The required side c' is found immediately by noting that the two polygons are similar, and the ratio of their sides is the ratio of their apothems. Since the apothem of the circumscribed polygon is R, and that of the inscribed polygon $\sqrt{R^2 - \frac{c^2}{4}}$, the required side is given by the proportion

$$\frac{c'}{c} = \frac{R}{\sqrt{R^2 - \frac{c^2}{4}}}.$$

We have just learned how to calculate the sides of the inscribed polygons with large numbers of sides: the preceding proportion gives us the sides of the corresponding circumscribed polygons.

181. Knowing the side c of a regular polygon inscribed in a circle of radius R, we can also calculate the side c_1 and the apothem a_1 of the regular polygon with twice the number of sides inscribed in the same circle (which gives us the side of the circumscribed polygon without an additional square root) by the following method.

In Fig. 170, let C' be the point where the extension of radius OC intersects the circle. Triangle ACC' is a right triangle and gives us (123, Remark)

$$AC \cdot AC' = CC' \cdot AH = 2R \times \frac{c}{2} = Rc.$$

On the other hand,

$$AC^2 + AC'^2 = CC'^2 = 4R^2.$$

Multiplying the first equation by 2 and adding it to the second, we get:

$$AC^2 + AC'^2 + 2AC \cdot AC' = (AC + AC')^2 = 4R^2 + 2Rc.$$

Thus

$$AC + AC' = \sqrt{4R^2 + 2Rc} = 2\sqrt{R\left(R + \frac{c}{2}\right)}.$$

If we multiply the first equation by 2, then subtract it from the second, we have:

$$AC^2 + AC'^2 - 2AC \cdot AC' = (AC' - AC)^2 = 4R^2 - 2Rc.$$

Thus

$$AC' - AC = \sqrt{4R^2 - 2Rc} = 2\sqrt{R\left(R - \frac{c}{2}\right)}.$$

Adding and subtracting these equalities member by member, these two equations give us

$$AC = \sqrt{R\left(R + \frac{c}{2}\right)} - \sqrt{R\left(R - \frac{c}{2}\right)}; \quad AC' = \sqrt{R\left(R + \frac{c}{2}\right)} + \sqrt{R\left(R - \frac{c}{2}\right)},$$

which solves the problem, since AC is equal to the required chord c_1 and AC' is twice the apothem a_1.

We have thus learned how to calculate the chords of half of the two arcs intercepted by a given chord on a circle of given radius.

182. The isoperimetric method. We can present the preceding method in a slightly different form.

In effect, the problem consist in calculating the ratio of the perimeter p of an inscribed regular polygon to the radius r of the circumscribed circle, or to the apothem a, which is the radius of the inscribed circle, and to do this for polygons whose number of sides increases indefinitely. But it makes no difference whether or not these polygons are inscribed in the same circle, since the ratios $\frac{p}{r}$ and $\frac{p}{a}$ depend only on the number of sides of the polygon (163).

In the isoperimetric method we consider regular polygons whose number of sides doubles indefinitely, and which have the same perimeter. We must therefore solve the following problem:

Problem. Knowing the radius r and apothem a of a regular polygon, calculate the radius r' and apothem a' of a regular polygon with twice as many sides, isoperimetric to the first.

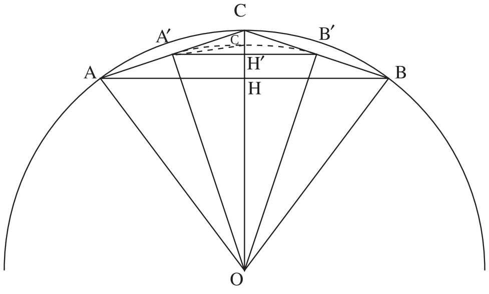

Figure 171

Let AB (Fig. 171) be a side of the regular polygon with n sides inscribed in a circle with radius $OA = r$. We drop perpendicular $OH = a$ to AB, and extend it to its intersection C with the circumscribed circle, which is also the midpoint of arc $\widehat{AB}$. We draw AC and BC, and let A', B' be the midpoints of these segments. Let $A'B'$ intersects OC in a point H'.

Segment $A'B'$ is the side of a regular polygon with $2n$ sides inscribed in the circle with radius OA'.

Indeed, since angle AOB intercepts an arc equal to the n^{th} part of the circle with radius OA, angle $A'OB'$ which is half of it (because $A'OC$ is half of AOC and

B OC half of BOC) will intercept an arc equal to the 2nth part of the circle with radius OA .

This polygon is isoperimetric to the first.

This is true because side A B joins the midpoints of AC, BC, and is therefore half of the original side AB, and because the new polygon has twice as many sides.

The required lengths will thus be r = OA , a = OH .

Now H is the midpoint of CH, so we have

$$OH \quad OH = OC \quad OH .$$

This can be written as

$$2OH = OC + OH,$$

or

$$OH = \frac{OC + OH}{2}.$$

In other words, OH is the arithmetic mean of OC and OH.

On the other hand, right triangle OA C gives

$$OA = \overline{OC \times OH} .$$

That is, OA is the geometric mean of OC and OH .

Thus we can calculate a by the formula

$$a = \frac{r + a}{2},$$

and r by the formula

$$r = \overline{ra} .$$

Repeating this operation of doubling, we obtain values of r and a for polygons with larger and larger numbers of sides. The ratios of these quantities to the common semi-perimeter of these polygons will give approximate values for $\frac{1}{}$, one less than the limit, the other greater, and both growing closer.

Suppose, to simplify the situation, that the common perimeter of the polygons is equal to two units of length, and take a square as the initial polygon. The apothem is half the side, or $\frac{1}{4}$, and the radius is equal to the side divided by $\overline{2}$, or $\frac{1}{2\ 2}$. Taking a = $\frac{1}{4}$, r = $\frac{1}{2\ 2}$ in the preceding formulas will give the values of a , r for the octagon, and so on.

But if we take[9] a = 0, r = $\frac{1}{2}$, our formulas yield precisely a = $\frac{1}{4}$, r = $\frac{1}{2\ 2}$. We then obtain the following proposition (a theorem of Schwab).

Theorem. If we form a sequence of numbers starting with 0 and $\frac{1}{2}$, and each successive term is alternately the arithmetic mean or the geometric mean of the preceding two terms, then the numbers in this sequence tend to $\frac{1}{}$.

183. Since the numbers a and r, consecutive terms of the preceding sequence, approach the limit $\frac{1}{}$ from below and from above respectively, the error committed in taking either for an approximate value of $\frac{1}{}$ is less than r a.

---

[9] These numbers correspond to the division of the circle into two equal parts. If the division points are A and B, diameter AB can be thought of as the side of a regular polygon with two sides, whose perimeter is 2AB. If this perimeter is 2, the radius must be $\frac{1}{2}$ and the apothem (the distance from the side to the center) is zero.

Also we have

$$r \quad a < \frac{r \quad a}{4}.$$

To prove this, we revisit Figure 171 and lay off on OC a length OC = OA = r . Segment C H can represent r a . The two angles C A H , C A C are equal, since on the circle OA they are measured by one half the equal arcs $\overset{\frown}{C\ B}$, $\overset{\frown}{A\ C}$ (one is an inscribed angle, the other is formed by a tangent and a secant). The angle bisector theorem (see 115) then shows that the ratio of H C to C C is equal to the ratio of H A to A C. Thus H C is less than half of H C, which is equal to a quarter of CH; that is, to $\frac{r \quad a}{4}$.

The first two terms in the Schwab sequence give r a = $\frac{1}{2}$. Thus, replacing $\frac{1}{}$ by the 2nth term in this sequence, we commit an error less than

$$\frac{1}{2 \times 4^n} = \frac{1}{2^{2n+1}}.$$

184. The Greek geometer Archimedes, who was the first to define and calculate the length of the circle, used the method of perimeters to find the value for

$$\frac{22}{7}$$

which is greater than by less than one hundredth.

Note that one can obtain only approximate values for , and never the exact value, because it can be proved that this number is irrational; that is, it is not an integer or a ratio of two integers.

The first decimals of and $\frac{1}{}$ are[10]

$$= 3.141592653\ldots, \qquad \frac{1}{} = 0.3183098\ldots.$$

We often use the value 3.1416, which is slightly too large, for .

The famous problem of the quadrature of the circle amounts (as we will see later) to constructing a segment equal to the length of a circle with given radius. It is impossible to solve this problem using only straightedge and compass. This impossibility, which does not necessarily follow[11] from the irrationality of , has also been proved.[12]

---

[10] These values have not been obtained by the methods just explained, but by incomparably faster ones borrowed from the differential calculus. One can easily remember these decimals, using the following verse: Que j aime á faire apprendre un nombre utile aux sages in which the number of letters of the words give the consecutive digits of . (This French mnemonic given above has various analogues in English; for example, May I have a large container of coffee? transl.)

The value $\frac{355}{113}$, greater than by less than one millionth, was given by Adrien Metius.

[11] For instance, the ratio of the diagonal of a square to its side is irrational, but one can easily construct the diagonal knowing the side.

[12] The irrationality of was proved by Lambert (1770). The impossibility of the quadrature of the circle is due to Lindemann, who proved it in 1882, by generalizing results of the great French mathematician Hermite.

CHAPTER II

Transversal

192. Theorem. If sides BC, CA, AB of a triangle are intersected by a line at a, b, c (Fig. 174) we have the following relation among the segments determined on the sides:

$$\frac{aB}{aC} \bullet \frac{bC}{bA} \bullet \frac{cA}{cB} = 1. \qquad (2)$$

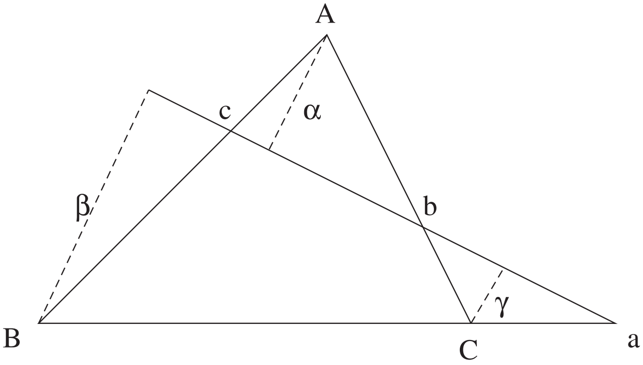

Figure 174

To prove this, we draw three segments parallel to an arbitrary direction through the vertices of the triangle , on which we choose the same positive sense, and extend them to intersect the transversal. Let , , be the distances from the vertices to the transversal, measured along these parallel lines. We have, in magnitude and sign,

$$\frac{aB}{aC} = \frac{}{},$$
$$\frac{bC}{bA} = \frac{}{},$$
$$\frac{cA}{cB} = \frac{}{}.$$

Multiplying, we obtain $\frac{aB}{aC} \bullet \frac{bC}{bA} \bullet \frac{cA}{cB} = \frac{}{} = 1.$[1] QED

---

[1] If the transversal is parallel to BC, the point a should be considered as thrown to infinity, and the ratio $\frac{aB}{aC}$ taken equal to one. The relation in the statement then reduces to $\frac{bA}{bC} = \frac{cA}{cB}$; that is, to the theorem of 114. If sides AB, AC of the triangle are parallel, and point A is at

193. Converse. Theorem of Menelaus.[2] If we choose three points a, b, c on sides BA, CA, AB of triangle ABC which satisfy the the relation

$$\frac{aB}{aC} \cdot \frac{bC}{bA} \cdot \frac{cA}{cB} = 1, \tag{2}$$

then these three points lie on a straight line.

This is true because line ab intersects side AB in a point c such that

$$\frac{aB}{aC} \cdot \frac{bC}{bA} \cdot \frac{c\,A}{c\,B} = 1.$$

Comparing this relation with relation (2), we see that

$$\frac{cA}{cB} = \frac{c\,A}{c\,B},$$

and therefore the points c and c coincide. QED

Remark. This theorem is actually equivalent to the one proved in 144. Indeed, we can find three lengths , , such that we have (in magnitude and sign):

$$\frac{aB}{aC} = \frac{}{}, \quad \frac{bC}{bA} = \frac{}{},$$

which, together with (2), imply

$$\frac{cA}{cB} = \frac{}{}.$$

Therefore, if we draw three homothetic figures in which A, B, C are three corresponding points, and , , three corresponding segments, then their centers of similarity are a, b, c.

194. This theorem is useful in showing that three points are collinear.

Example I. The midpoints of the three diagonals of a complete quadrilateral (see 145) lie on a straight line.

Consider the complete quadrilateral ABCDEF (Fig. 175), whose diagonals AB, CD, EF have midpoints L, M, N. Consider the triangle ACE formed by three sides of the quadrilateral, and let a, c, e be the midpoints of CE, EA, AC. Line ce is parallel to CE and passes through point L; line ea is parallel to EA and passes through M; line ac is parallel to AC and passes through N. To show that L, M, N are on a straight line it suffices to prove the relation

$$\frac{Lc}{Le} \cdot \frac{Me}{Ma} \cdot \frac{Na}{Nc} = 1.$$

Parallel lines Lec, BCE give

$$\frac{Lc}{Le} = \frac{BE}{BC},$$

and likewise we obtain

$$\frac{Me}{Ma} = \frac{DA}{DE}, \quad \frac{Na}{Nc} = \frac{FC}{FA}.$$

---

infinity, the expression $\frac{aB}{aC} \cdot \frac{bC}{bA} \cdot \frac{cA}{cB}$ can be rewritten in the form

$$\frac{aB}{aC} \cdot \frac{bC}{cB} \cdot \frac{cA}{bA},$$

and we can replace $\frac{cA}{bA}$ by 1. We then obtain the statement in 117.

[2] The name Theorem of Menelaus in more recent sources refers variously to this theorem, to its converse in 192, or to both statements taken together. transl.

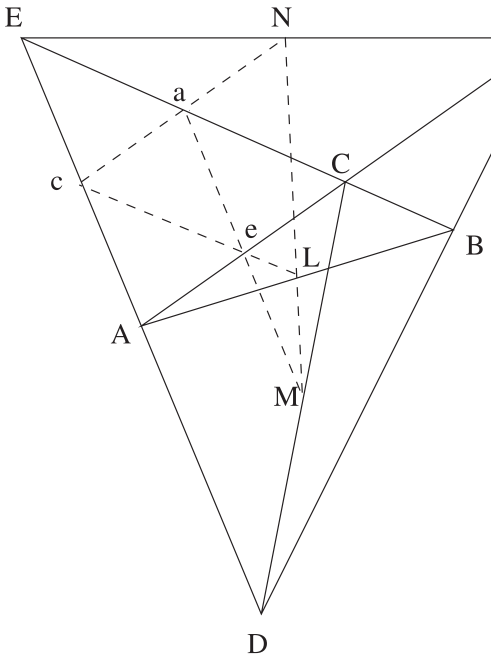

Figure 175

The product of the right hand sides

$$\frac{BE}{BC} \cdot \frac{DA}{DE} \cdot \frac{FC}{FA}$$

is indeed 1 since points B, D, F, taken on the sides of triangle ACE, lie on a straight line.

195. Example II. If the vertices of triangles abc, a b c are situated so that the lines aa , bb , cc , joining corresponding vertices, intersect in a point o, then the intersection points of the corresponding sides are on a straight line.

Consider the intersections of bc, b c , m of ca, c a , and n of ab, a b (Fig. 176). To show that these points are on a straight line, we must verify that

$$\frac{b}{c} \cdot \frac{mc}{ma} \cdot \frac{na}{nb} = 1.$$

Now triangle abc is cut by transversal b c , giving us

$$\frac{b}{c} \cdot \frac{c\,c}{c\,o} \cdot \frac{b\,o}{b\,b} = 1.$$

Likewise, triangles oca, oab cut, respectively, by mc a , na b give

$$\frac{ma}{mc} \cdot \frac{a\,a}{a\,o} \cdot \frac{c\,o}{c\,c} = 1, \quad \frac{na}{nb} \cdot \frac{b\,b}{b\,o} \cdot \frac{a\,o}{a\,a} = 1.$$

Multiplying these equalities, the factors a a, b b, c c, a o, b o, c o cancel out, and we obtain the required relation.

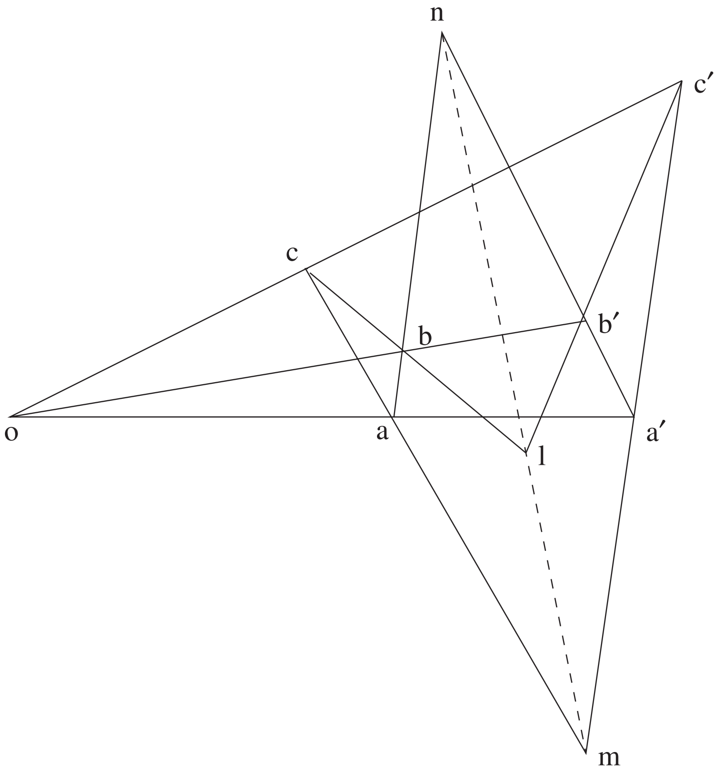

Figure 176

Two triangles, situated so that the lines joining the corresponding vertices are concurrent, are said to be homologic.[3]

196. Example III (Pascal s Theorem). In a hexagon inscribed in a circle, the intersection points of opposite sides are on a straight line.

Suppose the inscribed hexagon is ABCDEF (Fig. 177), and that opposite sides AB, DE intersect in L, BC, EF meet in M, and CD, FA meet in N. Points L, M, N are on sides JK, KI, IJ of the triangle IJK formed by the lines AB, CD, EF. They will be on a straight line if

$$\frac{LJ}{LK}\cdot\frac{MK}{MI}\cdot\frac{NI}{NJ}=1. \tag{3}$$

Cutting the triangle IJK by the remaining sides DE, BC, FA of the hexagon, we obtain

$$\frac{LJ}{LK}\cdot\frac{EK}{EI}\cdot\frac{DI}{DJ}=1,\quad \frac{MK}{MI}\cdot\frac{CI}{CJ}\cdot\frac{BJ}{BK}=1,\quad \frac{NI}{NJ}\cdot\frac{AJ}{AK}\cdot\frac{FK}{FI}=1.$$

We now multiply these relations, grouping the factors in the numerator and denominator appropriately, to obtain

$$\frac{LJ}{LK}\cdot\frac{MK}{MI}\cdot\frac{NI}{NJ}\cdot\frac{CI\cdot DI}{EI\cdot FI}\cdot\frac{AJ\cdot BJ}{CJ\cdot DJ}\cdot\frac{EK\cdot FK}{AK\cdot BK}=1.$$

---

[3] The more modern terminology for such triangles is perspective. transl.

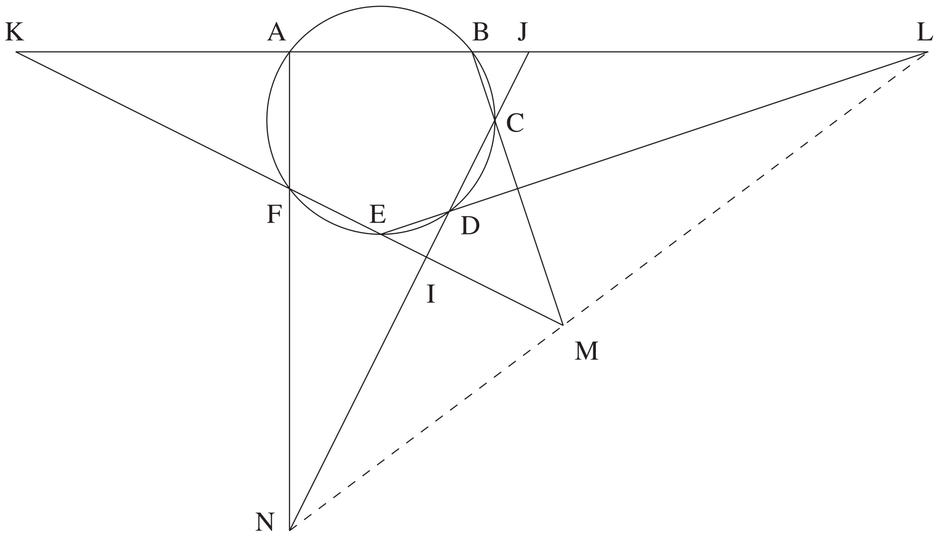

Figure 177

Each of the last three fractions is equal to one; for instance, the products $CI \cdot DI$ and $EI \cdot FI$ are both equal to the power of I with respect to the circle.

We conclude that (3) is true, and the theorem is proved.

Remark. The preceding proof remains valid if the pairs of points A, B; C, D; E, F are made to coincide, so that the sides of the triangle IJK become tangents to the circle. The theorem becomes the following statement: The tangents to the circumscribed circle at the vertices of a triangle intersect the corresponding sides in three collinear points.

197. Theorem. Through the vertices A, B, C of a triangle, we draw segments Aa, Bb, Cc concurrent at a point O, where a, b, c are on the corresponding sides BC, CA, AB. Then:

$$\frac{aB}{aC} \cdot \frac{bC}{bA} \cdot \frac{cA}{cB} = 1. \tag{4}$$

Indeed, triangle AaC (Fig. 178), cut by transversal BOb gives us[4]

$$\frac{Ba}{BC} \cdot \frac{bC}{bA} \cdot \frac{OA}{Oa} = 1;$$

triangle AaB, cut by transversal Cc gives

$$\frac{Ca}{CB} \cdot \frac{cB}{cA} \cdot \frac{OA}{Oa} = 1.$$

We divide these two equalities; the ratio $\frac{OA}{Oa}$ cancels out, and we obtain

$$\frac{aB}{aC} \cdot \frac{bC}{bA} \cdot \frac{cA}{cB} \cdot \frac{CB}{BC} = 1,$$

---

[4] This reasoning remains correct when point O is thrown to infinity; that is, when lines Aa, Bb, Cc are parallel. Indeed, we have seen that the theorem in 192 is true when a transversal is parallel to one of the sides of the triangle.

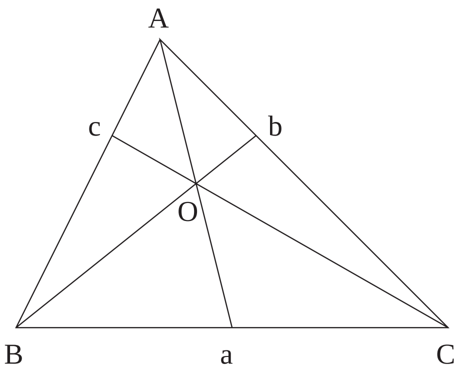

Figure 178

which is equivalent to relation (4), because $CB = BC$.

198. Converse (Theorem of Ceva[5]). If we take points a, b, c on the sides BC, CA, AB of a triangle, such that

$$\frac{aB}{aC} \cdot \frac{bC}{bA} \cdot \frac{cA}{cB} = 1,$$

then the lines Aa, Bb, Cc are concurrent.

Indeed, consider the intersection O of Aa and Bb. The line CO intersects AB in a point c such that

$$\frac{aB}{aC} \cdot \frac{bC}{bA} \cdot \frac{c\ A}{c\ B} = 1.$$

This, combined with the hypothesis, gives $\frac{cA}{cB} = \frac{c\ A}{c\ B}$, so that the points c, c coincide. QED

If the lines Aa, Bb were parallel, the line Cc would be parallel to them, and the three lines must be considered as concurrent at infinity.

This result is useful in proving that three lines are concurrent.

Example. The medians of a triangle are concurrent.

This is true because, if a, b, c denote the midpoints of the three sides of the triangle, each of the ratios $\frac{aB}{aC}, \frac{bC}{bA}, \frac{cA}{cB}$ is equal to 1.

One can prove analogously that the angle bisectors of a triangle are concurrent, etc.

Exercises

Exercise 223. Deduce the theorem of Menelaus, in the case for which the division points are external, from the fact that the three circles which determine the required point in Exercise 127 have the same intersection (see 189).

---

[5] The term Ceva s Theorem in recent sources, can refer to this theorem, to its converse, or to both statements taken together. See the footnote to 193. transl.

Exercise 224. A line intersects the sides of a triangle ABC in three points a, b, c. Take the point symmetric to each of these points with respect to the midpoint of the side which contains it. Show that the points a′, b′, c′ obtained in this way are also collinear.

If the points a, b, c are the projections of a point on the circumscribed circle onto the three sides (Exercise 72), the same is true for a′, b′, c′.

Exercise 225. One side OAB of an angle is fixed, as well as the two points A, B on it. The other side, OA′B′, turns around O, carrying with it two points A′, B′ at fixed distances from O. What is the locus of the intersection of AA′ and BB′?

Exercise 226. What does Ceva's theorem (198) give us when applied to the altitudes of a triangle?

Exercise 227. Three concurrent lines through the vertices of triangle ABC intersect the opposite sides in a, b, c. We take points a′, b′, c′ symmetric to these points with respect to the midpoints of the sides which contain them. Show that Aa′, Bb′, Cc′ are also concurrent.

Exercise 228. The lines joining the vertices of a triangle to the points of contact of the opposite sides with the inscribed circle are concurrent.

Exercise 229. Consider triangle A′B′C′ obtained (as in 53) from triangle ABC by drawing, through each vertex, a parallel to the opposite side. Let a, b, c be points on BC, CA, AB, respectively.

If Aa, Bb, Cc are concurrent, so are A′a, B′b, C′c.

Exercise 230. Suppose lines Aa, Bb, Cc are concurrent. The harmonic conjugates of a, b, c with respect to the sides BC, CA, AB, on which they are situated, are on a straight line.

Application: Aa, Bb, Cc are the angle bisectors.

Exercise 231. If lines Aa, Bb, Cc, bounded by the sides BC, CA, AB of triangle ABC are concurrent, and if circle abc intersects the sides again at a′, b′, c′, then lines Aa′, Bb′, Cc′ are also concurrent.

CHAPTER V

Inverse Figures

214. The inverse of a point M with respect to some point O (called the pole of inversion, Figures 186, 187) is a point M' on line OM such that:

$$OM \cdot OM' = k,$$

for some constant k, called the power of inversion. Point M' is also called the transform of M with respect to reciprical radius vectors.

As usual, the segment[1] OM' is taken in the direction of OM (Fig. 186) or in the opposite direction (Fig. 187) according as k is positive or negative.

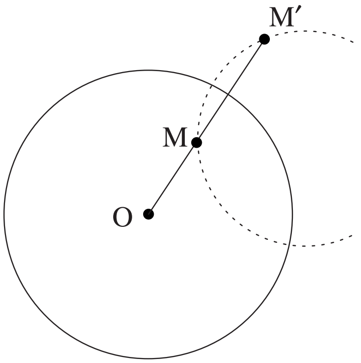

Figure 186

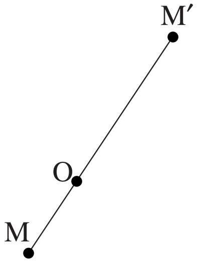

Figure 187

We see immediately that:

1°. Every point has an inverse except for the pole, whose inverse is thrown to infinity.

2°. If M' is the inverse of M then, reciprocally, M is the inverse of M'.

The figure F' formed by the inverses of all the points in a figure F is called the inverse figure of F.

215. Theorem. Two figures, both inverse to a third figure F with respect to the same pole O, are homothetic to each other.

Indeed, let M be a point of F; let M', M'_1 be the points which correspond to it under the two inversions with common pole O and with powers k, k_1. Division of the equation

$$OM \cdot OM' = k$$

---

[1] The segments OM, OM' are called radius vectors of the points M, M'.

by the equation

$$OM \cdot OM_1 = k$$

gives the equation $\frac{OM_1}{OM} = \frac{k_1}{k}$. QED

Thus the power of the inversion does not influence the shape of the figure obtained. This shape is changed only by changing the pole of inversion.

216. When the power of inversion k is positive, we can construct a circle centered at the pole of inversion and with radius $\sqrt{k}$ (Fig. 186). This circle, which clearly suffices to define the inversion, is called the circle of inversion. It is the locus of points which coincide with their inverses.

Two inverse points are conjugate with respect to the circle of inversion, and belong to the same diameter.

Every circle passing through two inverse points intersects the circle of inversion at a right angle (135). Conversely, if two points M, M′ have the property that every circle passing through them is orthogonal to a given circle, the two points are inverses with respect to this circle (135–137).

When two points are symmetric with respect to a line, any circle passing through these points cuts the line at right angles, since the line is a diameter of the circle. We are thus led to consider symmetry with respect to a line as a limiting case of inversion, the circle of inversion being replaced by the line and, consequently, the pole thrown to infinity.

217. Any two points A, B and their inverses A′, B′ are on the same circle (131b).

It follows (82) that the angle made by AB with the line OAA′ is equal to the angle made by A′B′ with OBB′, but in the opposite sense of rotation. Thus if we know the direction of AB and of the radius vectors, we also know the direction of A′B′.

This direction A′B′ is said to be antiparallel to AB with respect to angle AOB. It is parallel to the reflection of AB in the bisector of this angle since, in this reflection, the line OA becomes OB and angle BAO becomes an angle which is equal, but in the opposite sense.

218. **Problem.** Knowing the distance between two points A, B, and their radius vectors, find the distance between their inverses A′, B′.

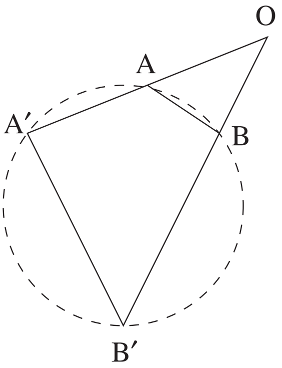

Figure 188

Similar triangles OAB, OB A (Fig. 188) give us $\frac{A\ B}{OA} = \frac{BA}{OB}$.

Solving this equation for A B , then replacing OA by $\frac{k}{OA}$, we obtain A B = BA $\cdot\, \frac{k}{OA \cdot OB}$.

Remark. This argument does not work when A, B, O are collinear, but the result is still true, even in magnitude and sign (if a positive direction has been chosen on the common radius vector). This is easily seen if we replace A B and AB by OB OA = $\frac{k}{OB}$ $\frac{k}{OA}$ and OA OB.

219. **Theorem.** The tangents at corresponding points of two inverse curves make equal angles, but in opposite senses, with the common radius vector of their points of contact.

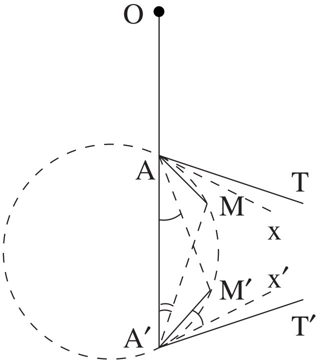

Figure 189

Let A (Fig. 189) be a point on curve C, and A the corresponding point on the inverse C . Consider a point M on C, close to A, and let M be its inverse. We draw tangents Ax, A x to the circle passing through A, A , M, M (217). When M approaches A as close as we like (and, consequently, M approaches A) angles AA M, A AM will tend to zero, and the same will be true for angles MAx, M A x , which are equal to the first two. Therefore, if the line AM tends to a limiting position AT, then Ax will tend to the same limiting position. Therefore line A x will have a limiting position A T which makes the same angle as AT with line OAA , but in the opposite sense. Since angle M A x tends to zero, A M will also tend to A T . QED

Corollary. The tangents at corresponding points of two inverse curves are symmetric with respect to the perpendicular bisector of their points of contact.

Remark. The preceding results are also obviously true if the inversion becomes a line reflection.

Theorem. Two curves intersect at the same angle as their inverses (or their symmetric curves), except for the sense of rotation.

Indeed, the angle formed by the tangents to the curves at their common point A, and the angle formed by the tangents to the inverse curves at the corresponding point A , are symmetric with respect to the perpendicular bisector of AA .

Corollary. If two curves are tangent, the same is true for their inverses.

220. Inverse of a line.

Theorem. The inverse figure of a line is a circle passing through the pole of inversion.

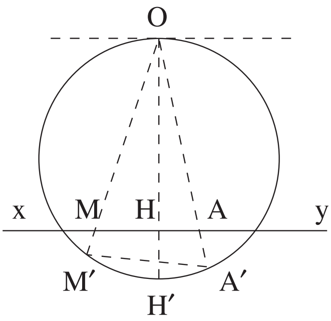

Figure 190

Let xy (Fig. 190) be a line whose inverse we seek, and let O be the pole of the inversion. Take any point A,[2] and let A' be its inverse. Next take a variable point M on xy and its inverse M'. The angle between $M'A'$ and OM' is equal to the angle between AM and OA, and in the opposite sense. Therefore this angle is constant as point M varies along the line, and the locus of M' is a circle passing through O and A. QED

In particular, we can choose, for point A, the projection H of O onto xy. Let H' be its inverse. Angle $OM'H'$ is therefore a right angle, and we see that the tangent at O of the inverse circle is parallel to the given line, and its diameter is $\frac{k}{\ }$, where k is the power of the inversion, and is the distance OH from the pole to the line.

Remark. The preceding statement is valid for lines which do not pass through the pole. A line passing through the pole is its own inverse.

Corollary. The inverse figure of a circle passing through the pole is a line; namely, the line perpendicular to the diameter of the pole at the inverse point of the point diametrically opposite to the pole.

221. The inverse of an arbitrary circle.

Theorem. The inverse of a circle not passing through the pole is a circle.

1 . First, if the power of inversion k is equal to the power p of the pole with respect to the given circle, this circle is its own inverse, as the intersection points of any secant from the pole are inverses of each other.

2 . If the power k is arbitrary (Fig. 191), the inverse figure will be a circle homothetic to the one considered above (215) with the pole as center of similarity and ratio of similarity $\frac{k}{p}$.

---

[2] i.e. on line xy. transl.

222. Conversely, two arbitrary circles C, C′ (Fig. 191) can be considered as inverses of each other in two different ways, since they are homothetic in two different ways. The pole of inversion is then a center of similarity, and the power of inversion is equal to the power of this pole with respect to the first circle, multiplied by the ratio of similarity.

These similarities are the only two which transform one of these circles into the other. Indeed, if they are inverse with respect to some pole S, the two circles must be homothetic with respect to S, since one of them is its own inverse with respect to this pole.

223. By the preceding argument, if a secant from a center of similarity S intersects C in M, N, and C′ in M′, N′, so that M′ corresponds to M and N′ corresponds to N under a homothecy beween the two circles, then M and N′ on the one hand, and M′ and N on the other, are pairs of inverse points.

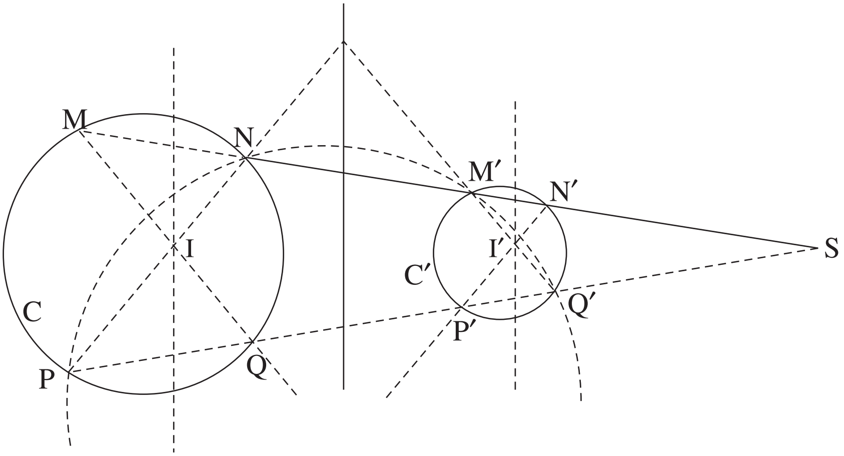

Figure 191

The points M and N′ are sometimes called antihomologous points.

The only pairs of points which are both homologous and antihomologous are the points of contact of the common tangents from point S.

The common points of two circles, if any exist, are their own anti-homologues.

The antihomologous chord of a chord given by two points in the first circle, is the chord in the second circle determined by the anti-homologues of the first two points.

224. Two pairs of antihomologous points lie on the same circle (217) and consequently two antihomologous chords intersect on the radical axis (139).

Moreover, two antihomologous chords intersect the polars of the center of similarity, with respect to their respective circles, in two corresponding points. This is true because the chord N′P′, antihomologous to MQ (Fig. 191), corresponds to NP, which intersects MQ in a point I situated on the polar of S with respect to circle C (211) and whose corresponding point I′ is the intersection of N′P′ with the polar of S with respect to C′.

This double property allows us to determine the anti-homologue of a given chord without involving the endpoints of the chord.

This applies, of course, to the tangents at antihomologous points, which are the limiting cases of the preceding chords.

Remark. If the two circles are identical (case 1 of 221), the two chords MQ, NP, joining two points to their inverses, intersect on the polar of the pole S of the inversion. From this point of view, this polar plays the role of the radical axis of the two identical circles, if they are considered as inverses of each other with respect to the point S.

225. If the two circles are congruent, the exterior center of similarity is thrown to infinity, and the corresponding homothecy reduces to a translation, while the corresponding inversion reduces to a line reflection; the properties of antihomologous points are the same as in the general case.

226. A line and a circle can also be regarded as inverse figures in two different ways. The poles of inversion will be (220) the endpoints of the diameter perpendicular to the line. The theory of antihomologous points leads us to consider these as centers of similarity of the line and the circle.

Of two antihomologous chords, one is on the given line, and therefore we can still say that these two chords intersect on the radical axis, in the sense of 158 (Construction 12, remark).

Finally, two lines are symmetric to each other in two different ways, the axes of symmetry being the bisectors of the angles formed by these lines. The antihomologous chords are the lines themselves, and therefore intersect in a fixed point.

227. When two circles are inverse to each other, every circle which passes through two antihomologous points is its own inverse, since the power of the pole with respect to is equal to the power of inversion. Such a circle must therefore intersect the two circles at the same angle and, if it is tangent to one, it must be tangent to the other.

Conversely, any circle which intersects two circles C, C at the same angle (Fig. 192) intersects them in two pairs of antihomologous points.

Indeed, let A, B; A , B be the four points of intersection, labeled so that the angles formed by circles C, at A, and of the circles C and at A (which are equal by hypothesis) are in opposite senses, and so that the same is true for B, B . If S is the intersection of AA and BB , and k is the power of S with respect to circle , then the inversion with pole S and power k does not change : it takes A onto A and B onto B . Thus this inversion transforms C into a circle which passes through A , B , and is tangent to C at A (by hypothesis, and 219); that is, this circle coincides with C (90).

This conclusion remains true if is tangent to C and C . To see this, it suffices to repeat the preceding argument while taking S to be the intersection of AA and BB , with A and A being the points of contact of , and B, B the second intersections of C, C with any circle passing through A, A (Fig. 192).

In this case, the proposition also follows from the theorem of 144, because the points of contact are centers of similarity, one for and C, the other for and C . Therefore they are collinear with a center S of similarity of C and C . We also see that the center of similarity is external if the points of contact are of the same kind[3], and internal otherwise.

---

[3] That is, both external or both internal.

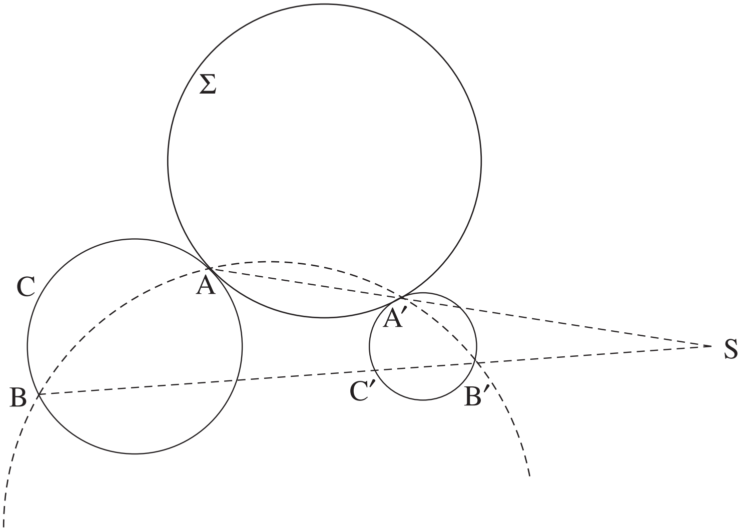

Figure 192

Of course, the arguments just presented remain valid when one or both of the circles C, C , or circle , are replaced by lines.

227b. If circle cuts circles C, C at right angles, we can consider any pair of the points of intersection, chosen arbitrarily, as antihomologous. Indeed, two right angles can always be considered equal and of opposite senses (by replacing, if necessary, one side by its extension). Thus, a circle which cuts C, C at right angles corresponds to itself in either of the two inversions which transform C into C .

228. If the inversion with pole S interchanges circles C and C and it has a circle of inversion , this circle cuts at right angles, since the power of point S with respect to is equal to the power of the inversion.

This property corresponds to the property of the bisectors of the angles formed by two lines. Indeed, these bisectors are the locus of the centers of circles tangent to the two lines, which amounts to saying that any one of these circles intersects one of these bisectors at right angles. Here we see that any circle , tangent to C and C , or, more generally, any circle which cuts C and C at equal angles, is orthogonal to circle , or to the analogous circle centered at the other center of similarity (if these circles exist).

The circle always exists if the circles C, C intersect: in this case it passes through their common points.

In general, when it exists, it has the same radical axis as C and C since these three circles have the same set of orthogonal circles (by the preceding section).

Exercises

Exercise 242. When two points are inverses with respect to a circle, the ratio of their distances to a variable point on the circle is constant.

Exercise 243. Show that Exercise 68, in the case where the given circle intersects the line in a point I, can be reduced to Exercise 65 by means of an inversion with pole I.

Exercise 244. Through a common point A of two circles C, C' we draw secants AMM', ANN', which intersect C in M, N and C' in M', N'. Circles AMN', ANM' intersect at A and at another point. Find the locus of this point as the two secants turn, independent of one another, about point A.

Exercise 245. The inverses of circles with a common radical axis are also circles with a common radical axis.

Exercise 246. Transform the definition of a circle by inversion (7) to obtain a new proof of the theorem of 116.

Exercise 247. When we take the inverse of a circle, what is the point whose image is the center of the transformed circle?

Exercise 248. Two given circles can always be transformed, by the same inversion, either into two parallel lines, or into two concentric circles.

Exercise 249. Given three points on a line, find a fourth point on the same line such that if we invert with respect to this point, the three given points divide the line into two equal parts.

Exercise 250. Two figures are inverse to each other with respect to an inversion S. We apply some inversion T to both figures. Show that the new figures obtained are again inverse to each other, and find the new pole of inversion. In particular, examine the case when the power of the inversion S is positive. (The new circle of inversion is obtained by applying the inversion T to the circle of inversion of S.)

Exercise 251. An inversion S is applied to a figure A to obtained a figure B, which is then transformed into a figure A' by an inversion S'. Assume that the powers of inversion are positive.

1°. Show that by applying an appropriate inversion T to A, A', we can transform these figures into congruent or homothetic figures, these two possibilities being mutually exclusive;[4]

2°. Show that we can find infinitely many pairs of inversions S_1, S_1', equivalent to S, S'; that is, such that consecutive application of S_1 and S_1' to the figure A yields figure A'. In particular, we can always replace the two given inversions by an inversion preceded or followed by a line symmetry, except in one case (the case where figures A, A' are similar);

3°. When are the figures obtained by applying T (of 1°) to A, A' images of each other under translation?

4°. What happens if we apply the operations S, S' several times in succession (that is, we apply S to transform A' into B', then apply S' to transform B' into A'', then apply S to transform A'' into B'', then apply S' to transform B'' into A''', etc.)? Can it happen that we eventually obtain the original figure A?

---

[4] Except in the case mentioned in 3°, which can be considered a common limiting case, since a translation can be viewed as a limiting case of a homothecy.

Exercise 252. We successively apply inversions S, S', S'', etc. (as in the preceding exercise). Show (limiting the discussion to the case of positive powers of inversion) that this sequence of operations can be replaced by a single inversion preceded or followed by one, two, or three line symmetries, unless the final figure and the original figure are similar (preceding exercise, 2°, and Exercise 94).

Exercise 253. In the preceding exercise, assume that an odd number of inversions S, S', S'', . . . has been applied. Find a point which returns to its original position.

Exercise 253b. In a given circle, inscribe a polygon whose sides pass through given points, or are parallel to given directions (preceding exercise).

Exercise 254. On a fixed tangent to a circle, with point of contact T, we draw variable segments TM, TN whose product is constant. Let T' be the point on the give circle which is diametrically opposite T.

1°. Show that the line joining the second intersections of $T'M$, $T'N$ with the circle passes through a fixed point;

2°. Same problem for the line joining the points of contact of the second tangents from M, N (reduce this to the preceding case).

3°. Find the locus of the intersection of these two tangents.

Exercise 255. Given a point O on the plane of a circle, we draw a variable secant which intersects the circle in M, N. The circles with diameters OM, ON intersect the given circle again in M', N'. Find the locus of the intersection of MN', $M'N$ as the secant turns about point O.

Exercise 256. When a variable circle intersects two fixed circles at a constant angle, it also cuts any fixed circle having the same radical axis as the first two at a constant angle.

Exercise 257. On two segments AB, CD on the same line, we draw arcs of circles with the same central angle V. As the angle V varies, find:

1°. the locus of the midpoint of the common chord of the two circles of which these arcs are a part;

2°. the locus of the intersection of these circles; in other words, the locus of points at which the given segments subtend equal or supplementary angles. (Use Exercise 219b.)

CHAPTER VI

The Problem of Tangent Circles

229. **Problem.** Draw a circle passing through two given points, and tangent to a given line or a given circle.

We have already solved this problem (159). Inversion allows us to give another solution. Let us transform the figure by an inversion with its pole at one of the given points. The required circle becomes a line passing through a known point and tangent to a known circle (the inverses of the second point and of the given circle).

230. **Problem.** Draw a circle passing through a given point and tangent to two given lines or circles.

First method. The required circle corresponds to itself in one of two inversions (or line symmetries) which transform one of the lines into the other. Thus, in addition to the given point, we know a second point; namely the point which is inverse or symmetric to the first. We are thus led to the preceding problem. There can be four solutions, since the preceding problem has two.

Second method. Invert the given figure, with the given point as pole. We are led to the construction of the common tangents to two circles.

231. **Problem.** Draw a circle tangent to three given circles.

This can be reduced to the preceding problem.

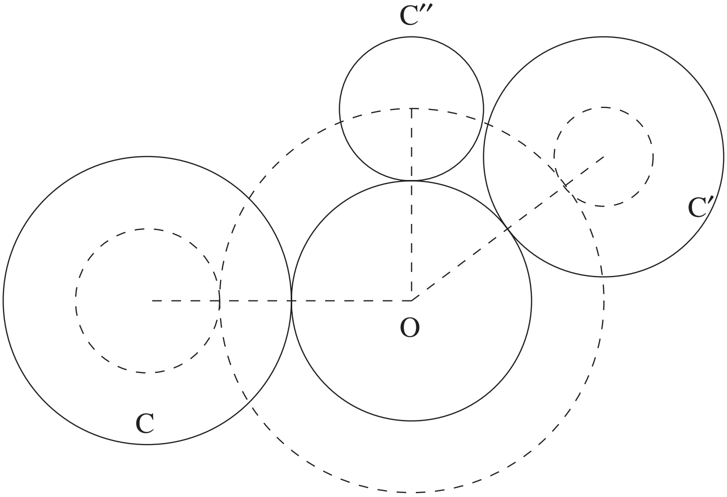

Figure 193

Indeed, consider, the given circles C, C , C (Fig. 193) with radii r, r , r , and a circle with center O and radius R, which, let us say, is externally tangent to the three circles. Then a circle with center O and radius R + r passes through the center of C , and is tangent to the circles concentric to C, C with radii equal to the difference between r and the radii r, r , respectively.

The cases where the required circle is tangent internally to one or more of the given circles are treated analogously, except that certain differences of radii are replaced by sums.

232. We can also solve the same problem using an entirely different method (due to Gergonne).

Let A, B, C be the given circles. We first look for a circle (Fig. 194) which is tangent in the same way to the three given circles, at points a, b, c.

If such a circle exists, there must necessarily be a second[1] circle . Indeed, the radical center I of the three circles has same power with respect to these circles. The inversion with I as a pole and this common power as the power of inversion will not change the given circles, and will transform into a circle tangent to A, B, C at points a , b , c which are the inverses of a, b, c. The contacts will be of the same type; that is, all of the same type as for or the opposite type, according as whether I is an external or internal center of similarity for the circles and .

We will prove that the radical axis xy of the circles , is precisely the axis of direct similarity (145) of the given circles. To see this, consider the intersection S of the lines ab, a b . This point is on the radical axis of , , because the points a, a and b, b are inverse pairs with respect to point I. This point S is the center of direct similarity for the circles A, B (227). In the same way, we can show that the radical axis xy passes through the other two centers of direct similarity of the given circles.

Having established this, we draw the common tangents of A and , which pass through a, a . The point where these tangents intersect will be on xy, because points a, a are inverse with respect to I. This point will be the pole of aa with respect to circle A.

Thus the chord aa passes through the pole p of the direct axis of similarity with respect to the circle A.

We are thus led to the following construction:

Determine the radical center I and the axis of direct similarity xy of the given circles. Join I to the poles p, q, r of xy with respect to these circles. The lines obtained in this way intersect the corresponding circles in the required points a, a ; b, b ; c, c .

233. It remains to prove that this construction will indeed provide circles satisfying the conditions of the problem.

To do this, we will show that the points a, b, c, a , b , c obtained above are antihomologous in pairs in the given circles.

Let us look for the chord in circle B which is antihomolgous to chord aa in circle A. This chord is determined (224) by the following two conditions:

1 . the two chords intersect on the radical axis of the two circles;

---

[1] Circle is different from . Indeed, unless the line Ia is tangent to A, point a is different from a. Likewise, Ib would be tangent to B, and Ic to C. But if a, b, c were chosen this way, the circle abc would be orthogonal, rather than tangent, to A, B, C.

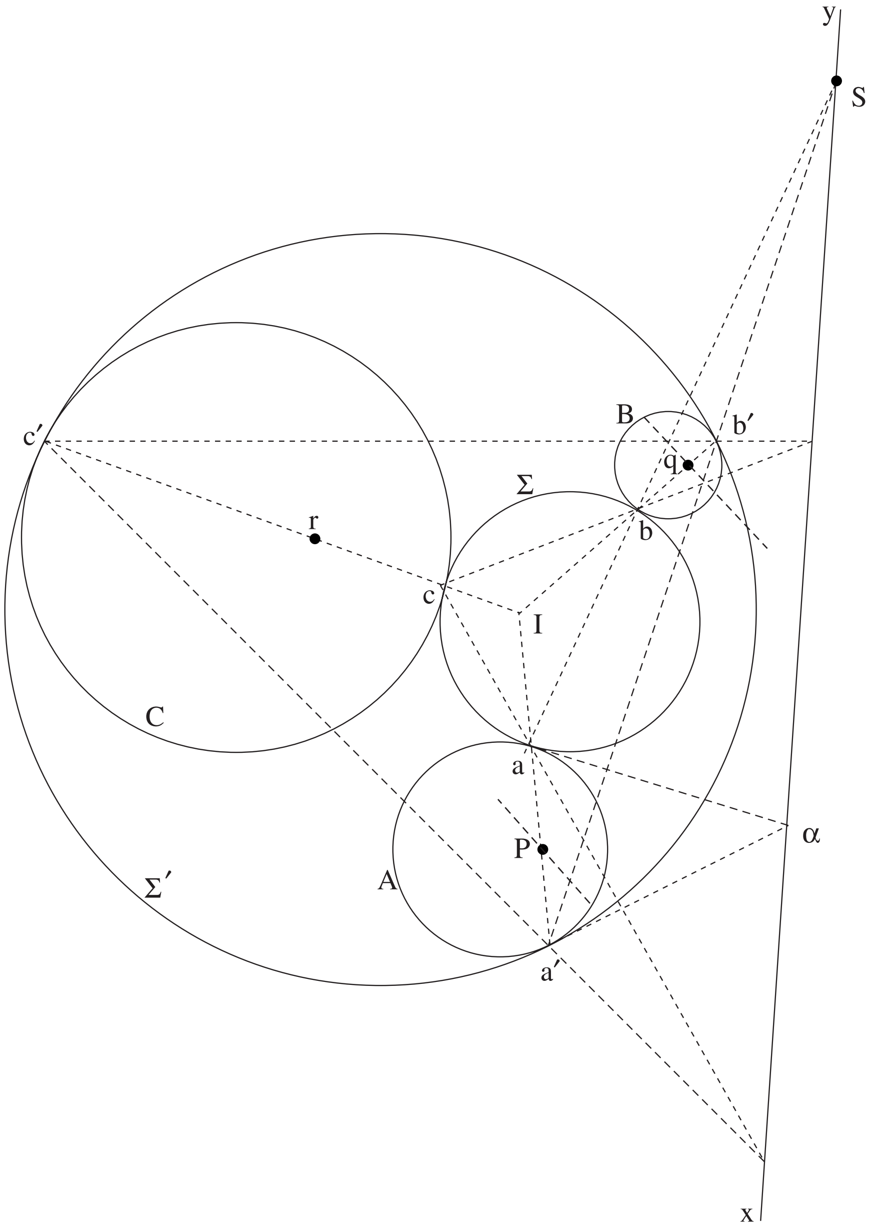

Figure 194

2 . the points where they meet the polars of S with respect to the two circles correspond to each other in the homothecy with center S taking one circle onto the other.

Now condition 1 is satisfied by aa and bb since their intersection I in fact belongs to the radical axis of A and B. Condition 2 is also satisfied. Indeed, points p, q are the poles of xy with respect to circles A, B, so they lie on the polars of S with respect to these circles. And these points correspond to each other in the homothecy with center S which brings circle A onto circle B, since line xy corresponds to itself, and so its poles in the two circles correspond to each other. The chord antihomologous to aa is therefore bb. In the same way, we can show that chords cc, aa are antihomolgous in circles C, A, and chords cc, bb are antihomoogous in circles C, B.

We will denote by b, c the two antihomologous points for a (without having yet proved that these two points are antihomologous); then b, c will be the antihomologues points for a. Let us draw a circle through a, b, c and a circle through a, b, c.

These two circles are inverse to each other with respect to point I, since the the pairs a, a; b, b; c, c are inverse with respect to this point. The circle inverse to that of abc is therefore a b c.

The radical axis of these circles is xy because this radical axis must pass through the intersection of ab, a b, and through the intersection of ac, a c.

Now let $_1$ be the intersection of the tangents to circle A at a, a. This point is on xy, since aa passes through point p; it is also on the perpendicular bisector of aa.

But the point , where the tangents at a, a to , intersect, is also on xy, because this line is the radical axis of , ; it is also on the perpendicular bisector of aa because the tangents a, a, to circles and respectively, are equal.[2]

Therefore points and $_1$ coincide, and the circles , are tangent to A at a, a. They are likewise tangent to B and C at b, b; c, c (227).

234. We have sought a circle tangent to A, B, C with contacts of the same kind. We would find circles which have contacts of different kinds with the circles A, B, C by replacing the direct axis of similarity with an inverse axis of similarity in the preceding reasoning.

As there are four axes of similarity, the problem of tangent circles can have eight solutions. However, some or all of these solutions may be missing: this will happen, for instance, if line Ip does not intersect circle A. We can see that if the power of the point I with respect to the three circles is negative, and therefore the point I is interior to the circles, all eight solutions exist. These eight solutions also exist if the three circles are exterior to each other, as can easily be seen solving the problem by the method of 231.

235. Gergonne's solution can also be applied when two of the given circles are replaced by points or lines. This can be seen by repeating the reasoning of 232 using these new conditions. However, the construction only yields the points of contact with the circles. In particular, it does not yield any result if all circles are replaced by points or lines.

236. Gergonne's solution fails to apply in certain special cases. Indeed, if the three centers are collinear, the radical center and the three poles of each axis of similarity are thrown to infinity in the direction perpendicular to this axis. This position can be avoided by first applying an inversion to the figure.

Conversely, three circles can, in general, be transformed by an inversion into three circles with collinear centers. For this to be possible, it is sufficient that the common power of the radical center be positive and consequently that there exist a circle cutting the three given circles at right angles. If we take any point at all on this circle as the pole of inversion, the given circles are transformed into three circles which are intersected at right angles by the same line, and therefore their centers will be on that line.

---

[2] The original text here refers to the tangents $_1$a, $_1$a . Since the points and $_1$ in fact coincide, this statement is correct, but the passage seems clearer if we refer to the point here as . transl.

The inconvenience which we just noted would therefore disappear if we could formulate a solution in terms of properties which do not change under an inversion, such as the tangency of two circles, the angle between them, etc. One can in fact modify Gergonne's solution in this way.[3]

Exercises

Exercise 258. Construct a circle passing through two points and cutting a given circle at a given angle.

Exercise 259. Construct a circle orthogonal to two given circles and tangent to a third given circle. More generally, construct a circle orthogonal to two given circles and cutting a third given circle at a given angle. (See Exercise 248.)

Exercise 260. Through two points A, B we draw two circles tangent to the same circle C, and a third one which is orthogonal to C. Show that this last circle divides the angle made by the other two into equal parts, and that its center is the intersection of their common tangents (see 229).

Exercise 261. Through a point A we draw two tangent circles (with contacts of the same kind) to two given circles, and a third one which is orthogonal to them. Show that this last circle passes through the second common point B of the first two, and possesses the properties indicated in the preceding exercise.

Exercise 262. Two tangent circles are drawn through a point A as in the preceding exercise. Let P, Q be their points of contact with the first given circle, and P', Q' the points of contact with the second.

1°. The circles APQ, $AP'Q'$ are tangent. They are orthogonal to the third circle of the preceding problem;

2°. The circles APQ, BPQ (where B is the second common point of the circles APP', AQQ', as in the preceding exercise) are inverse to each other with respect to the first of the given circles; the circles $AP'Q'$, $BP'Q'$ are inverse with respect to the second.

3°. What happens to these statements when the given circles are replaced by lines? Show that in this case the four circles APQ, $AP'Q'$, BPQ, $BP'Q'$ are equal.

Exercise 263. Draw a circle passing through a given point and tangent to two given lines by first drawing an arbitrary circle C tangent to the two lines, then noting that the required circle must be homothetic to C with respect to the intersection point O of the lines.

Exercise 264. Use an analogous method to construct a circle tangent to two given lines and to a given circle. (The line joining O to the point of contact cuts circle C and the given circle at equal angles.)

---

[3] See Note C at the end of this volume.

Exercise 265. The same problem, but the two lines are replaced by two concentric circles. (Use a circle concentric to the given circles, and passing the point of contact of the required circle with the third given circle.)

Exercise 266. Two variable tangent circles are each tangent to two fixed circles. Find the locus of their point of contact. (The first method of 230 shows when two circles tangent to two given circles can have two identical intersection points.)

Exercise 267. Pairs of the centers of the eight circles tangent to two given circles are on the perpendiculars dropped from the radical center to the four axes of similarity.

Exercise 268. Through a point inside an angle, draw a transversal forming a triangle of minimum perimeter with the sides of the angle (not extended past the vertex). (Use the indirect method (Exercise 174) and Exercise 90.)

CHAPTER VII

Properties of Cyclic Quadilaterals. Peaucellier's Inverter

237. **Ptolemy's Theorem.** The product of the diagonals of a cyclic quadrilateral is equal to the sum of the products of opposite sides.

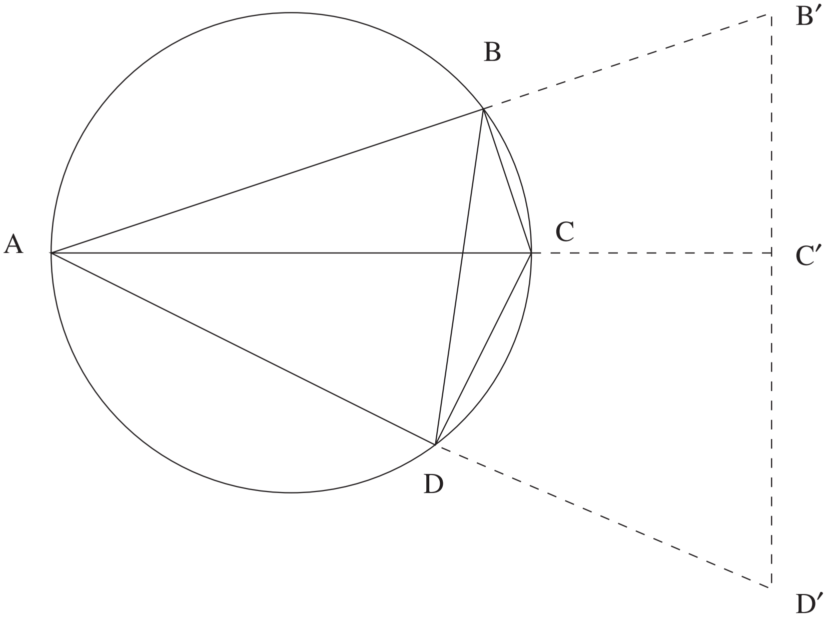

Figure 195

Suppose quadrilateral ABCD (Fig. 195) is inscribed in a circle. We transform the figure by an inversion with its center at point A. Circle ABCD is transformed into a line which passes through the inverses B′, C′, D′ of B, C, D. If C is the vertex of the given quadrilateral opposite to A, the points B, D will be on different sides of the line AC, and therefore so will points B′, D′. Thus point C′ is between B′ and D′, and we have (in absolute value)

$$B'D' = B'C' + C'D'.$$

But if k is the power of inversion, we have (218):

$$B'D' = DB \cdot \frac{k}{AB \cdot AD}, \quad B'C' = CB \cdot \frac{k}{AB \cdot AC}, \quad C'D' = DC \cdot \frac{k}{AC \cdot AD}.$$

Substituting these values into the preceding equality, then multiplying by $AB \cdot AC \cdot AD$, and dividing by k, we obtain the stated relation:

$$AC \cdot BD = AD \cdot BC + AB \cdot CD.$$

237b. The preceding property actually characterizes cyclic quadrilaterals. This is the result of the following theorem:

Theorem. If a quadrilateral is not cyclic, then the product of the diagonals is smaller than the sum of the products of opposite sides (and greater than their difference).

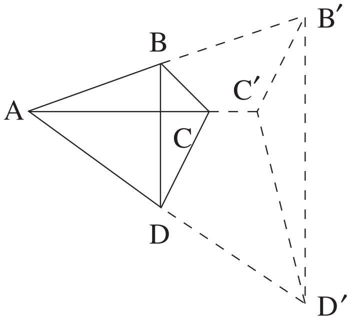

Figure 195b

Suppose $ABCD$ (Fig. 195b) is a quadrilateral which is not cyclic. If we repeat the preceding construction, points B', C', D' are no longer collinear, and they will form a triangle.

The values found in the previous section for $C'D'$, $D'B'$, $B'C'$ are proportional to the products $DC \cdot AB$, $BD \cdot AC$, $CB \cdot AD$. Therefore any of these products is less than the sum of the other two.[1]

238. The relation in Ptolemy's theorem is still true, and is proved in the same way, when the four points A, B, C, D are situated in this order on a straight line rather than a circle (Fig. 196). Thus, if four points are collinear, the product of the overlapping segments they form is equal to the sum of the products of the non-overlapping segments.

Figure 196

Taking signs into account, this relation can be written as

$$AB \cdot CD + AC \cdot DB + AD \cdot BC = 0.$$

---

[1] Hadamard's text does not mention this directly, but this observation also proves the assertion made about the difference between the products of opposite sides. transl.

This is the result of repeating the argument of 237: the relationships we used are, in fact, true in magnitude and in sign (218, Remark).

239. Problem. Knowing the chords AB, AC (Fig. 197) of two arcs in a circle of radius R, find the chord of the sum or difference of the two arcs.

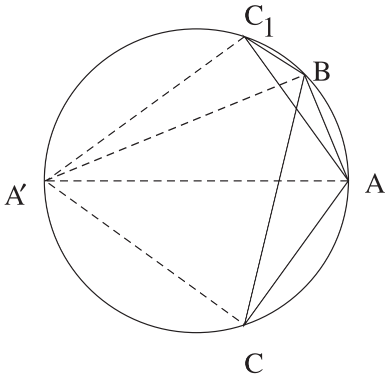

Figure 197

This is the problem we had to solve in 174 in order to calculate the sides of the various regular pentadecagons.

1°. Assume that arcs $\overset{\frown}{AB}$, $\overset{\frown}{AC}$ are described in contrary senses, so that arc $\overset{\frown}{BC}$ is their sum. If we draw diameter AA', we have:

$$AA' = 2R, \quad A'B = \sqrt{4R^2 - AB^2}, \quad A'C = \sqrt{4R^2 - AC^2}.$$

The cyclic quadrilateral $ABA'C$ gives

$$BC \cdot AA' = AB \cdot A'C + AC \cdot A'B,$$

a relation in which every quantity is known, except BC, and which gives us:

$$BC = \frac{AB\sqrt{4R^2 - AC^2} + AC\sqrt{4R^2 - AB^2}}{2R}.$$

2°. Assume that the arcs $\overset{\frown}{AB}$, $\overset{\frown}{AC_1}$ are described in the same sense, so that arc $\overset{\frown}{BC_1}$ is their difference. The cyclic quadrilateral $AA'BC_1$ now gives us:

$$A'B \cdot AC_1 = AB \cdot A'C_1 + AA' \cdot BC_1$$

so that

$$BC_1 = \frac{A'B \cdot AC_1 - AB \cdot A'C_1}{AA'} = \frac{AC_1\sqrt{4R^2 - AB^2} - AB\sqrt{4R^2 - AC_1^2}}{2R}.$$

240. Theorem. The ratio of the diagonals of a cyclic quadrilateral is equal to the ratio of the sums of the products of the sides which meet at their endpoints.

Suppose the diagonals of cyclic quadrilateral $ABCD$ (Fig. 128) intersect at O. Triangles OAD, OBC are similar (131), and give us:

$$\frac{OA}{OB} = \frac{AD}{BC} = \frac{OD}{OC},$$

which can be rewritten as

$$\frac{OA}{AB \cdot AD} = \frac{OB}{AB \cdot BC}, \qquad \frac{OC}{BC \cdot CD} = \frac{OD}{AD \cdot CD}.$$

Likewise, the similar triangles OAB, OCD yield

$$\frac{OA}{OD} = \frac{AB}{CD}, \quad \text{or} \quad \frac{OA}{AB \cdot AD} = \frac{OD}{AD \cdot CD}.$$

Thus the four ratios

$$\frac{OA}{AB \cdot AD}, \quad \frac{OB}{AB \cdot BC}, \quad \frac{OC}{BC \cdot CD}, \quad \frac{OD}{CD \cdot DA}$$

are equal. Adding the numerators and denominators of the first and third, and of the second and fourth, we obtain the desired relation

$$\frac{AC}{AB \cdot AD + BC \cdot CD} = \frac{BD}{AB \cdot BC + CD \cdot AD}.$$

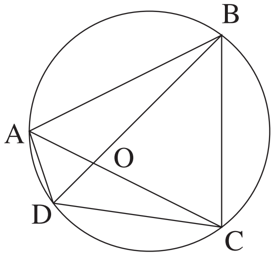

Figure 198

Another proof. Let a = AB, b = BC, c = CD, d = DA be the four sides of the quadrilateral. Permuting these sides in all possible ways, we obtain other quadrilaterals inscribed in the same circle, because the sum of the arcs corresponding to these four chords will always be the whole circle. Clearly, we can always take a to be the first side, so we have the six possible permutations

abcd, adcb,
acdb, abdc,
adbc, acbd.

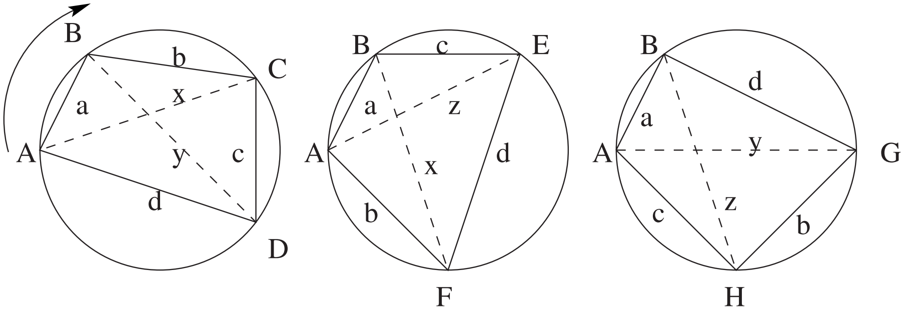

Figure 198b

However, the permutations in the same row give the same quadrilateral: for example, in quadrilateral $ABCD$ (Fig. 198b) the order of the sides is a, b, c, d if we read them in the order indicated by the arrow, and a, d, c, b if we read in the opposite direction. The remaining three permutations are $abcd$, $acdb$, $adbc$ which correspond to quadrilaterals $ABCD$, $ABEF$, $ABGH$ (Fig. 198b). Arc $\overset{\frown}{BF}$ is equal to $\overset{\frown}{AC}$, since it is the sum of equal arcs. Likewise, arc $\overset{\frown}{BH}$ is equal to $\overset{\frown}{AE}$ and $\overset{\frown}{BD}$ to $\overset{\frown}{AG}$. The three quadrilaterals have only three distinct diagonals: $AC = BF = x$, $BD = AG = y$, $AE = BH = z$, and applying Ptolemy's theorem to quadrilaterals $ABEF$, $ABGH$ gives

$$xz = ad + bc, \quad yz = ab + cd,$$

which gives us, by division, the required ratios.

240b. **Problem.** Calculate the diagonals x, y of a cyclic quadrilateral with sides a, b, c, d.

We know the product and the ratio of the diagonals:

$$xy = ac + bd, \quad \frac{x}{y} = \frac{ad + bc}{ab + cd}.$$

Multiplication yields

$$x^2 = \frac{(ac + bd)(ad + bc)}{ab + cd},$$

and we can find y^2 similarly.[2]

Problem. Calculate the radius of the circumscribed circle for a cyclic quadrilateral with sides a, b, c, d.

In triangle ABD (Figures 195 or 198), the radius R of the circumscribed circle is given by the formula (130, 130b):

$$R^2 = \frac{a^2 d^2 \cdot BD^2}{[(a + d)^2 - BD^2][BD^2 - (a - d)^2]}.$$

Replacing $BD = y$ by the value found above we obtain

$$(a + d)^2 - BD^2 = \frac{(a + d)^2(ad + bc) - (ac + bd)(ab + cd)}{ad + bc} = \frac{ad[(a + d)^2 - (b - c)^2]}{ad + bc}$$
$$= \frac{ad(a + d + b - c)(a + d + c - b)}{ad + bc};$$
$$BD^2 - (a - d)^2 = \frac{ad(b + c + a - d)(b + c + d - a)}{ad + bc}.$$

Thus we find

$$R^2 = \frac{(ac + bd)(ab + cd)(ad + bc)}{(b + c + d - a)(c + d + a - b)(d + b + a - c)(b + a + c - d)},$$

an expression independent of the order of the sides, which is consistent with our earlier remarks (240). Denoting by p the semi-perimeter (so that $2p = a + b + c + d$), we can rewrite the formula as follows:

$$R^2 = \frac{(ac + bd)(ab + cd)(ad + bc)}{16(p - a)(p - b)(p - c)(p - d)}.$$

---

[2] That is, by dividing. — transl.

241. Peaucellier's inversion cell.

Theorem. Consider a rhombus $MPM'Q$ and a point O such that $OP = OQ$ (Fig. 199). Assume that the rhombus is articulated (46b), the (equal) lengths OP, OQ held constant, and the point O remains fixed. Then the points M and M' move along two figures inverse to each other.

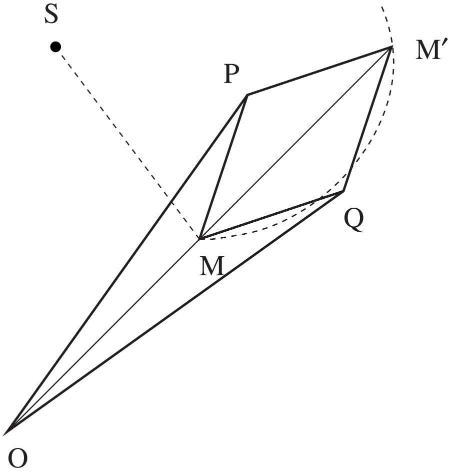

Figure 199

Indeed, points M, M', O are equidistant from P, Q, and they are therefore on the same line; namely, the perpendicular bisector of PQ. Let us draw a circle with center P and passing through M and M'. The power $OM \cdot OM'$ of O with respect to this circle is then equal to $OP^2 - PM^2$, and it therefore remains constant. QED

This theorem allows one to solve a problem of theoretical, if not practical, importance.

The apparatus used to draw circles, the compass, is accurate by definition: the two points will remain at a constant distance provided there is sufficient friction at the hinge of the compass.

On the other hand, the correctness of a ruler depends on its edge having the form of a straight line. This can be realized only by approximation, which is more or less exact depending on the care with which the instrument is manufactured.

Can one draw a straight line without having such a line in advance, using only properties of figures we can be sure of?

This is precisely what the apparatus described in the preceding result, due to Peaucellier, allows us to do. Indeed, assume that OP, OQ, PM, PM', QM, QM' are rigid rods[3] attached to each other, and the point O is fixed. Then M, M' must be inverses of each other with respect to point O. Let us make point M describe a circle, by attaching it to a fixed point S using a seventh rod (Fig. 199). If this circle passes through point O (that is, if $SM = SO$), point M' will describe a straight line.

---

[3] In Figure 199, we have represented OP, OQ, ... by straight lines, but it is not necessary that they should have this form. It is only necessary that the points O and P, for instance, should be kept at a constant distance, no matter how this is done.

241b. **Hart's inversion cell.** Let ABCD be a anti-parallelogram (46b, Remark II; Fig. 199b) formed by the diagonals and the non-parallel sides of an isosceles trapezoid. Let O, M, M′ be the three points where sides AB, AD, BC intersect a line parallel to the bases of the trapezoid. If the anti-parallelogram is articulated while the common length a of sides AB, CD remains constant, as well as the common length b of BC and AD, and while points O, M, M′ remain attached to the corresponding sides (that is, the lengths AO, AM, BM′ remain constant in magnitude and sense) and finally, if the point O remains fixed, then the points M and M′ move along two figures inverse to each other with respect to the pole O.

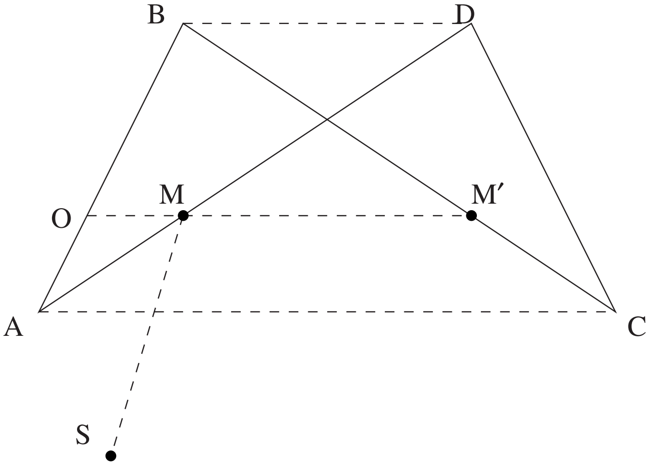

Figure 199b

Proof. We know (46b) that the quadrilateral will remain an anti-parallelogram.

On the other hand, the lines OM, OM′, which we assumed were parallel to the bases of the trapezoid in the initial position of the figure, will remain so, because this parallelism is characterized by the proportions

$$\frac{AM}{AD} = \frac{AO}{AB}, \quad \frac{BM'}{BC} = \frac{BO}{BA},$$

which, by hypothesis, do not change.

In particular, we see that points O, M, M′ remain collinear.

Having seen this, assume for the moment that not only O, but the entire side AB remains fixed. Then points M, M′ will move along circles with centers A, B, and radii AM, BM′ = M′D, respectively.

Since the ratio of these radii is equal to the ratio of the distances OA, OB, point O is one of the centers of similarity for the two circles. Since the radii with endpoints M, M′ are not parallel, these points will be (223) antihomologous, and therefore inverse. The product OM • OM′ therefore remains constant as the anti-parallelogram is deformed, and while points A, B remain fixed.

Since this product is not changed by a rigid rotation around O, the theorem is proved. QED

Corollary. If point M is attached to a fixed point S by a rigid rod of length equal to SO, point M will move along a straight line.

Remark. The product of the bases AC, BD remains constant as the figure is deformed. Indeed, the ratio of BD to OM is constant and equal to $\frac{1}{h} = \frac{AB}{AO}$, and the ratio of AC to OM is equal to $\frac{1}{h} = \frac{BA}{BO}$.

Exercises

Exercise 269. The converse of Exercise 99: If a point M in the plane of an equilateral triangle ABC is such that $MA = MB + MC$, this point is on the circumscribed circle. Otherwise, $MA < MB + MC$.

Exercise 270. If we had started the proof in 237 and 238 with a vertex other than A, we would have obtained a triangle analogous to $B\ C\ D$.

1 . Show that all of these triangles are similar;

2 . Calculate the angles of any one of these triangles, knowing the angles made by the sides and diagonals of the given quadrilateral;

3 . Show that we would obtain triangles similar to the preceding ones by dropping perpendiculars from one of the four vertices A, B, C, D to the sides of the triangle formed by the other three; or by joining B and D to the third vertex of a triangle similar to ABC, with the same sense of rotation, in which the side corresponding to AC is AD;

4 . Show that the shape of the similar triangles considered above is preserved, except for the sense of rotation, if points A, B, C, D are all subject to the same inversion; in other words, show that if we operate on these transformed points as we have operated in 1 , 2 or 3 on the points A, B, C, D, we will obtain triangles similar to the first ones;

5 . Conversely, if two quadrilaterals $ABCD$, $A_1B_1C_1D_1$ are such that the triangles resulting from the preceding constructions applied to each of them are similar, show that there exists[4] an inversion which transforms A, B, C, D into four points forming a quadrilateral congruent to $A_1B_1C_1D_1$. Determine this inversion.

Exercise 270b. Find an inversion which transforms three given points into three other points forming a triangle congruent to a given triangle.

Exercise 271. Peaucellier s inversion cell would still function if the articulated quadrilateral $MPM\ Q$ were not a rhombus, but if $MP = M\ P$, $MQ = M\ Q$, and $OP^2 \quad OQ^2 = MP^2 \quad MQ^2$.

Exercise 271b. In Hart s inversion cell, calculate the power of the inversion knowing the sides a, b of the anti-parallelogram, as well as the ratios h and $h \ = 1 \quad h$. Calculate the product of the bases of the trapezoid knowing a and b.

Problems for the Complements to Book III

Exercise 272. The radical axis and the center of similarity divide the segment joining two antihomologous points in a constant cross ratio.

Exercise 273. The cross ratio of four points on a circle is equal to the cross ratio of their inverses on a circle (or line) inverse to the first.

---

[4] The case where $ABCD$, $A\ B\ C\ D$ are similar is an exception transl.

Exercise 274. The cross ratio of four points on a circle is obtained by dividing the products of the opposite sides of the quadrilateral they form, or dividing one of these products by the product of the diagonals.

Exercise 275. Which inversions transform two given circles into equal circles? Find an inversion which transforms three given circles into three equal circles.

Exercise 276. Given three circles, we draw the three circles (228) with respect to each pair of these circles, and with centers at the three centers of similarity situated on the same axis. Show that these three circles have the same radical axis.

Exercise 277. What is the locus of the centers of the inversions which transform two given circles into two others such that the first divides the second into equal parts; or, more generally, such that the first intercepts on the second an arc corresponding to a given angle at the center of the second?

Exercise 278. The segments intercepted by two circles on a line subtend, at the limit points (Exercise 152), angles having the same bisector, or perpendicular bisectors. Special case: the line is tangent to one of the circles.

Exercise 279. Prove Pascal's theorem (196) by forming three circles, each pair of which has a center of similarity at the intersections of two opposite sides of the hexagon. (Each of these circles passes through two opposite vertices.)

Exercise 280. Use Exercise 253 to construct the circles tangent to three given circles.

Exercise 281. A right angle pivots around a fixed point in the plane of a circle. We draw tangents to the circle at the intersection points with the sides of the angle. Find the locus of the vertices of the quadrilateral obtained in this way. (This locus is the inverse of that obtained in Exercise 201.)

Exercise 282. A quadrilateral ABCD is inscribed in a circle O and circumscribed around a circle o. Let a, b, c, d be its points of contact with o.

1 . The point P where the diagonals of ABCD and abcd intersect (exercise 239) is a limit point of the circles O, o (Exercise 241, part 2).

2 . The diagonals of abcd bisect the angles formed by the diagonals of ABCD (Exercise 278).

3 . If we apply the preceding exercise to circle o and point P, we obtain circle O.

4 . Conclude that, given two circles, we cannot generally find a quadrilateral inscribed in one and circumscribed about the other. For this to be possible, a certain relation must be satisfied by the radii and the distance between the centers. If this relation is satisfied, there are infinitely many quadrilaterals satisfying the conditions.

Exercise 283. If a triangle has an obtuse angle, there exists a circle (and only one) with respect to which this triangle is conjugate (211, Remark). The center of this circle is the intersection of the altitudes of the triangle.

Exercise 283b. For the existence of a triangle inscribed in a given circle, and conjugate to another given circle, it is necessary that the square of the radius of the second circle be equal to one half the power of its center with respect to the other circle. If this condition is satisfied, there are infinitely many triangles with both required properties. (Use Exercise 70.)

Exercise 284. Given three circles, each pair of which intersect, we construct a curvilinear triangle whose three vertices are intersection points of the circles, and whose sides are arcs of these circles which do not contain any other intersection points. Show that the sum of the interior angles of the three circles is less than, or greater than, two right angles, according as whether there exists or not a circle orthogonal to the three given circles.[5]

Exercise 285. Since the necessary and sufficient condition for a quadrilateral $ABCD$ to be cyclic is that the points B', C', D', inverse to B, C, D with respect to A, are collinear, all properties of cyclic quadrilaterals can be deduced from this condition.

In particular, deduce the theorem on the ratio of the diagonals. (Application of Stewart's theorem, 127.)

Exercise 286. Through two points which divide a diameter of a circle harmonically, we draw perpendiculars to this diameter. These lines are intersected by an arbitrary tangent at two points such that the ratio of their distances to the center is constant.

---

[5] See Note A, 290.

Book IV

On Areas

CHAPTER I

The Measure of Areas

242. Two polygons are adjacent (Figs. 200, 200b) if they have one or more common sides or portions of sides (Fig. 200b), without having any interior point in common.

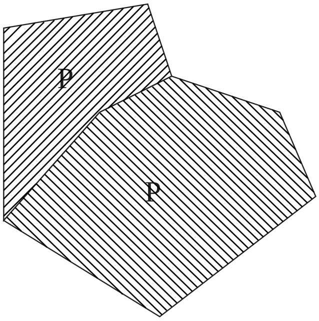

Figure 200

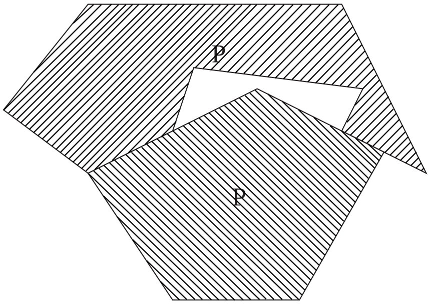

Figure 200b

If we remove the common sides of two adjacent polygons P, P, we form[1] a third polygon P called the sum of the first two. The interior of this polygon consists of the interior points of the original polygons, and only these points.

243. We define the areas of plane polygons by associating with each polygon a quantity (called the area or surface area of the polygon) satisfying the following properties:

I. Two congruent polygons have the same area, regardless of their position in space;

II. The sum P of two adjacent polygons P, P has an area equal to the sum of the areas of P and P.

We assume that such a correspondence can be made.[2]

244. Areas can be defined in infinitely many ways, because if we associate a quantity with each planar polygon so as to satisfy conditions I and II, a quantity proportional to the one we have used will also satisfy these conditions. In order to measure areas, as we are about to do, we must start by designating a polygon whose area is taken as the unit area. The measure of an arbitrary area will be the ratio of this area to the unit.

---

[1] In Book IV we suppress the restriction on the meaning of the word polygon formulated in 20 of Book I. The shaded portion of the plane in Figure 19 will therefore be treated in this book as a polygon. This polygon can be formed by taking the sum of two ordinary adjacent polygons, as shown in Figure 200. On the other hand, we consider in this book only proper polygons.

[2] This assumption is not really necessary, as it can be proved. See note D.

We agree from now on to take, as the unit of area, the area of a square whose side is the unit of length. The theorems we will state assume this convention, and it will not be necessary to repeat it in each individual case.

245. Two polygons with the same area are said to be equivalent. Two congruent polygons are therefore equivalent. The converse, naturally, is not true: two equivalent polygons need not be congruent. For instance, we will show that one can construct a square equivalent to any given polygon.

246. A base of a rectangle is one of its sides. The length of the side perpendicular to the base is then called the altitude of the rectangle. More generally, we can call one of the sides of a parallelogram its base; the altitude is then the distance from the base to the opposite side (measured, of course, along a common perpendicular).

Finally, a base of a triangle is just an arbitrary side, and an altitude is the perpendicular dropped on this side from the opposite vertex.

247. Theorem. The ratio of the areas of two rectangles with the same base is equal to the ratio of their altitudes.

Indeed:

1. Two rectangles with the same base and same altitude are congruent, and therefore equivalent by property I.

2. If three rectangles $ABCD$, $A'B'C'D'$, $A''B''C''D''$ (Fig. 201) have the same base, and the altitude of the third is the sum of the altitudes of the first two, the area of the third will be the sum of the areas of the first two (property II). Indeed, the third can be considered as the sum of two rectangles $A''B''EF$, $C''D''EF$ which are congruent, respectively, to the first two.

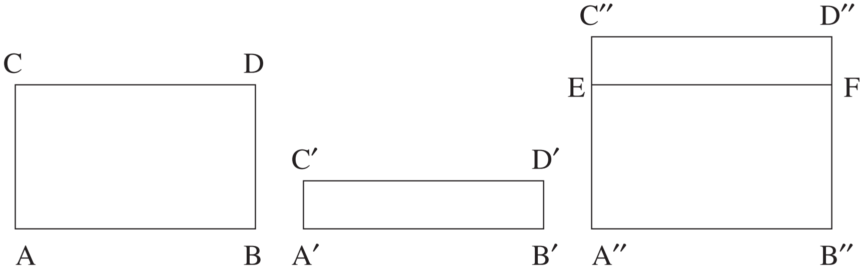

Figure 201

From these two facts we can prove, as in 113 (Book III) or 17 (Book I), and as is explained in the study of arithmetic[3] that an approximation to within $\frac{1}{n}$ of the ratio of the two areas is equal to an approximation within $\frac{1}{n}$ of the two altitudes, which proves the theorem.

Corollary. Since either side of a rectangle can be taken as a base, or as an altitude, any result concerning altitudes is also true for bases. In other words, the ratio of the areas of two rectangles with one equal side is equal to the ratio of the unequal sides.

---

[3] Leçons d'Arithmetique, chap. XIII, n° 493.

Theorem. The ratio of the areas of two rectangles is equal to the product of the ratios of the corresponding dimensions.

Indeed, we have just seen that the area of a rectangle is proportional to its base, and it is also proportional to its altitude, when these dimensions vary separately. The area is therefore proportional to the product of the base and the altitude.

We could also repeat the reasoning usually followed in arithmetic in such cases. Let A be the area of a rectangle with sides a, b, and A' the area of a rectangle with sides a', b'. Consider a rectangle with sides a' and b. The area A'' of this rectangle satisfies

$$\frac{A}{A''} = \frac{a}{a'}, \quad \frac{A''}{A'} = \frac{b}{b'}.$$

In this equation we can think of A, A', A'' as representing the numbers measuring the corresponding areas (relative to a given unit), rather than the areas themselves. For example, we might choose (as we have here), the unit area to be the area of a square constructed on a line segment of unit length. Under these conditions, we can multiply the two equations, and write the product $\frac{A}{A''} \bullet \frac{A''}{A'}$ as $\frac{AA''}{A''A'} = \frac{A}{A'}$. Thus the ratio $\frac{A}{A'}$ is indeed equal to the product of the ratios $\frac{a}{a'}$ and $\frac{b}{b'}$.

Theorem. The area of a rectangle is equal to the product of its two dimensions.

This theorem is the same as the preceding one, applied to the given rectangle and to the square with unit side. The area A' of the square is the unit area, and its dimensions a', b' are both equal to one, so that the ratio $\frac{A}{A'}$ is just the measure of the area A, and the ratios $\frac{a}{a'}$, $\frac{b}{b'}$ are the measures of the lengths a, b.

Remark. 1°. The statement above only makes sense if read according to the conventions of 18 (which we also recalled in 106, Book III). The meaning of the statement is: the *number* which measures the area of a rectangle is equal to the product of the *numbers* which measure the base and the altitude.

2°. This statement is precise only if read according to the convention of 244, which is therefore assumed here implicitly. It is clear *a priori* that the stated equality does not hold if the unit of length and the unit of area are chosen arbitrarily, and independently of each other.

We see from this that we can choose the unit of length arbitrarily, but once this choice is made, the choice for the unit of area is determined. We sometimes say that the unit of area is a derived unit.

248. *Theorem.* The area of a parallelogram is the product of its base and its altitude.

Suppose the parallelogram is ABCD (Fig. 202). We draw perpendiculars from A, B to side AB, and extend them to their intersections c, d with line CD, to form rectangle ABcd. This rectangle is equivalent to the parallelogram, because if we add to these quadrilaterals the right triangles BdD, AcC (which are congruent, having a pair of equal angles and a pair of equal sides) we obtain the same sum; namely, trapezoid AcBD. The rectangle has dimensions equal to the base and altitude of the parallelogram, so the theorem is proved.

249. *Theorem.* The area of a triangle is equal to half the product of the base and the altitude.

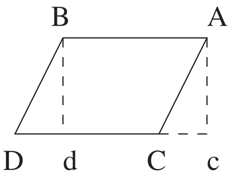

Figure 202

Suppose the triangle is ABC (Fig. 203). We draw parallel AD to BC and parallel CD to AB. The parallelogram ABCD thus formed has the same base and altitude as the triangle. This parallelogram is divided into two congruent triangles ABC, ADC by its diagonal AC (46). Thus triangle ABC is half the parallelogram.

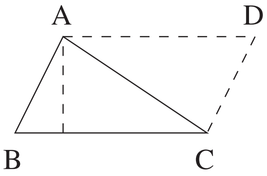

Figure 203

250. Corollary. The locus of the vertices of a triangle with base AB and constant area is composed of two lines parallel to AB.

This is because the vertices in question (Fig. 204) are just those points which are at a fixed distance from AB.

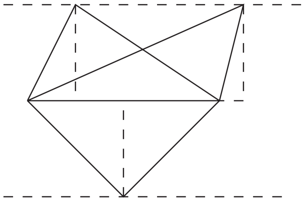

Figure 204

251. Problem. Calculate the area of a triangle knowing the three sides.

We denote the sides of the triangle by a, b, c, and the semi-perimeter by p (so that $a + b + c = 2p$). We have seen (130) that the altitude AH corresponding to side a is

$$AH = \sqrt{\frac{4p(p-a)(p-b)(p-c)}{a^2}} = \frac{2}{a}\sqrt{p(p-a)(p-b)(p-c)}.$$

The area is then given by

$$\begin{aligned} S = \frac{a \cdot AH}{2} &= \sqrt{p(p-a)(p-b)(p-c)} \\ &= \frac{1}{4}\sqrt{2b^2c^2 + 2c^2a^2 + 2a^2b^2 - a^4 - b^4 - c^4}. \end{aligned}$$

Remark. The product of the three sides of a triangle is equal to four times the product of its area and the radius of the circumscribed circle.

In triangle ABC, where AH is the altitude from A, and R the radius of the circumscribed circle, we have (130b) $AB \bullet AC = 2R \bullet AH$. Multiplying both sides by BC, we obtain

$$AB \bullet AC \bullet BC = 2R \bullet AH \bullet BC = 4RS.$$

252. The area of a polygon. The area of an arbitrary polygon can be obtain by decomposing it into triangles, then adding their areas.

The following two results are just examples of this method.

Theorem. The area of a trapezoid is equal to half the sum of the bases times the altitude.

Suppose the trapezoid is ABCD (Fig. 205). Drawing diagonal AD, we divide the base into triangles ABD, ACD. We take their bases to be AB, CD. Then the corresponding altitudes DD , AA are equal to each other and to altitude h of the trapezoid. The area of ABCD is therefore equal to

$$h \bullet \frac{AB}{2} + h \bullet \frac{CD}{2} = \frac{h(AB + CD)}{2}.$$

252b. Corollary. The area of a trapezoid is the product of its altitude and the segment joining the midpoints of the non-parallel sides.

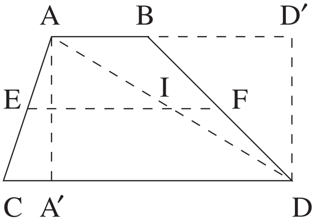

Figure 205

Indeed, the midpoints E, F of sides AC, BD (Fig. 205) and midpoint I of AD are on the same parallel to the bases, and segment EF is equal to half the sum of the bases, since it consists of the pieces EI, IF which are equal to $\frac{CD}{2}$, $\frac{AB}{2}$, respectively.

253. Theorem. The area of a regular polygon is equal to the perimeter times half the apothem.

Indeed, we decompose regular polygon ABCDEF (Fig. 206) into triangles OAB, OBC, . . . , which are all congruent and therefore have the same altitude, equal to the apothem OH. Thus

$$\text{area } OAB = OH \cdot \frac{AB}{2}$$
$$\text{area } OBC = OH \cdot \frac{BC}{2}$$
$$\cdots\cdots\cdots$$
$$\text{area } OFA = OH \cdot \frac{FA}{2},$$

and addition gives us:

$$\text{area } ABCDEF = \frac{OH(AB + BC + \cdots + FA)}{2}.$$

QED

Remark. If the polygon has an even number of sides, its area is equal to half the radius times the perimeter of the polygon obtained by joining every other vertex.

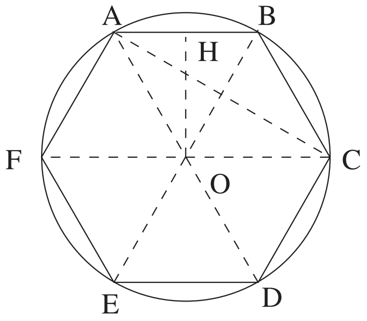

Figure 206

This is true because the area of triangle OAB (Fig. 206) is also equal to half the product of OB and the altitude AI from A, which is equal to half of AC.

253b. A polygon bounded by a broken line inscribed in a circle (Fig. 207), and by the two radii of the circumscribed circle corresponding to the endpoints of the line, is called a polygonal sector.

The polygonal sector is said to be regular if the broken line which serves as its base is regular.

Theorem. The area of a regular polygonal sector is the product of the perimeter of the base and half the apothem.

The proof of this result is identical to the preceding one.

254. Theorem. The area of a convex polygon circumscribed about a circle (and containing the circle in its interior) is equal to the product of its perimeter and half the radius of the inscribed circle.

The polygon (Fig. 208) can be decomposed into triangles with a common vertex at the center of the circle. These triangles, which have as bases the various sides, also have a common altitude equal to the radius.

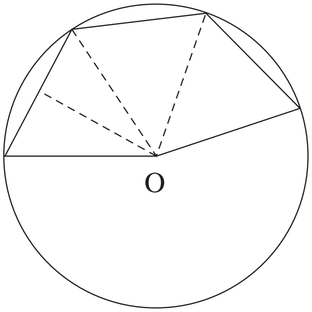

Figure 207

255. Problem. Find the area of a cyclic quadrilateral knowing its four sides.

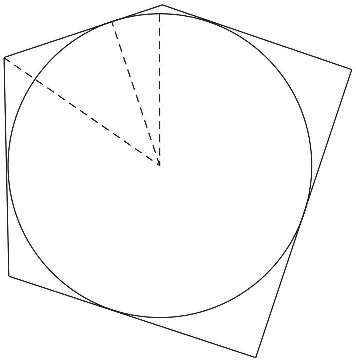

Figure 208

Consider cyclic quadrilateral ABCD in which AB = a, BC = b, CD = c, and DA = d. If R is the radius of the circumscribed circle, we have (251, Remark)

$$a \cdot b \cdot AC = 4R \times \text{area } ABC, \quad c \cdot d \cdot AC = 4R \times \text{area } ACD.$$

The required area S is the sum of the areas of ABC and ACD, so that

$$4RS = AC(ab + cd) = \sqrt{(ac + bd)(ad + bc)(ab + cd)}.$$

Replacing R by the value found in 240b, we have:

$$S = \sqrt{(p - a)(p - b)(p - c)(p - d)}.$$

Remark. The result is independent of the order of the sides, which is obvious a priori if we note that quadrilaterals ABCD, ABEF, ABGH (see 240) are equivalent, being composed of pairs of congruent triangles.

Exercises

Exercise 287. Find the area of an equilateral triangle with side a.

Exercise 288. What is the side of an equilateral triangle with an area of 1 square meter?

Exercise 289. We travel around the perimeter of a square in a determined direction, and join each vertex to the midpoint of the side which precedes the opposite vertex. Show that the lines obtained in this way form a new square, whose area is one-fifth the area of the original square.

Exercise 290. Through a point on diagonal AC of parallelogram ABCD we draw lines parallel to the sides. The parallelogram is divided into four smaller parallelograms, two of which have a diagonal on AC. Show that the other two are equivalent.

Exercise 291. Among all triangles with the same base and same angle at the opposite vertex, which one has the greatest area?

Exercise 292. In a trapezoid, the triangles formed by each diagonal with one of the non-parallel sides are equivalent, and conversely.

Exercise 293. Through the midpoint of each diagonal of a quadrilateral, we draw a parallel to the other diagonal, then join the intersection point of these parallels to the midpoints of the four sides. Show that the quadrilateral is divided by these segments into four parts with equal areas.

Exercise 294. Through each vertex of a quadrilateral, we draw a parallel to the diagonal which does not pass through that vertex. Show that the parallelogram formed this way has twice the area of the quadrilateral.

Two quadrilaterals in which corresponding diagonals are equal and intersect at the same angle are equal in area.

Exercise 295. Find a point inside a triangle such that when this point is joined to the three vertices, three equivalent triangles are formed. More generally, find a point such that the three triangles formed are proportional to three given lengths or numbers.

Exercise 295b. Using area considerations (see the preceding exercise), show that if we join a point to the three vertices of a triangle, the lines formed divide the opposite sides into ratios whose product is one. (This theorem was proved in 197.)

Exercise 296. We join a point O in the plane to the vertices of a parallelogram ABCD (in which AC, BD are diagonals).

1 . If the point O is inside the parallelogram, the sum of the triangles OAB, OCD is equivalent to the sum of OBC, ODA.

2 . For any point O, the triangle OAC is equivalent to the sum or difference of OAB, OAD.

Exercise 297. The area of a trapezoid is equal to the product of a non-parallel side and the perpendicular dropped to this side from the midpoint of the opposite side. Prove this in two different ways:

1 by rewriting the expression given in 252b;

2 by showing directly that the trapezoid is equivalent to a parallelogram with the base and altitude indicated above.

If we join the midpoints of the non-parallel sides of a trapezoid to the endpoints of the opposite side, the triangle obtained has half the area of the trapezoid.

Exercise 298. The sum of the distances of a point inside a regular polygon to its sides is constant.

Exercise 299. The area of a triangle is equal to the product of the semi-perimeter and the radius of the inscribed circle.

The area of a triangle is also equal to the product of the radius of an escribed circle and the difference between the semi-perimeter and the corresponding side (or the radius of an escribed circle and half the difference between this side and the sum of the other two).

Exercise 300. The inverse of the radius of the inscribed circle of a triangle is equal to the sum of the inverses of the radii of the three escribed circles.

Exercise 301. If x, y, z denote the distances from a point inside a triangle to the three sides, and h, k, ℓ are the corresponding altitudes, then

$$\frac{x}{h} + \frac{y}{k} + \frac{z}{\ell} = 1.$$

What happens if the point is outside the triangle?

CHAPTER II

Comparison of Areas

256. Theorem. The ratio of the areas of two triangles with a pair of equal (or supplementary) angles is equal to the ratio of the products of the sides containing these angles.

We can superimpose the angles if they are equal, or make them adjacent if they are supplementary. The two triangles will then be ABC, AB C , with sides AC, AC in the same direction, while the sides AB, AB are either in the same direction (Fig. 209), or are extensions of each other (Fig. 210).

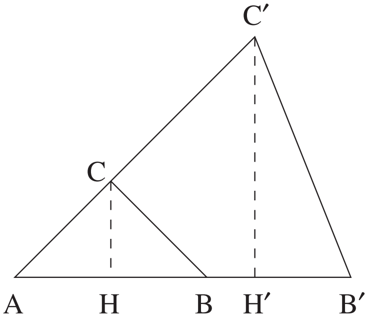

Figure 209

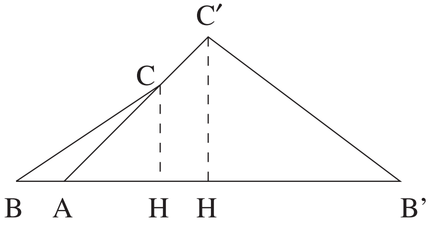

Figure 210

The ratio of the two triangles will be equal to the ratio of their bases AB, AB , multiplied by the ratio of their altitudes CH, CH , and this last ratio is obviously equal to $\frac{AC}{AC}$. QED

257. Theorem. The ratio of the areas of two similar polygons is equal to the square of their ratio of similarity.

We will distinguish two cases.

1 . If we are dealing with two similar triangles ABC, A B C , it suffices to observe that these triangles will have angle A = A . Therefore the ratio of the areas is equal to the product of the ratios $\frac{AB}{A\ B}$ and $\frac{AC}{A\ C}$, that is, to the square of one of them, since these two ratios are equal.

2 Now consider two arbitrary similar polygons, ABCDE, A B C D E (Fig. 211), with a ratio of similarity equal to k.

These polygons can be decomposed into similar triangles, arranged similarly: ABC, ACD, ADE; A B C , A C D , A D E , and as seen in case 1,

$$\frac{ABC}{A\ B\ C} = \frac{ACD}{A\ C\ D} = \frac{ADE}{A\ D\ E} = k^2.$$

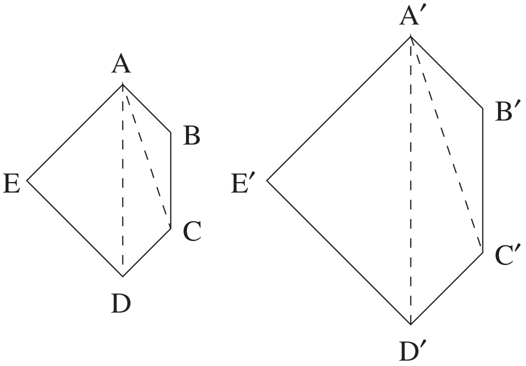

Figure 211

Taking the sum of the numerators and of the denominators we obtain

$$\frac{ABCDE}{ABCDE} = k^2.$$

QED

258. Theorem. The square constructed on the hypotenuse of a right triangle is equivalent to the sum of the squares constructed on the two legs.

Let the right triangle be ABC, and construct squares ABEF, ACGH, and BCIJ, outside this triangle (Fig. 212), on legs AB, AC and on hypotenuse BC.

We drop perpendicular AD from A to BC, and extend it to its intersection K with IJ. We claim that rectangle BDIK is equivalent to square ABEF.

To prove this, we join AI and CE. Then triangle ABI has the same base BI and the same altitude AL = BD as rectangle BDIK; it is therefore equivalent to half this rectangle. Also, triangle EBC has the same base BE and the same altitude CM = AB as square ABEF, so it is equivalent to half this square. Now triangles ABI, EBC are congruent, since they have an equal angle at A (angle B of the triangle plus a right angle) contained between equal corresponding sides (AB = BE and BI = BC). Thus we see that rectangle BDIK is indeed equivalent to square ABEF.

In the same way, we can show that rectangle CDKJ is equivalent to square ACGH. Thus square BCIJ, the sum of the two rectangles, is indeed equivalent to the sum of the two squares.

Remark. This theorem is the same as the one we proved in 124, since the three squares ABEF, ACBH, BCIJ have areas equal to the squares of the numbers which measure the sides. The proof also follows the same line, because the equivalence of rectangle BDIK to square ABEF expresses the same idea as the equation $AB^2 = BC \cdot BD$, which we used at that point.

Exercises

Exercise 302. The three sides of a triangle are divided into given ratios, and a new triangle is formed whose vertices are the points of division. Find the ratio of the area of the new triangle to that of the original triangle. Examine the case

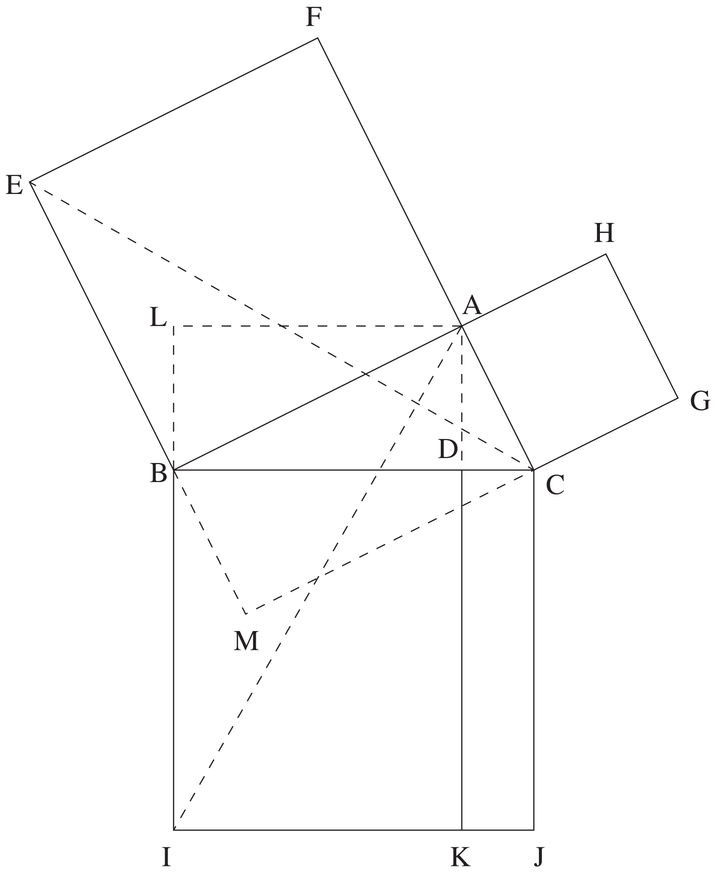

Figure 212

in which one or several of the division points is outside the triangle. Deduce from this proofs for the theorems in 192 193.

Exercise 303. Divide a triangle into two equivalent parts by a line parallel to the base.

Exercise 304. Divide a trapezoid into two equivalent parts by a line parallel to the bases.

Exercise 305. An equilateral triangle is inscribed in a given circle. The radii passing through its vertices are extended to intersect a new circle, the one circumscribing a square which is circumscribed about the original circle. Prove that these points form a triangle equal in area to the regular hexagon inscribed in the original circle.

Exercise 306. Through each vertex of a quadrilateral, we draw a line parallel to a fixed direction, and find the intersection of each of these parallels with the diagonal which does not pass through that vertex. Prove:

1 . that the quadrilateral formed by these intersections is equivalent to the original quadrilateral;

2 . that this new quadrilateral is a trapezoid or a parallelogram, if the original is. More generally, the ratios in which the opposite sides (extended) divide each other are the same in the two quadrilaterals.

Exercise 307. Given some arbitrary polygons in the plane, we draw parallels through each of their vertices in a fixed direction, then measure off on each parallel a distance proportional to the distance from the vertex considered to a fixed line (in the sense corresponding to the sense of the segment from the vertex to the fixed line).

Show that the endpoints of these segments form polygons whose areas are proportional to those of the original polygons (Exercise 297).

When are the new polygon equal in area to the original polygons?

Exercise 308. Show that the preceding exercise contains Exercise 306 as a special case (use Exercise 129).

Alternative Proofs of the Theorem on the Square of the Hypotenuse

Exercise 309. In Exercise 43 (Book I), show that the third square $HBKF$ is equivalent to the sum of the two given squares. Deduce from this the theorem of 258.

Exercise 310. Prove the theorem on the square of the hypotenuse using the theorem of 257, and observing that the right triangle is the sum of the triangles into which it is divided by its altitude.

Exercise 311. Given an arbitrary triangle ABC, we construct any parallelograms $ABEF$, $ACGH$, on bases AB, AC, and outside the triangle. Then we extend EF, GH to their intersection point M. Show that the parallelogram having BC for one side, and the other parallel and equal to AM, is equivalent to the sum of the first two parallelograms.

Show that the previous result is a special case of the theorem on the square of the hypotenuse.

CHAPTER III

Area of the Circle

259. We define the area of a circle as the limit approached by the area of an inscribed or circumscribed polygon, all of whose sides tend to zero.

To show that this limit exists and is independent of the way in which the sides tend to zero, we follow reasoning similar to that used to study the length of the circle. We start by considering regular inscribed polygons with a number of sides which is doubled indefinitely, and the corresponding circumscribed polygons (Fig. 168). Under these conditions:

The areas of the inscribed polygons increase, because each one contains the preceding one. Any of these areas is smaller than the area of an arbitrary circumscribed polygon. Therefore these areas tend to a limit.

In the same way, the areas of the circumscribed polygons decrease, because each one is contained in the preceding one. Each of these areas is greater than the area of any inscribed polygon. Therefore the areas of the circumscribed polygons also tend to a limit.

These two limits are equal, since the ratio of the area of an inscribed polygon and the corresponding circumscribed polygon is equal to the square of the ratio of similarity, which tends to one (176).

260. Let S be the common value of these limits, obtained by starting from the square, for instance, and considering the polygons with $4, 8, 16 \ldots, 2^n \ldots$ sides. Now consider arbitrary inscribed polygons a b c ... (Fig. 169) and the corresponding circumscribed polygons A B ..., imposing only the condition that the number of sides of these polygons increases indefinitely, in such a way that all the sides tend to zero.

The area of the inscribed polygon a b c ... is smaller than S because S is the limit of areas of circumscribed polygons, which are all greater than a b c ....

Since S is contained between the inscribed and circumscribed polygons, it differs from each of them by less than they differ from each other.

Now this difference tends to zero. Indeed, it is composed of triangles a b A , b c B ,..., and is thus equal in area to

$$\frac{1}{2}(ab \cdot AH + bc \cdot BK + \cdots) < \frac{1}{2}(ab + bc + \cdot) ,$$

where A H, B K,... (Fig. 169) are the altitudes of these triangles, and denotes the greatest of these altitudes.

The factor a b + b c + ••• approaches the length of the circle, while the altitudes A H, B K,... all tend to zero. Indeed, the lengths OH, OA , for instance, both tend to the radius of the circle, and therefore their difference A H tends to zero.

Thus, the areas of inscribed and circumscribed polygons tend to a unique limit S which is the area of the circle.[1]

261. Theorem. The area of a circle is numerically equal to the length of the circumference, multiplied by half the radius.

Indeed, the area of a regular convex polygon is the product of its perimeter and half the apothem. As the number of sides increases indefinitely, the perimeter approaches the length of the circle, and the apothem approaches the radius.

Remark. We obtain the same result using the theorem of 254 about the circumscribed polygon. Indeed, the perimeter of such a polygon will approach the length of the circle as the number of sides increases indefinitely.

Corollary. The area of the circle with radius R is R^2.

Indeed, $2\ R \times \frac{R}{2} = \ R^2$.

262. A circular sector is a portion of the plane bounded by a circular arc and the radii corresponding to its endpoints.

The area of such a sector is the limit of the areas of inscribed polygonal sectors as all the sides decrease indefinitely. The existence of this limit is established as in the case of the circle.

Theorem. The area of a circular sector is equal to the arc which bounds it, multiplied by half the radius.

Indeed, the perimeter of the regular inscribed broken line approaches the length of the arc, and the apothem approaches the radius.

The length of an arc of n gradients in a circle of radius R is $\frac{nR}{200}$, and therefore the area of the corresponding sector is $\frac{R^2 n}{400}$.

Analogously, the area of a sector of a circle with radius R, corresponding to an angle equal to $m\ n\ p$ will be

$$\frac{R^2}{360}\ \ m + \frac{n}{60} + \frac{p}{3600}\ \ .$$

263. Areas bounded by circular arcs. A segment of a circle (Figures 213 and 214) is the area contained between an arc and its chord.

Clearly, the area of a segment is obtained from the area of the corresponding sector by subtracting the triangle with the chord as base and the center as its vertex, provided that the arc is less than a semicircle (Fig. 213), and by adding the same triangle in the opposite case (Fig. 214).

More generally, the calculation of the area of a region bounded by arcs of circles can be reduced to that of a polygonal area by adding or subtracting sectors or segments of circles.

---

[1] The distance ab approaches zero, independent of the position of arc $\overset{\frown}{ab}$ on the given curve. This condition is satisfied if the analogous condition in the note to 179 is satisfied. We are then assured that the difference between the areas of the inscribed and circumscribed polygons approaches zero as the sides of these polygons approach zero.

As has been already indicated in the note mentioned above, the argument can be divided into two parts, corresponding to sections 259 and 260 in the text.

As for non-convex areas, they may be evaluated as sums or differences of convex ones.

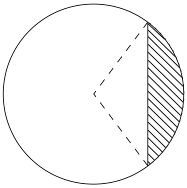

Figure 213

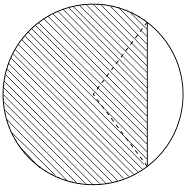

Figure 214

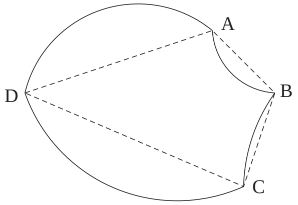

Figure 215

For instance, the curvilinear area ABCD (Fig. 215) is equal to the area of the ordinary quadrilateral ABCD, diminished by the segments AB, BC, and increased by the segments CD, DA.

In conclusion, we know how to find the area of any portion of the plane bounded by lines and circular arcs.

Exercises

Exercise 312. What is the radius of a circle with an area of one square meter?

Exercise 313. What is the radius of the circle in which a sector of $15^{G}25$ has an area of one square meter?

Exercise 314. What is the radius of a circle in which the segment contained between an arc of 60 and its chord has an area of one square meter?

Exercise 315. Prove that the area of the annulus bounded by two concentric circles is equal to the area of a circle whose diameter is the chord of the larger circle which is tangent to the smaller one.

Exercise 316. On a quarter circle AC we take points B, D at equal distances from the endpoints. We then drop perpendiculars BE, DF to radius OC. Show that the curvilinear trapezoid BEFD is equivalent to sector OBD.

Exercise 317. On the legs of a right triangle as diameters, we draw semicircles outside the triangle. We draw a third semicircle on the hypotenuse as diameter, but this time on the same side of the hypotenuse as the triangle. Show that the sum of the two lunes, or crescents, contained between the smaller semicircles and the large one is equal to the area of the triangle.

Exercise 318. On side AB of a square inscribed in circle O, we draw a new semicircle, outside the square. Radius OMN intersects this semicircle at N and the original circle at M. Show that the area bounded by segments MN and by arcs $\widehat{MA}$, $\widehat{NA}$ can be squared; that is, we can construct, with straightedge and compass, a square equivalent to it.

Note A:
On the Methods of Geometry

268. We would like to collect here some advice which we believe to be very useful for the understanding of mathematics in general and, in particular, for solving problems.

We must convince students that they will not be able to benefit from their study of mathematics, will not be able to pursue this study without excessive effort, and will not be able to form a proper idea of what geometry consists in, unless they not only understand the proofs they read, but also construct for themselves, to a greater or lesser extent, proofs of theorems or solutions to problems.

Contrary to common prejudice, this understanding can be achieved by anyone, or at least by anyone willing to think and to direct their thoughts methodically. The precepts which we will indicate derive from the most ordinary common sense. There is not one among them which may not seem a pure banality to the reader. However, experience shows that forgetting one or another of these obvious rules is the cause of almost every difficulty encountered in the solution of elementary problems; this is also true, more often than one might think, in research in more or less advanced parts of the mathematical sciences.

(a) Theorems to Prove

269. To prove a theorem means to pass, by way of reasoning, from the hypothesis to the conclusion.

Consider the theorem (Book I, 36): Every point on the bisector of an angle is equidistant from the two sides of this angle. The hypothesis and conclusion are: Hypothesis: If the point M is on the bisector of the angle BAC (Fig. 35) Conclusion: Then it will be equidistant from AB and AC.

We have to deduce the second from the first, to transform the properties stated in the hypothesis, so as to derive the truth of those which constitute the conclusion.

Obviously, it is necessary to know very precisely what the hypothesis is and what the conclusion is, of the theorem we want to prove. The student must therefore practice stating them without any hesitation.

270. Before we continue, we can already make an important observation. In every proof, one proposes to show that the conclusion holds when the hypothesis is supposed true. If the hypothesis is not considered certain, nothing can assure us of the truth of the conclusion. Thus, in the preceding example, if the point M were not on the bisector, we in fact know (36) that it would not be equidistant from the two sides.

It is clear that it would not serve any purpose to suppose that something is true, if the reasoning carried no trace of this assumption, if this assumption were not used at some point. We see that the hypothesis must be used in the proof and even, generally, the entire hypothesis.

271. We will return a little later to the preceding rule. But first, we have an immediate need to formulate another, analogous rule. We must call special attention to it, since, while indispensible, it is often misunderstood. It refers to the definitions of the terms used.

On the one hand, it is obvious that we could not know how to reason about notions which have not been defined; on the other, as before, it is clear that it is the same thing to ignore a definition, or not to use it in our reasoning.

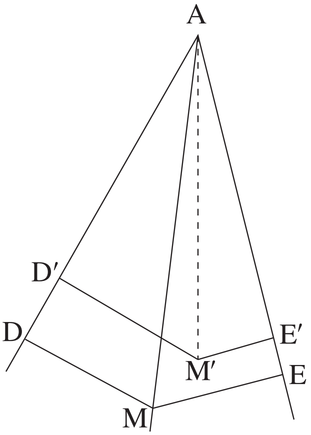

Figure 35

Therefore it is of paramount importance that we refer to the definitions of all the notions involved in the situation at hand.

Example. Consider the same theorem:

Every point on the bisector of an angle is equidistant from the two sides of this angle.

We must start by asking the following questions:

What does it mean that the line MA is the angle bisector?

ANSWER: That it divides the angle A into two equal parts.

What is the distance from M to line AB?

ANSWER: It is the length of the perpendicular dropped from this point to this line.

So our statement becomes:

Hypothesis: $MAD = MAE$; MD is perpendicular to AD; ME is perpendicular to AE.

Conclusion: $MD = ME$

We hope that this example will clarify sufficently the meaning of this rule, which Pascal places at the basis of all logic: we must substitute the definition in the place of the term which it defines.[1]

---

[1] It is even necessary, in general, to use all the parts of the definition when there are several. We may note in this respect the remarks made, a little later, about the hypothesis (275).

272. The definition of the same term can sometimes be given in several forms, among which we must choose the one which is the most convenient for the purpose we have in mind. Thus, we can define the bisector AM of the angle as the line which forms an angle equal to one half of the original angle with one of its sides (in the appropriate sense of rotation).

This formulation of the definition would not have been advantageous for the preceding theorem. On the other hand, it is the form which served best, for instance, in the proof of the theorem in 16 (Book I).

Certain theorems allow us, in the same way, to replace a definition with an equivalent one. Thus, the original definition of parallels (38) is no longer used in the original form of 39, where we learned to replace it by the following form, which is exactly equivalent to the first: Two lines are parallel if they form equal alternate interior angles with the same transversal (or equal corresponding angles, or supplementary interior angles on the same side).

273. The rule just stated is perhaps the most important one that we are going to discuss. Its importance is apparent when we think of the great number of auxiliary constructions, which sometimes seem arbitrary, but which are a direct consequence of this rule.

To give just one example, at the beginning of Book II, when we reason about an arbitrary point on a circle, we always start by joining it to the center. The reader who has reflected on the preceding remarks will understand that there is nothing artificial about this construction: its necessity is immediately apparent. In fact, it comes from the definition of a circle, according to which, if we say that a point M belongs to a circle with center O, we are saying that the distance OM is equal to the radius of the circle.

Starting with Chapter IV (73 and later) we see things change: it is not always the case that a point on the circle must be joined to the center in order to reason about it. We have now learned to replace the original definition of the circle with another, given in 82. Using this definition to express the fact that a point M belongs to a circle, we can join M to three points A, B, C on the curve, and show that quadrilateral $ABCM$ is cyclic, using one of the conditions listed in 81. From this point on, in every proof involving a circle, we can choose between these two definitions. The one which we use depends on the circumstances.[2]

274. Having been cautioned by what we have just mentioned, we must, as we have said, transform the given hypothesis so as to find in it evidence for the conclusion.

In the simplest cases, we can find a theorem which allows us to make such a transformation.

Example. The hypothesis we discuss in 271 immediately furnishes the corresponding conclusion, through one of the cases of congruence for right triangles.

In other cases, however, we must pass through one or several intermediary transformations. For example, we can seek to state the hypothesis in a form as close a possible to the conclusion.

Example. Suppose we want to prove the theorem (25): In any triangle, the greater angle is opposite the greater side.

---

[2] Later, we encounter other definitions, equivalent to the original; for instance, in Book III, 131.

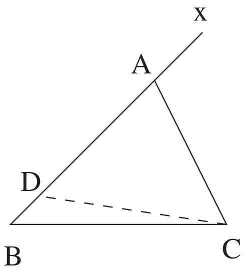

Figure 217

We need to express the fact that AB is greater than AC, so we take point D on AB, between A and B, such that $AD = AC$. The hypothesis and conclusion are therefore

(I) Hypothesis: DA is the extension of DB, $DA = AC$.

Conclusion: $ACB > ABC$.

Using isosceles triangle ADC, in which the base angles must be equal, allows us to reformulate the hypothesis in a new way.

(II) Hypothesis: DA is the extension of DB, $ADC = ACD$.

Conclusion: $ACB = ADC + DCB > ABC$.

Or, more simply,

(III) Hypothesis: Dx is the extension of DB (Fig. 217).

Conclusion: $xDC + DCB > xBC$,

which is obvious from the theorem on the exterior angle of a triangle (same section).

We have arrived at the result by a series of successive transformations.

275. In performing these transformations, it is especially important that we not neglect our first rule (270) and that we examine whether any part of the hypothesis remains unused or has been abandoned. In this way we can make sure that the new hypothesis is the same as the old, or that the two are entirely equivalent.

Example. In the preceding example, form (II) of the hypothesis is completely equivalent to form (I). In other words, if hypothesis (I) is true, then so is hypothesis (II), and conversely. Indeed, the only difference is that the equality $AC = AD$ has been replaced by $ADC = ACD$. But we know that either of these conditions implies the other. Thus hypothesis (II) can be entirely substituted for hypothesis (I): to assume one or the other amounts to the same thing.

While it may happen that an element of the hypothesis can be abandoned without consequence,[3] this is not generally the case.[4] When we find ourselves blocked in the course of a proof, we must ask ourselves whether the difficulty in reaching the goal is not due to the fact that we have lost part of the given hypothesis on the way.

---

[3] This is what happens in the preceding example with hypothesis (III) and hypothesis (II). Hypothesis (II) is exactly equivalent to (II′): Dx is the extension of DB, and there is a point on Dx such that the triangle with this vertex, and with base DC, has equal angles at the base. Indeed, such a point could obviously be labeled A. But this point might not exist, even if hypothesis (III) (which states that Dx is the extension of DB), is satisfied. For such a point to exist, the angle xDC must be acute, according to the exterior angle theorem.

Thus hypothesis (III) can hold, without hypothesis (II) being true.

[4] One must take care to state results in a form in which the hypothesis does not contain any useless element. In the most advanced research, and particularly in applications of mathematics,

Example. Suppose we must prove the following theorem:

Given point M in the plane of triangle ABC, we construct angle BAP = MAC and length AP = AM. Likewise, we construct CBQ = MBA, BQ = BM and ACR = MCB, CR = CM. Then points M, P, Q, R lie on the same circle (Fig. 218).

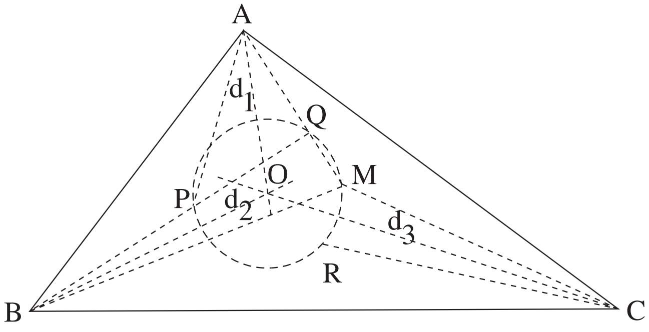

Figure 218

In other words,

(I) Hypothesis:

$$BAP = MAC, \quad AP = AM$$
$$CBQ = MBA, \quad BQ = BM$$
$$ACR = MCB, \quad CR = CM.$$

Conclusion: M, P, Q, R lie on the same circle.

Let d_1 be the bisector of angle A. Then sides AB, AC are symmetric with respect to this line, and because BAP = MAC, we see that AM and AP are also symmetric with respect to d_1. Thus point P is symmetric to M with respect to d_1. Likewise, Q is symmetric to M with respect to the bisector d_2 of B, and R is symmetric to M with respect to the bisector d_3 of C. Thus we are tempted to transform the hypothesis as follows:

(II) Hypothesis:
P is symmetric to M with respect to d_1,
Q is symmetric to M with respect to d_2,
R is symmetric to M with respect to d_3.

Conclusion: M, P, Q, R lie on the same circle.

However, if we started from this form of the statement, it would be impossible to find a proof; indeed, the proposition thus formulated is false. It is not true that a point M and its symmetric points P, Q, R with respect to three arbitrary lines

---

the greatest difficulty often consists in recognizing, among the given elements of the problem, those that will be useful.

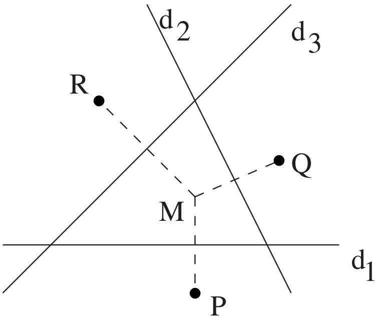

Figure 219

are on the same circle. We can see this simply by inspecting figure 219, or by noting that any three points P, Q, R can be viewed as symmetric to a point M with respect to three lines d_1, d_2, d_3; namely, the perpendicular bisectors of MP, MQ, MR.

Thus we must have made an error in substituting form (II) of the hypothesis in place of (I). The error consists in the fact that lines d_1, d_2, d_3 are not arbitrary: they are the angle bisectors of the given triangle and, as such, are concurrent. The correct form of (II) is then[5]

(II) Hypothesis:

P is the point symmetric to M with respect to d_1,
Q is the point symmetric to M with respect to d_2,
R is the point symmetric to M with respect to d_3;
lines d_1, d_2, d_3 are concurrent at point O,

and this leads immediately to a proof, because we see that the four points M, P, Q, R are on a circle with center O.

276. Instead of transforming the hypothesis in order to make it more similar to the conclusion, it is often advantageous to operate on the conclusion, and to replace it by another which implies the original, and which can be deduced more easily from the hypothesis.

Example. Suppose we want to demonstrate the following theorem (Exercise 72):

From a point M on the circumscribed circle of triangle ABC, we drop perpendiculars MP, MQ, MR to the sides of the triangle. Then the feet of these perpendiculars are on a straight line.

We will have proved that P, Q, R are collinear (Fig. 220) if (joining PQ, PR) we show that the angles BPR, CPQ, which are opposite and have the same vertex, are equal. Thus, if the statement is:

Hypothesis: Points A, B, C, M are on the same circle;
MP, MQ, MR are perpendicular to BC, CA, AB, respectively,

we can give the conclusion the form

Conclusion: BPR = CPQ.

---

[5] This hypothesis can indeed be substituted for the original one: three concurrent lines can generally be viewed as the bisectors of the angles of a triangle (Exercise 38).

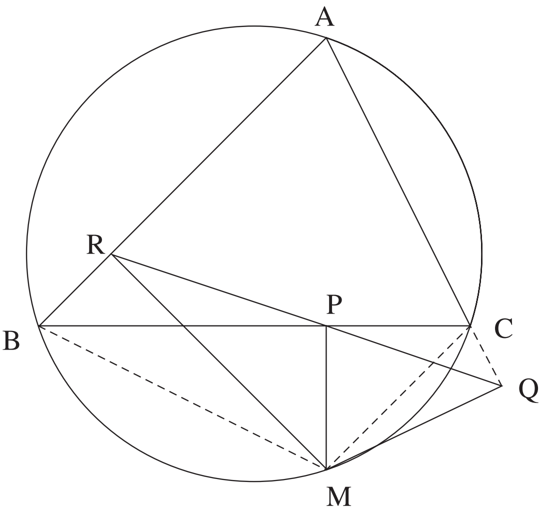

Figure 220

But, because of the right angles BRM, BPM, quadrilateral BRPM is cyclic (81), so that BPR = BMR; likewise, quadrilateral CQMP is cyclic, so that CPQ = CMQ. It will suffice to establish (with the same hypothesis):

Conclusion: BMR = CMQ.

The original conclusion is therefore replaced by another, whose proof is simpler and can easily be found by the reader.[6]

277. We now return to an important remark which we were constrained to neglect, but which must be applied to the reading of any statement of a problem.

This is the observation that many theorems can be stated in several different forms. We have already noted some examples in the text.

Example I. We have observed in 32 that the proposition:

Every point equidistant from two points A, B is on the perpendicular bisector of AB.

can also be stated as follows: A point which is not on the perpendicular bisector of AB is not equidistant from A and B.

We have seen that this is an instance of a general principle: the contrapositive of an arbitrary proposition is equivalent to the original proposition.

This idea is related to the mode of proof by contradiction which consists in showing that if we assume that the hypothesis true, and at the same time the conclusion false, we are led to a contradiction.

Example II. Consider the statement (23):

The bisector of the angle at the vertex of an isosceles triangle is perpendicular to the base, and divides it into equal segments.

---

[6] We have given an argument based on the diagram as drawn in fig. 220. We can modify this proof to make it independent of this particular position. This is easily done using the remarks in 83. However, in solving the problem itself, we can always arrange the argument to use the case we have described; it suffices to change, if necessary, the order of the letters A, B, C.

This statement amounts, as we have seen,[7] to either of the following statements:

The altitude from the vertex falls on the midpoint of the base, and divides the angle at the vertex into two equal parts.

The perpendicular bisector of the base passes through the vertex, and is the bisector of the angle at the vertex.

Clearly this example, like the preceding one, is an instance of a general principle. We have encountered this principle, for instance, in 63, Book II. Indeed, it is encountered at the very beginning of geometry. The proof of 41 (the converse of the theorem of 38) is obviously just a remark of this kind.

These are two general categories of situations in which a statement can be replaced by an equivalent statement, but they are not the only such situations. Some reflection should, in any particular case, help find the different forms which a proposition can take. It is essential to review these forms, in order to choose the one which lends itself the most to proof; in other words, to ask the question in the form in which the solution is easiest to find.[8]

278. This last observation concludes the exposition of the fundamental rules which we wanted to indicate. It will be useful to study the proofs given in the book from the point of view of the application of these principles, and to ask questions such as the following:

To prove the theorem on the medians of a triangle (56), we have taken the midpoints of BG and CG (Fig. 53). Was it logically necessary to think of this construction? Could it be replaced by others?[9]

In Exercise 8, do both parts of the conclusion assume that the given point is inside the triangle? Does the answer to this question indicate which theorem must be used for the proofs of the two parts?

In the proof of 27, at which point do we use the fact that the enveloping polygon is convex?

Etc., etc.

(b) Geometric Loci Construction Problems

279. What we have just said about the proof of theorems allows us to shorten our remarks on other possible types of questions, whose solutions must be sought according to the same principles. We are about to see this in problems concerning geometric loci and construction.

Geometric loci. In the text, we have learned how to find a number of geometric loci: the locus of points equidistant from two given points, or two given lines, the locus of points at a given distance from a given line, etc.

Other geometric loci are obvious on their own. For instance, the locus of points with the property that the lines joining them to a fixed point A are parallel to a fixed line xy, is simply the parallel to xy passing through A.

Having seen this, if we are given a property of a point M or, more generally, properties of a variable figure containing this point, the locus of M can be found by transforming the given properties into others which correspond, for this point, to a known locus.

---

[7] We recall (see 41) that this equivalence depends on the fact that there is only one bisector of the angle at the vertex, only one altitude, only one perpendicular bisector of the base, etc.

[8] One should give the problem a form in which it can always be solved (Abel).

[9] One of these is given in Exercise 37.

We are thus faced with a question analogous to the one encountered in proving a theorem. In that case, we had to deduce, from a collection of given properties (the hypothesis), another collection, also provided (the conclusion). Here the same sort of transformation must be performed. The only difference is that now, while the starting point is given, the end point, or conclusion, is not. We only know that it must be of the sort that will furnish the required locus. It is clear that we must look for common properties of the various positions of the variable figure and, particularly, the elements of this figure which do not change as the figure varies.

The path we must follow is the same as in the preceding case, and we would only need to repeat here the precepts just formulated.

One of these applies even more strictly here than in the case of the proof of a theorem. For proofs, we have seen that that part of the hypothesis may be abandoned in our successive transformations. This can never be allowed in searching for a geometric locus, because the locus must contain the points possessing the given properties, and only these. We must therefore make sure that the conclusion is exactly equivalent to the hypothesis.

This is in fact what we have done for most of the loci obtained in the text (33, 36, 77, etc.); we have omitted this second part of the reasoning only in those cases where it was so easy to supply that it was not necessary to do so explicitly.

280. Construction problems. Suppose now that we must construct a figure with given properties. The nature of the answer to such a question can vary significantly, depending on whether or not the given conditions are enough to determine exactly the unknown figure.

Examples. (1) Construct a line tangent to a given circle.

The tangent at an arbitrary point on the circle will solve this problem. There are infinitely many solutions: the given conditions do not suffice to determine the figure. The problem is said to be underdetermined.

(2) Construct a line tangent to two given circles.

Here we have an additional condition. This time the problem is determined: there are (at most) four solutions (93).

(3) Construct a line tangent to three given circles.

In general there is no line solving this problem. The first two circles have (at most) four common tangents, so the required line can only be one of these four; but an arbitrary third circle, will in general be tangent to none of these lines. Thus the problem is, except in special cases, impossible. Too many conditions are required of the figure described.

The problems proposed for students will, generally, be determined.

281. The problem often reduces to the construction of a single point.

Example I. Construct a circle passing through three given points (90).

It is enough to determine the center.

Example II. Construct a triangle knowing a side, the opposite angle, and the corresponding altitude.

If we place the given side arbitrarily, we need only find the opposite vertex.

In this situation, the method generally used is the construction by intersecting geometric loci, which consists in deducing from the given conditions two curves on which the unknown point must be found: the intersection of the curves will locate this point.

Example I. In order to find the center of the circle passing through three points A, B, C, it was enough to observe that the condition that this center be equidistant from A and B provides a first geometric locus, and the condition that it be equidistant from B and C a second locus.

Example II. In order to construct a triangle ABC knowing the side BC, the angle A, and the corresponding altitude, having chosen a location for BC, we have two loci for A: 1 The circular arc along which segment BC subtends the given angle; 2 a line parallel to BC, at a distance equal to the given altitude.

Let us say that a condition on a point is a simple condition if the set of points satisfying the condition is a curve. A point is then determined by two simple conditions, and if the two loci corresponding to the simple conditions are known[10], the required point will be their intersection.

More generally, a figure is determined by a certain number of simple conditions (we will return to this point in the second volume, Chapter X, and Note E). A polygon with n sides is determined in size and position by $2n$ simple conditions, since there are n points to be determined. To determine the polygon in size and shape only, $2n - 3$ simple conditions will suffice, since we can choose one of the vertices, and the direction of one of the sides ending in that vertex, both arbitrarily. This number $2n - 3$ is equal to n for a triangle, but larger when n is greater than 3: thus the remarks of 46b (Remark III) and 147.

282. According to the observation above, when we are given a construction problem, we try to change it so that it is reduced to questions whose solution we know; for example, by deducing two geometric loci for one of the points of the required figure.

Thus, one can consider a figure which is assumed to satisfy the given conditions,[11] and these conditions will serve as our hypothesis. We will then have to find the conclusion and, for this purpose, we will have to ask what the known elements in the figure are.

In this instance again, the general rules are the same as in the proof of a theorem. As in the case of a geometric locus, the conclusions we obtain must be fully equivalent to the hypothesis. This is true because, on the one hand, the conditions of the problem must imply the construction we find, and, on the other hand, every figure formed by this construction must satisfy all the conditions in question.

We will not dwell any longer on the particular features presented by construction problems, but simply refer the reader to the excellent work Methods and Theories for the Solution of Construction Problems in Geometry by Petersen,[12] which we have found very useful in the preparation of this volume.

---

[10] In elementary geometry, we limit ourselves to the solution of construction problems with straightedge and compass, so that the loci in question must always be straight lines or circles.

[11] This is what is meant, for instance in 93, by saying that we assume the problem solved.

[12] Translated by O. Chemin, Gauthier-Villars, 1880

(c) The Method of Transformations

283. The student who is familiar with the advice in the preceding sections, who can substitute, more or less mechanically, the defined terms for the definitions, who knows how to find quickly the various forms in which a problem he is trying to solve can be presented, will soon be able to solve a great number of problems posed in elementary geometry. Other problems, however, will seem to him inaccessible or very difficult, although they admit in reality of very simple solutions. It is just that these solutions do not depend simply on the direct form of reasoning which we have discussed, but require the aid of simplifications which we have yet to discuss: the method of transformations.

Properly speaking, after the preceding discussion, all geometric methods can be legitimately called “transformation methods”. However, we reserve this name for methods which consist in passing from the properties of a figure to the properties of another figure.

To define a transformation is to associate to each figure another figure, following a certain rule, such that the second figure is completely determined by the first, and conversely. From each property of one of the figures one can derive a property of the other, which is, in some sense, a restatement of that property.

Examples. We have defined a figure F' homothetic to a figure F, with respect to a given center of homothecy and ratio of similitude. Given figure F, we can construct figure F'. We have seen that to each line of F there corresponds a parallel line in F', to each triangle in F there corresponds a similar triangle in F', to each circle in F there corresponds a circle in F', and so on.

In the same way, given a figure F, we can construct a figure F' derived from the first by a rotation, or a translation, or a given line reflection; or more generally, a figure F' similar to F, and such that the points corresponding to two given points A, B are two other given points A', B'. The properties of F immediately imply corresponding properties of F'.

284. In some cases, a transformation need not be applied to the entire figure. It is often useful to transform only part of a figure.

This happens, in particular, with the simple transformations mentioned above: translation, line reflection, homothecy, or a general similarity. There is usually no advantage in applying such a transformation to the entire figure, since the properties of the transformed figure are neither simpler nor more complicated than those of the original figure: they are exactly the same.[13] On the other hand, it is often necessary to apply one of these simple transformations to a certain part of the figure.

Example I. Consider the problem (Exercise 32): Given two parallel lines, and two points A and B outside these parallels, and situated on different sides, what is the shortest broken line joining these two points in such a way that the portion contained between the parallel lines has a given direction?

Suppose the required line is $AMNB$ (Fig. 221). Point N is obtained from M by a translation which is obviously known, since the length of the segment intercepted by the given parallels on any line with a given direction is the same. We can apply this translation to segment AM; point A is changed into a known point C, and

---

[13] Geometry studies exactly those properties which are not changed by rigid motions.

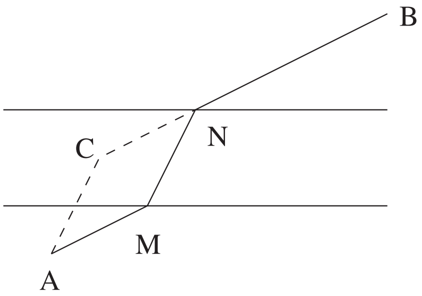

Figure 221

segment AM into an equal segment CN. We deduce easily that points B, N, C are on a straight line.

Analogous considerations apply to Exercises 118 122 (Book II).

Example II. In Exercise 14, segment AM, after reflection in the given line xy, will be collinear with the segment BM.

285. In solving certain construction problems, however, it is useful to transform an entire figure, by similarity or rigid motion. The advantage obtained by such a transformation is that it can transform unknown parts of the figure into known parts of the transformed figure.

Example. In quadrilateral ABCD, inscribe another quadrilateral similar to a given quadrilateral mnpq.

There exists a figure similar to the one required, in which the required quadrilateral MNPQ corresponds to quadrilateral mnpq. Quadrilateral ABCD will correspond, in this similar figure, to a quadrilateral abcd, circumscribed about mnpq, and which can be constructed[14] by the solution of Exercise 213.

286. Other transformations that we have encountered change the figures to which they are applied in a more or less remarkable way.

An example is transformation by inversion, which changes a line of the original figure into a circle of the transformed figure. Another example is transformation by reciprocal polars. These transformations have been used in the complements to Book III to simplify the proofs of a number of theorems.

Another transformation, which we have only alluded to, but must be mentioned, is perspective. As we have defined it in plane geometry, it is only applied to figures composed of points on a straight line. We obtain the transformed figure by joining every point on the original figure to a fixed point, outside the line, then cutting the rays obtained with another line, then subjecting the figure obtained on this transversal to an arbitrary displacement.

287. It is appropriate to note an essential difference which distinguishes the transformation by polars from others considered above, such as similarity, inversion,

---

[14] The author has in mind here the following construction: using the method of Exercise 213, construct a quadrilateral similar to ABCD with sides passing through points m, n, p, q. Then the required points M, N, P, Q are those that correspond to m, n, p, q under the similarity in question. transl.

or perspective. These last are point transformations, in the sense that each point in the original figure corresponds to a definite point in the transformed figure. This is not true of a transformation by polars, in which a line in one figure corresponds to a point in the other.

Another transformation used in the text, and which shares this character of not being a point transformation, is the one which may be called a dilation, and which we have applied to figures formed by circles and lines. In this operation one increases or decreases (as the case requires) the radius of each circle by a certain quantity a. It may happen, of course, that the radius of a circle becomes zero, and the circle becomes a point. Conversely, under this transformation a point can be considered as a circle of zero radius, and may be transformed into a circle of radius a. Each line in the figure will be transported in a perpendicular direction, in one sense or the other, by the same quantity.[15]

The most important property of a dilation is that two tangent curves remain tangent, after the dilation has been applied appropriately (Exercise 59).[16] It is this property that we have used in 93 and 231.

288. Reduced forms. Since the purpose of a transformation is to simplify the figure we are working with, we should try to simplify the situation as much as possible.

To this end, we remark that the various kinds of transformations just mentioned involve some arbitrary elements. For example, for a homothecy we must specify the center and the ratio of similarity; for an inversion, we must specify the pole and the power;[17] for a dilatation, we must specify the quantity a discussed in the previous paragraph; etc.

Each type of transformation therefore includes infinitely many particular transformations.

Among these we must choose a particular transformation, such that the transformed figure satisfies one or several required conditions, and in general we want it to satisfy as many of these conditions as we can, taking into account what we noted in 280. The transformed figure will then be called a reduced form of the original figure.

Example I. We can always subject a circle to a dilation which reduces it to a point; it suffice to dilate by a quantity equal to the radius of the circle.

A reduced form, reduced by dilation, of a figure containing a circle, is one in which this circle is reduced to a point. We have used such a reduced form in 93 and 231.

Example II. Two circles with a common point can be transformed by a single inversion into two lines (by taking the common point as the pole). Two circles with no common point can be transformed into concentric circles (Exercise 248). In other words, the reduced form of a figure consisting of two circles is made up of two lines or two concentric circles, according as whether the original circles had or did not have a common point.

---

[15] A dilation of a circle or a line can be performed in two different ways, between which one can choose according to each particular case

[16] Dilation can be extended (using methods which go beyond the framework of this book) to figures which contain arbitrary curves, and it can be proved that this extended transformation still preserves the property of two curves being tangent. This property also holds for the transformation by polars, generalized in an analogous fashion. (See Volume II (Solid Geometry), 771.)

[17] We have seen (215) that the choice of the pole is the more important.

Example III. In the example of 285, we have used a reduced form of the required figure. The figure was reduced using a similarity, and the reduced form was determined by the requirement that quadrilateral MNPQ be transformed into the given quadrilateral mnpq.

289. Invariants. The advantage of a transformation can prove illusory, if, by simplifying certain properties of the figure, we have made others more complicated. We should apply a transformation only in those cases where the various properties in the statement are sufficiently simplified.

As it happens, in almost all the categories of transformations reviewed above, there are certain properties which are not changed at all, which remain, as we say, invariant.

Example I. We have seen that in a homothecy, the angles of the transformed figure are the same as those in the original figure. Likewise, the ratios of lengths do not change, and so on.

Example II. We have seen that a dilation changes tangent circles into tangent circles. Thus tangency is an invariant property for dilation.

Example III. The angle of two curves is an invariant for inversion (219).

Etc.

290. There can be no inconvenience in applying a transformation if only invariant properties are mentioned in the statement of the problem. In these cases, we can always assume the figure is in its reduced form.

Examples. Since dilations preserve tangency, we can assume, in constructing the common tangents to two circles, that one of the circles is reduced to a point. We followed this path in 93.

The same observation applies to the construction of a circle tangent to three given circles (231).

Tangency is also invariant for inversion. Thus, when searching for circles tangent to three given circles, we may assume that two of them are reduced to two lines or two concentric circles (Exercises 264–265).

Similar observations apply to the proof of theorems such as the following: All the circles which intersect two given circles at constant angles, are tangent to two fixed circles; or to the result of Exercise 285, etc.

291. Groups.[18] The fact that the various transformations we discussed possess invariants is a consequence of another property about which we will say a few words.

The transformation equivalent to the successive[19] application of two transformations is called the product of these two transformations. In other words, if the transformation S changes figure F into figure F', and the transformation T, applied to figure F , changes it into figure F , the product of these transformations will be the transformation that changes F to F .

---

[18] The final part of this note is addressed especially to those readers who have studied the complements to Book III.

[19] In general, the product of two transformations depends on the order of the factors. Thus, the product of two reflections in two different lines is a rotation or a translation which is double the rotation or translation which would make the first line coincide with the second.

Example. The result of 102 can be stated as follows: The product of two line reflections is a rotation or a translation.

Having said this, a set of transformations is said to form a group if the product of any two of them is also a member of this set.[20]

For example, the set of all homothecies is a group: this amounts to saying that two figure homothetic to a third are homothetic to each other. The set of all homothecies whose centers are on a given line also form a group because, as we have seen, the center of the product of two homothecies is on the line passing through their centers.

The set of all rigid motions form a group, because two plane figures, congruent to a third and with the same orientation, are also equal.

292. The collection of inversions does not form a group. The product of two inversions is not an inversion, but we may consider the group of transformations obtained by successive application of several inversions.

For the sake of brevity, let us call the product of any number of inversions, or line reflections, an S-transformation. This category includes, in particular, all rigid motions, because each rigid motion is the product of two line reflections; all homothecies, because a homothecy results from the application of two inversions with the same pole and different powers. Therefore all similarities are also S-transformations since a similarity is a homothecy, possibly followed by a rigid motion and a line reflection.

It would seem, from their definition, that to obtain all S-transformations we should consider all products of n inversions, n denoting an arbitrary positive integer, and that stopping at some fixed value of n would not suffice.

This however is not the case: every S-transformation amounts to an inversion followed or preceded by one, two, or three line reflections, except for the case when the transformation is a similarity (Exercise 252). Therefore, four simple operations (inversions or line reflections) suffice to produce any S-transformation.

Since the product of two S-transformations is again an S-transformations, the S-transformations form a group which one may call, for the sake of brevity, the group of inversions.

293. Two figures F, F which are changed into one another by a transformation in a group are said to be homologous with respect to this group. For instance, two congruent figures with the same orientation are homologous with respect to the group of rigid motions.

According to the definition of a group, two figures F, F , homologous to a third F , are also homologous to each other, since the transformation that passes from F to F is the product of the transformations which pass from F to F and from F to F .

The reduced form of a figure F with respect to a given group is a figure homologous to F with respect to this group, which satisfies certain additional conditions. If these conditions are sufficient in number, and well chosen, they will suffice to determine completely the reduced form F_0 of F.

---

[20] The original text makes no mention of the existence of an inverse transformation for each element of a group of transformations. transl.

Suppose this has been done. If we then apply one of the transformations of the group to F, the new figure F' obtained will also have the reduced form F_0, since the figures homologous to F' are exactly those which are homologous to F.

The reduced form of F is thus also the reduced form of any figure homologous to F, and therefore every property of the reduced form is an invariant property of F.

294. We will clarify this remark by an example.

Consider the figure formed by four arbitrary points A, B, C, D. We propose to find the properties of this figure which are invariant for the group of inversions. For this purpose, take the inverse of the figure, using an inversion I with point A as its pole. If the inverse points for B, C, D are b, c, d respectively, they form a figure homologous to the original (a reduced form) with respect to the group, in which one of the four points (the one that corresponds to A) is thrown to infinity. We will see, by retracing our general argument as applied to this special case, that the angles of triangle bcd are the invariants of the figure $ABCD$. (A direct proof of this fact is the object of Exercise 270.)

Let A', B', C', D' be the points corresponding to A, B, C, D under an arbitrary transformation T of the group. We operate on these points just as we operated on the original points; that is, we apply an inversion I' with pole A' to obtain the homologous points b', c', d'. We can pass from the figure formed by triangle bcd and a point at infinity to the figure formed by triangle $b'c'd'$ and a point at infinity by a transformation in our group; namely, the product of the three inversions I, T, I'. As we know, this transformation is either a similarity, or an inversion followed by line reflections. The second alternative occurs only if T itself is an inversion, because then it would send a point at infinity into a finite point (namely, the pole). We conclude that the triangles bcd, $b'c'd'$ are in fact similar. QED

Thus, the angles and the ratios of the sides of the triangle bcd are indeed the invariants of the figure $ABCD$ relative to the group of inversions. There are only two independent invariants, that is, knowledge of two of them is sufficient to calculate the others: two angles of triangle bcd are indeed sufficient to construct a triangle similar to it.

295. We have just seen that the existence of invariants follows from the existence of of a group; conversely, the set of all transformations which have the same invariants forms a group. Indeed, if two transformations do not change a certain property, the same is true for their product.

Example I. A homothecy changes every segment into a parallel, proportional segment. Conversely, every point transformation with this property is a homothecy (142). Thus, the collection of homothecies forms a group. The reasoning of 144 is simply a different form of the argument just made.

Example II. A perspective preserves the cross-ratio of four points and, conversely, every transformation applied to a system of points on a straight line, and which conserves the cross-ratio, is a perspective.[21]

Thus the set of perspectives forms a group.

---

[21] This can be proved by moving the transformed figure so that one point coincides with its corresponding point, while the two lines remain distinct. We are then led to Exercise 233.

We will limit ourselves to these remarks on the general properties of transformations. As for their use, we refer the reader to the work of Petersen already mentioned.

Note B:
On Euclid's Postulate

I

296. We have assumed, as an axiom (40), that through a point there cannot pass more than one parallel to a given line.

This statement appears in the Elements of the Greek geometer Euclid,[22] where the principles of geometry are described completely for the first time, and with remarkable perfection, as well as in all subsequent expositions (which are all based on this first exposition). More precisely, Euclid gives the statement of 41 (Corollary I), which is equivalent to it:

If two lines make, with the same transversal, two interior angles on the same side whose sum is different from two right angles, then the lines are not parallel, and they intersect on the side of the transversal where the sum of the interior angles is less than two right angles.

This statement is taken to be among those considered obviously true.

The followers of Euclid, from antiquity to the middle ages and into modern times, have not stopped marveling at the place assigned to this proposition, which indeed does not exhibit the same obvious character shared by other propositions accepted without proof. Indeed, it does not seem any more evident than many of the propositions in whose proof it is used. In particular (and we will soon return to this point), they found it strange that Euclid accepted as obvious for straight lines a fact which is not at all true for curves in general.[23]

297. Many attempts were therefore made to prove this postulate: all of them failed. In particular, trying to argue by contradiction, and deducing all the possible consequences if the postulate is assumed false, one obtains a series of conclusions which are very different from the conclusions of the usual theory of parallel lines. But however far we push these conclusions, they never yield (at least when they are deduced correctly) a contradiction among themselves, or with earlier propositions, a contradiction which would prove the impossibility of the initial hypothesis.

298. The great mathematician Gauss[24] asked himself whether such a contradiction did in fact exist, if perhaps the opposite of Euclid's postulate is in fact compatible with the other axioms of geometry and with the consequences which would follow. In other words, perhaps it is impossible to prove the proposition in question.

---

[22] Around 300 B.C.

[23] Wallis, 1663. Cf. Stäckel et Engel, Die Theorie des Parallelinien, von Euklid bis Gauss, Leipzig, Teubner, 1895.

[24] 1777–1855.

Around the same time Lobachevsky[25] and Bolyai[26] looked at this same hypothesis independently, and constructed a geometry having in common with ordinary geometry all the propositions preceding, or independent of, Euclid s postulate, but in which all the others statements are modified. The results arrived at in such a geometry (called non-Euclidean geometry) often take an intriguing, paradoxal form, and contradict our usual way of visualizing things. But no matter how amazing these results may seem at first, there is none whose absurdity can be proved. Here are some of the simplest examples.

In non-Euclidean geometry:

Through a point A outside a line D, but in the plane which contains them, there are infinitely many lines which do not intersect[27] D. All of these non-secant lines are situated within a certain angle with vertex A (and in the corresponding vertical angle). This angle, called angle of parallelism, increases with the distance from the point to the line;

Every line D interior to the angle of parallelism has a unique common perpendicular with line D, which gives the shortest distance between points on the two lines. If a point M moves along D and away from the foot of the common perpendicular, its distance to D increases constantly and indefinitely. The same is not true of lines D_1, D_2 which are the sides of the angle of parallelism. These lines do not intersect D, but they approach D more and more closely as we move along them away from the point A, in the direction which makes an acute angle with the perpendicular from A to D. If a point M moves along one of these lines in this direction, its distance to D tends to zero. The locus of the points in the plane which are equidistant from a fixed line is a curve.

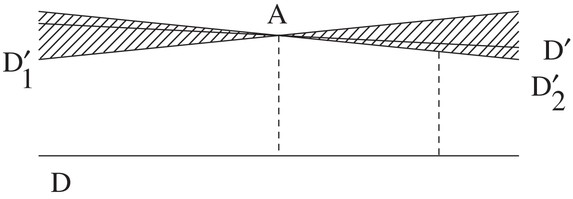

Figure 222

The sum of the angles of a triangle is less than two right angles, and the difference is proportional to the area of the triangle. It follows that this area is always less than a certain quantity, no matter how long the sides of the triangle may be (when the sides are very long, the angles become very small, and the triangle becomes very thin, as indicated in the figure). In the same way, the sum of the angles of a polygon with n sides is less than 2n 4 right angles, and the difference is proportional to the area of the polygon. Consequently, there are no rectangles: if a quadrilateral has three right angles, the fourth must be acute.

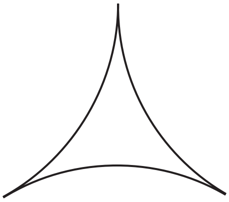
---

[25] 1793 1856.

[26] 1802 1860. Non-Euclidean geometry was also discovered, more or less completely, in a variety of places (Cf. the reference above to Stäckel and Engel).

[27] We can show that the Euclidean postulate is always true, or always false: we cannot show the existence of a single point outside a single line, for which the parallel through the point to the line is unique, without also being able to prove this uniqueness for all possible points and lines.

There are no similar figures[28] except, of course, congruent figures. Two triangles are congruent if they have equal corresponding angles. The assumption that there exist two non-congruent similar triangles is equivalent to the assumption of Euclid's postulate.
Etc.



There are in fact infinitely many non-Euclidean geometries. The relations between the various parts of a figure, under Lobachevsky's hypothesis, include in fact a certain number k^2, determined once and for all, but which can have an arbitrary value: for instance the ratio (which is constant, as we just mentioned) between the area of a triangle and the supplement of the sum of its angles. Euclidian geometry can be viewed as a limiting case of the non-Euclidean geometries: it corresponds to $k =$.

299. Is non-Euclidean geometry, which seems paradoxical, but also seems to be logically possible, really possible, as believed by its advocates? It may be that this is only an impression, due to the fact that the consequences have not been pushed far enough. Would it be possible, through deeper or better investigation, to encounter a contradiction which presented itself neither to Gauss, nor to Bolyai, nor to Lobachvsky?

We can state with confidence that this is not the case. Without developing in detail the reasoning which validates this statement,[29] we will borrow a simple and striking manner of presenting them from H. Poincare.[30]

Imagine a sphere S inside of which there is a medium whose temperature and index of refraction are variable. Suppose there are objects moving in this medium, and that their their movements are sufficiently slow and their specific heat sufficiently small that they immediately achieve temperature equilibrium with the medium; moreover, all of these objects will have the same coefficient of dilation, so that we can define the surrounding temperature by the length of any one of them. Let R be the radius of the sphere, and the distance from a point in this medium to the center of the sphere: we will assume that the absolute temperature[31] is $R^2 \quad ^2$ and that the index of refraction is $\frac{1}{R^2 \quad ^2}$.

---

[28] Contrary to our usage in the rest of this book, here we are speaking of similar figures as figures with equal corresponding angles, and proportional corresponding sides.

[29] We may note an analogy between the results mentioned above and certain results of spherical geometry, to which they are opposed in a certain sense. Thus, the sum of the angles in a spherical triangle is greater than two right angles, and the difference is proportional to the area of the triangle; two spherical triangles with equal corresponding angles are either congruent or symmetric, etc. In fact, the geometry of certain surfaces (called pseudospherical surfaces) is identical to Lobachevski's geometry. It is in this way that the logical possibility of non-Euclidean geometries was established, but this proof is not complete: 1 because pseudospherical surfaces cannot be considered to be limitless in all directions, as we would expect from a plane; 2 because they only pertain to plane non-Euclidean geometry, and would not prevent in principle a proof of the postulate by considerations of geometry in space.

[30] Revue generale des sciences pures et appliques, Volume III, 1892, p. 75.

What would an intelligent being think, who had never left such a world?

(1) Since the dimensions of two small objects transported from one point to another vary in the same ratio, because they have the same coefficient of dilation, these beings would believe that these dimensions have not changed. They would have no idea of what we call differences in temperature. No thermometer could reveal it, since the dilation of the container would be the same as that of the thermometric liquid.

(2) They would believe that this sphere S is infinite: they could never reach its surface because, as they approach it, they enter colder and colder regions; they would become smaller and smaller and, without realizing it, would make smaller and smaller steps.[32]

(3) What they would call straight lines would be circles orthogonal to the sphere S, for three reasons:

1 : They would be the trajectories of light rays;

2 : Measuring various curves with a ruler, our imaginary beings would find that these circles are the shortest paths from a point to another: indeed, their ruler would contract or dilate when passing from one region to another, and they would not doubt this phenomenon;

3 : If a solid body rotated so that one of its lines remained fixed, this line could only be one of these circles: this is because, if a cylinder turns slowly and is heated on one side only, the locus of the points which do not move will be a convex curve on the heated side, and not a straight line.

It follows that these beings would adopt Lobachevski's geometry.[33]

We see now that it is in fact impossible to prove Euclid's postulate with the help of earlier propositions: if such a proof existed, it would have to be admitted by the fictitious beings just described (since all earlier propositions are still true, from their point of view); but it would lead to an incorrect result since, for these beings, the postulate is false.

II

300. What role then must we assign to this proposition, which is not as obvious as the axioms, and which cannot be proved as a theorem?

This role is that of a definition. To explain what we mean by this, we refer to the preceding note (Note A, 271).

As we have seen there, we must have a definition for each term figuring in our statements, a definition whose role in the reasoning can be made clear by substituting it for the defined term each time it occurs.

---

[31] In physics, this is the temperature measured from a zero point, so that it is proportional to the volume of a thermometric body. (In physics, it is specifically assumed that this body is a gas sufficiently far from its liquefying point; here it can be any object, since all of them have the same coefficient of dilation, and the absolute temperature is proportional not to the volume, but to an arbitrary linear dimension.)

[32] We could add that, by the properties we have assumed for the index of refraction, they could not see what happens outside the sphere.

[33] The arbitrary constant introduced in non-Euclidean geometry is represented here by the radius R of the sphere.

Of course, there are terms which have not been, and cannot be, defined, because a notion can only be defined by use of earlier notions,[34] which is impossible for the first notions to be introduced.

But, since these notions are clear in themselves and have a number of obvious properties, the role of the definition (which is still needed in each case, as we have just recalled) is replaced by these properties, which we assume without proof. We proceeded this way in the case of the straight line, which we did not actually define in the proper sense, but rather defined indirectly, by assuming its fundamental properties.

301. It is important that we assume enough of these propreties to be able to characterize the notion they define, that is, to distinguish it from every different notion. For instance, we would have given a bad definition of the straight line if, instead of assuming, as we have done:

(1) that every figure congruent to a straight line is a straight line; and conversely, two lines can be superimposed in infinitely many ways;
(2) that one and only one line passes through two points,

we would have assumed the first property, but not the second. This first property is not, in fact, peculiar to straight lines: it is also satisfied, for instances, by circles with a radius of 1 meter. It would have been impossible to prove, starting from this definition, any property of straight lines which is not also shared by these circles. For instance, we could not have proved that the sum of two angles of a triangle is less than two right angles because this is not always true for curvilinear triangles whose sides are arcs of congruent circles.

302. All geometry rests on a fundamental notion, that of a rigid motion, which we have introduced in 2. At that point, we considered as self-evident the idea of a figure which can be moved without changing its shape or size; in other words, what we have called an invariant figure. Let us try to study how this notion is defined by its properties.

Given a figure which is subject to a rigid motion, and an arbitrary point M, we can imagine that this point is permanently attached to this figure and follows it in its motion, so that it comes to occupy some position M'. We can thus say that the rigid motion associates to each point M in space another point M', which is the position to which the point M is transported. A rigid motion is therefore a point transformation[35] of space.

It is also an obvious property of the notion we consider that two rigid motions, applied successively, are equivalent to another rigid motion. In other words, these transformations form a group.[36]

We can thus say:

An invariant figure is a figure to which we apply only transformations from a certain group (called the group of rigid motions), having the following properties:

(I)

There are infinitely many transformations in the group which transport a point A onto an arbitrary position A'.

---

[34] For instance, we cannot define a circle as the locus of points in a plane situated at a given distance from a given point of this plane , without having defined earlier the notions of distance, plane, and geometric locus.

[35] See Note A, 287, 291, and the passages that follow.

[36] Ibid.

> In general, there are no transformations of the group which, at the same time, bring two given points A, B to two given positions A′, B′. In order for such a transformation to exist, a certain quantity, depending on A and B, must be equal to the corresponding quantity for A′, B′.
>
> If there is a transformation in the group which takes A, B onto A′, B′, then there are infinitely many. In particular, there exist infinitely many transformations which leave two points A, B fixed but, for all of these transformations, there are infinitely many other points which are fixed. These points form a unique line, which extends indefinitely, called a straight line. One and only one straight line passes through two points. There exist surfaces (called planes) such that every line which has two points in a plane is entirely contained in it; one such surface passes through three arbitrary points in space,

etc.[37]

303. It is nonetheless essential to observe that the preceding definition, like all other indirect definitions, implies the following axiom:

AXIOM (A): There is a group possessing property (I).

We will also remark that the notions of straight line and plane derive from the notion of rigid motion, without which they cannot be defined.

304. Euclideans and non-Euclideans agree that the group of rigid motions satisfies property (I), and they therefore assume axiom (A). They are divided by the question as to whether the following statement is true or not:

(II)

> Through a point outside a line there is only one line parallel to a given line.

This statement must then express a property of the group of rigid motions, because straight lines and planes are defined by this group. The question then takes the following form:

Does the group of rigid motions defined by property (I), also satisfy property (II)?

Now, if it is not possible to answer this question, the reason can only be that it is ill posed: that the question does not have a precise meaning.

Indeed, the group of rigid motions is not well defined by property (I). If (in agreement with axiom (A), which we assume) there exists a group with these properties, then there are infinitely many such groups. The inhabitants of Poincaré’s world would have an entirely different notion from ours of an “invariant figure”, since the objects which they move would dilate or contract in the process. However, their group of rigid motions would satisfy property (I) in the interior of the sphere (that is, for all of space about which they could reason, which is infinite from their point of view).

The resolution of the question is now clear. Statement (II) will be precise if, among all the groups satisfying property (I), we reserve the name group of rigid motions for a group satisfying the condition of this statement; in other words, if this group is defined not just by property (I), but by properties (I) and (II).

---

[37] We do not pretend to list here all the properties needed to define the group of rigid motions. By “Property (I)” we mean those properties which we have assumed in Book I, prior to Euclid’s postulate.

305. But an objection can still be raised. Just as the original definition implied axiom (A), the one we now propose is not possible unless we resolve the following question:

Does there exist a group which satisfies both conditions (I) and (II)?

The answer is in the affirmative. One proves (assuming, of course, axiom (A)) that among the infinitely many groups satisfying condition (I) there are some which are non-Euclidean (for which Euclid's postulate is false) and some which are Euclidean (for which it is true).

Now every difficulty is removed. Euclid's postulate is part of the definition of the fundamental notions of geometry.

306. Are we then saying that one should not ask whether this postulate is true or false, that such a question is totally devoid of meaning?

We would have the right to do this, if we were free to define the notions of geometry in a completely arbitrary manner. But this is not the case: these notions are provided us by experience. The idea of an invariant figure is suggested by those invariant figures (namely, the solid bodies) which nature offers. We must define invariant figures and rigid motions with these solids and their displacements in mind if we want geometry to be applicable to real objects.

307. We see therefore that there is indeed a question about Euclid's postulate: the question is whether the definition given above accords with experience, whether or not the properties of natural motions which we observe are analogous to the properties of the Euclidean group.

But this is no longer a mathematical question. The solution of such a problem does not depend on reasoning, but on observation.

If we have been led to develop Euclid's conception rather that Lobachevsky's, it is because our senses, within their limitations, show us that the postulate is reasonably exact. We see that two lines parallel to a third are parallel, that there exist similar figures with arbitrary ratios of similarity, that there exist rectangles, etc.

308. This is, of course, a crude verification. To submit it to deeper examination, we must measure, with the greatest possible precision, the angles of a triangle, to discover whether their sum is equal to two right angles. We should use as large a triangle as possible, since it is for large triangles (298) that the discrepancy between the two hypotheses is greatest. Experiments have shown (to the extent allowed by experimental difficulties) that this equality is verified (or at least that the discrepancy is smaller than observational errors).

We would then be justified in asserting that the geometry which represents reality most accurately is Euclidean or, at least, it differs very little from Euclidean (in other words, the constant k is very large, or, if the geometry is comparable to Poincaré's imaginary world, the radius R is enormous relative to all usual lengths). In one word, Euclidean geometry is physically true.

308b. Things have changed following the recent[38] developments in our ideas about physics (the Theory of Relativity).

This new theory has profoundly modified the science of motion or kinematics (which is a direct application of geometry). The models used for velocities in the old kinematics were based on principles of Euclidean geometry (mainly on properties of parallelograms). This is still assumed to be practically correct for "very small" speeds — that is, measured by very small numbers in comparison to the speed V of light (which is approximately 300000 kilometers per second) — and so for all ordinary speeds,[39] but not for speeds comparable to V. For such speeds, it is Lobachevski's geometry which corresponds to physical reality. The role of the radius R is played by V.

---

[38] That is, at the time the author was writing. — transl.

Non-Euclidean geometry (and even other, more general, geometries) enter into still other parts of the theories of physics (General Relativity). However, one can see from the preceding discussion that none of these changes has any influence on everyday life (for instance, on the work of the engineer). Euclid's geometry retains its validity for all figures which we can view at a glance, or measure directly.

---

[39] Since V is so large, the speed of a military projectile, for instance, is "very small".

Note C:
On the Problem of Tangent Circles

309. As we discussed in 236, Gergonne s method for finding the circles tangent to three given circles does not apply in all possible cases: it gives no result if the three centers are collinear. We added that this inconvenience disappears if the solution is presented in a form in which the properties utilized do not change when an arbitrary inversion is applied. This is what we propose to do in this note.

Let the given circles be A, B, C, and take point b on B, antihomologuous[40] to a point a of A, with respect to a center of similarity S_{12} of the circles A and B. Let c be the point antihomologuous in C to b, with respect to a center of similarity S_{23} of B, C. The circle passing through a, b, c cuts the three circles again in a , b , c ; it cuts them at equal angles (227), so that a , b are antihomologous with respect to S_{12}, b , c with respect to S_{23} and, moreover, the pairs a, c ; c, a are antihomologous[41] with respect to a center of similarity S_{13} of circles A, C.

Replacing a by another point a_1 of circle A, we obtain a new circle $_1$, analogous to . Point S_{12} has the same power with respect to and $_1$ (equal to the power of the inversion which transforms A into B); the same is true for point S_{23}. Thus the radical axis xy of circles , $_1$ is an axis of similarity for the given circles, and it is clear therefore that the center of similarity S_{13} which we are discussing, belongs, along with the first two, to this axis of similarity.[42]

310. We see now that there are four series of circles (corresponding to the four axes of similarity), and that the circles in each series have the same radical axis. Conversely, every circle which has a common radical axis with two circles of one of these series must belong to that series (since it corresponds to itself in the two inversions with poles S_{12} and S_{13}). Therefore each of these series is determined by two of its circles, or by one circle and the radical axis xy. We can, generally, take this circle to be the circle $_0$, belonging to the series, which is orthogonal to the three given circles (227b).

The locus of the centers of the circles in one of the series is the perpendicular from the radical center of A, B, C to one of their axes of similarity.

---

[40] See 227b. transl.

[41] The fact that a is antihomologous to c rather than c is established by noting (cf. 227) the angles made by with A, C at the points a, c have the same orientation (rather than opposite orientation, as would be the case for antihomologous points).

[42] The reasoning does assume that the point S_{13} is the same for and for $_1$. But if this were not true, at least one of the two points S_{13} corresponding to and $_1$, for instance, the one that corresponds to $_1$, would be collinear with S_{12} and S_{23}. This point would then have the same power with respect to $_1$ as to ; namely, the power of the inversion which transforms A into C. Therefore the circle $_1$ would intersect A and C in points which correspond to each other in this inversion.

311. The circles which are tangent to the given circles obviously belong to the series just mentioned and, conversely, every circle in one of these series which is tangent to one of the given circles must be tangent to the others as well.

The problem of tangent circles is thus reduced to the following:

Find a circle with the same radical axis as two given circles , $_1$, and tangent to a third given circle A (Fig. 223).

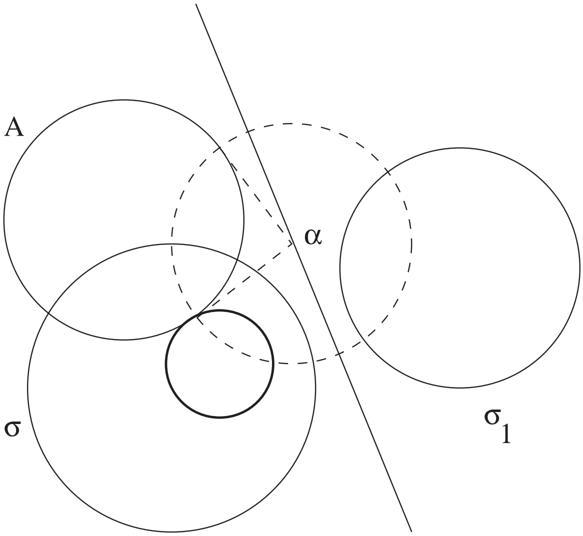


Figure 223

This last question is easily solved: if a is the point of contact of the required circle with the circle A, the circle passing through a and orthogonal to and $_1$ will also be orthogonal to the required circle, and therefore to A. These conditions allow us to find a (158, Construction 13). In other words, we have to draw a tangent to A passing through the radical center of , $_1$ and A, to find the required point of contact. Conversely, it is easy to see that the points obtained in this manner correspond to solutions of the problem.

As we remarked above, one of the circles , $_1$ can be replaced by their radical axis xy, so that the solution to the problem of tangent circles can also be reformulated as follows:

Through a point on circle A and its two antihomologous points, draw a circle . The common chord of A and intersects the axis of similarity xy at a point . The tangents from to circle A give the points of contact of the required circles.

311b. When circle is taken to be the circle $_0$ whose center is the radical center I of the three given circles, and which intersects them at right angles, we recover Gergonne s original solution. The common points of A and $_0$ are indeed the points of contact of the tangents from I to A, so that the common chord of the two circles is the polar of the point I with respect to A. The polar of the intersection point of this chord and xy is thus in fact the line joining I to the pole of xy.

We see now why this solution does not work when the centers of the given circles are collinear: both the circle $_0$ and the line xy coincide with the line of the centers. In order to remove the difficulty, it suffices, as we have said, to use a circle different from $_0$.

The method we offer also has the advantage (over Gergonne's method) of being applicable when one or several of the given circles are replaced by points or lines, yielding directly the points of contact with one of the lines: these are situated on a circle whose center is the intersection of the given line with the axis of similarity xy, and which intersects the circle $_1$ at right angles. This construction obviously generalizes Construction 14 (159). This construction even applies when there is no circle left, which is not the case for Gergonne's solution. It fails only when all three circles are reduced to points.

312. It follows from 309 that the common chord of circles A and is precisely the line we have called aa , where a is the point antihomologus to c.

Thus the construction indicated above consists in:

determining the point b antihomologous to a (which is taken arbitrarily on circle A) with respect to the center of similarity S_{12}, the point c antihomologous to b with respect to S_{23}, and the point a antihomologus to a with respect to S_{31};

joining aa ;

repeating this construction starting with another point a_1 on A.

The intersection of the two chords aa , a_1a_1 thus obtained is the point , from which we must draw tangents to circle A in order to obtain the points of contact of the required circles.

Discussion. Unlike Gergonne's form of the solution, ours allows a simple discussion of the number of actual circles which solve the problem.

We observe first that the above construction is or is not possible according as whether the point is exterior or interior to A.

Take an arbitrary point a_1 close to a. Clearly, the point will be inside A if the small arcs aa_1, a a_1 have the same sense, and outside if they have the opposite sense.

We must therefore determine whether, as point a moves along the circle A, point a moves in the same sense, or in the opposite sense.

To answer this question, we start by studying the sense in which the point b will move.

Since the point homothetic to a with respect to S_{12} clearly varies on B in the same sense as a on A, we see immediately (cf. 223) that b turns in the same sense as a if S_{12} is interior to B, and in the opposite sense if S_{12} is exterior.

Let us agree to say that a center of similarity S_{12} of two circles A, B is positive if it is outside these two circles, and negative if it is inside the circles. This amounts to saying that a center of similarity is considered positive or negative depending on whether, through this point, there are or are not real common tangents to the two circles.

If two circles are exterior, their centers of similarity are positive. If they intersect at two points, the exterior center of similarity is positive, and the other negative. If one circle is inside the other, both centers of similarity are negative.

According to this convention, whether the sense of the motion of b is the same as that of a depends on whether the center of similarity S_{12} is negative or positive.[43]

Similarly, the point c moves on C in the same sense as b on B, or in the opposite sense, according as S_{23} is negative or positive; and a moves in the same sense as c, or in the opposite sense, according as S_{31} is negative or positive.

Combining these remarks with the earlier ones, we see that is outside A in other words, there are two real points of contact if, among the three centers of similarity on the axis xy, one or three are positive.

To calculate the total number of real circles which answer the problem, it will suffice to apply this remark to each of the four groups of collinear centers of similarity.

In what follows, we will use the digit 0 to denote the group of three direct centers of homothecy; the digit 1 for the group for which B, C are directly homothetic, and for which both are inversely homothetic to A; and the digits 2 and 3 for the analogous groups obtained by replacing A by B, and then by C.

312b. Having said this, it is easy to see that (excluding the cases when two of the circles are tangent[44]) there are eleven possible positions for the three circles.[45]

In each case, the preceding considerations would immediately yield the result. For instance, in case I, all the centers of similarity are positive, so that there are eight solutions, while in case V, there are only four, because the centers of similarity of A with B or C are all negative. We would have to use the positive center of B and C, (that is, the exterior center of similarity) in order to obtain real solutions.

We thus arrive at the following table which indicates, in each of the eleven cases, the positive and negative centers (the letters S indicate the exterior centers of similarity, and the letters S the interior ones), the number of solutions, and the homothecy groups (numbered 0, 1, 2, 3, as above) which produce them.

---

[43] That is, the sense of motion is the same if the center of similarity is negative, and opposite if the center of similarity is positive. transl.

[44] These must be considered as limiting cases of those where the circles have 0 or 2 intersections, between which they are intermediary. If two of the given circles are tangent, then two of the solutions will coincide.

[45] In each of the positions shown in Figure 223b, the letters A, B, C can be permuted. The different figures which then correspond to these permutations will allow the same number of solutions, which is why we have kept only one of them in our enumeration.

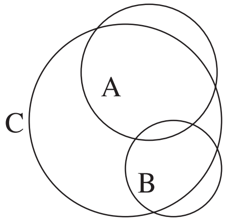

Figure XI

Figure XI is meant to include other possible positions in which the intersections of A and B, for instance, are both interior to C (instead of one inside and one outside, as in Fig. 223b). This would not change the result of the current discussion. The same remark could be applied to other problems, such as finding the circle orthogonal to A, B, C. These are numbered I to XI in Figure 223b.

We may observe that the number of cases to examine could have been reduced considerably by taking into account that cases I and II can be reduced to each other by an inversion; the same is true of cases III, IV, cases V, VI, VII, VIII, and cases IX, X.

Note D:
On the Notion of Area

313. In Book IV of this work, we have taken the usual path of assuming a priori (243) that it is possible to define the area of a polygon; that is, that we can associate a number to each polygon (called its area) possessing the following properties:

I. Two congruent polygons have the same area, regardless of their position in space;

II. The polygon P , the sum of two adjacent polygons P, P , has area equal to the sum of the areas of P and P .

The possibility of such a correspondence amounts, in this theory, to a postulate. But this postulate is useless. The fact in question need not be assumed, but can be proved by the following method, which must be regarded, for this reason, as superior to the previous one.

314. Theorem. In any triangle, the product of a side and the corresponding altitude is the same, regardless of the chosen side.

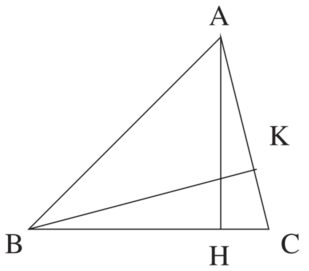

Figure 224

Let the given triangle be ABC (Fig. 224), in which altitudes AH, BK correspond to the sides BC, CA respectively. Right triangles ACH, BCK have angle C in common; therefore they are similar and give us

$$\frac{AH}{AC} = \frac{BK}{BC},$$

so that $BC \cdot AH = AC \cdot BK$. QED

The area of the triangle is what we call the preceding product, multiplied by a constant k, chosen once and for all, and whose choice will be discussed soon. This area is zero when the triangle ceases to exist properly speaking (when the three vertices are collinear) and only in that case.

The areas of triangles with the same altitude are proportional to their bases. It is clear that two congruent triangles have the same area.

315. Consider an arbitrary point O in the plane of a triangle. By joining it to the three vertices, we form three new triangles with the three sides of the original triangle as bases, and vertex O. One of these triangles will be said to be additive (for instance, triangle OBC in figure 228) if it is on the same side of the original triangle, relative to the common base; it will be called subtractive (for instance, triangle OBC in Figure 229) otherwise.[46]

Theorem. If an arbitrary point O is given in the plane of a triangle, and joined to its vertices, the sum of the areas of the additive triangles, minus the sum of the areas of the subtractive triangles, equals the area of the original triangle.

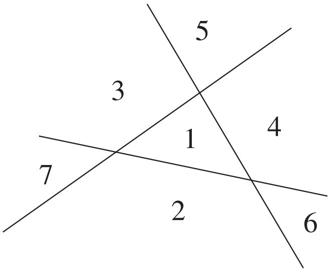

Figure 225

The sides of the given triangle divide the plane into seven regions (figure 225): one interior region; three regions (2–4 in the figure) separated from the first by one of the three sides; and three last regions (5–7) in the vertical angles corresponding to the angles of the triangle.

We now distinguish five cases.

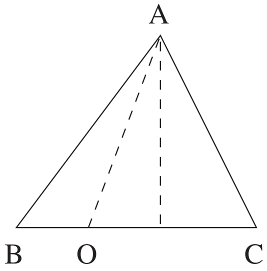

Figure 226

1°. Point O is on one of the sides. If point O is taken on side BC of triangle ABC (Fig. 226), there is no triangle OBC. Then the sum of the areas of the two triangles OAB, OAC is equal to the area of ABC because these triangles have the same altitude (the perpendicular from A to BC) and the third base BC is the sum of the first two bases OB, OC.

---

[46] If the vertices of the triangle are given in a fixed (but arbitrary) order, and those of one of the triangles with vertex O are given in such a way that the common vertices are in the same order, we can also say that this last triangle is additive or subtractive, depending on whether it has the same sense of rotation as the original triangle or not.

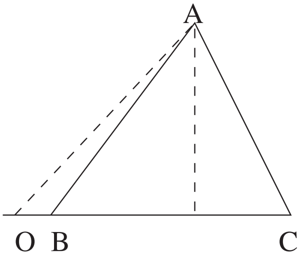

Figure 227

2°. Point O is on the extension of a side. If point O is on the extension of BC (Fig. 227), there is no triangle OBC. As for the triangles OAC, OAB, their difference is indeed ABC: these triangles have the same altitude, and the third base BC is the difference of the first two OC, OB.

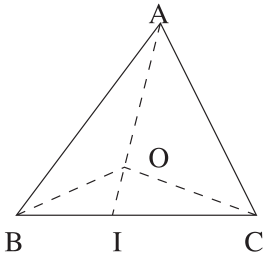

Figure 228

3°. Point O is inside the triangle (Fig. 228). We extend OA to its intersection I with BC. Triangle ABC is equal (1°) to the sum of the triangles ABI, ACI, which can in turn be decomposed into AOB + BOI, AOC + COI. Now the triangles AOB, AOC are additive triangles, and the triangles BOI, COI together give a third additive triangle BOC.

4°. Point O is outside triangle ABC, but inside one of its angles, for example A. If I is the intersection of OA and BC, the sum of the two additive triangles AOB, AOC can be replaced (1°) by the sum of the four triangles AIB, AIC, OIB, OIC. The sum of the first two of these is ABC, and the sum of the other two is OBC. Thus we have

$$AOB + AOC = ABC + OBC,$$

or

$$OAB + OAC - OBC = ABC,$$

which is the required relation, since triangle OBC is subtractive.

5°. Point O is in a vertical angle corresponding to one of the angles of the triangle, for instance A (Fig. 230). In this case A is inside triangle OBC, so that (3°)

$$OBC = ABC + OAB + OAC,$$

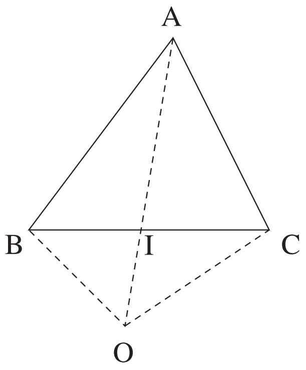

Figure 229

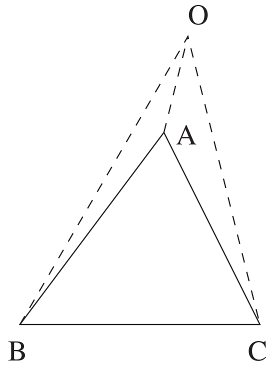

Figure 230

or

$$OBC - OAB - OAC = ABC,$$

which is the required relation because triangle OBC is additive, and the other two subtractive.

316. Now consider an arbitrary polygon ABCDE (Fig. 231) and an arbitrary point O in its plane. Joining O to the vertices, we form triangles with vertex O and the various sides as bases. Each of these triangles will be considered additive or subtractive depending on whether it is on the same side as the polygon,[47] relative to the common side.

Theorem. Consider a polygon, decomposed in an arbitrary manner into a number n of triangles, and a point O of the plane, joined to all its vertices. The difference S between the sum of the areas of the additive triangles with vertex O and the sum of the areas of the subtractive triangles (or just the first sum, if the second one does not exist) is equal to the sum Σ of the areas of the n triangles into which the polygon was decomposed.

---

[47] When we talk of the position of the polygon, relative to one of its sides, we refer to the region which is immediately next to this side. For instance, triangle OAB (Fig. 231) is additive because it is on the same side of AB as the area shaded in the figure.

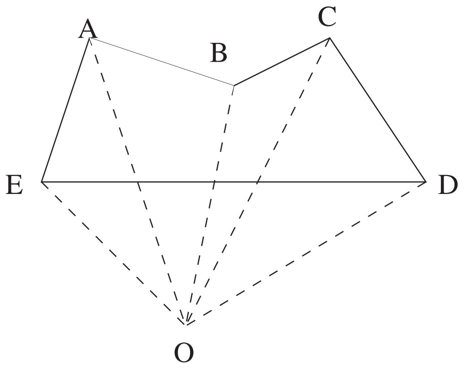

Figure 231

If the theorem is true for two adjacent polygons P, P decomposed into triangles, it is also true for their sum P . Indeed, we can distinguish two parts in the perimeters of P and P : the sides (or parts of sides) which are not common to both polygons, but which form part of the perimeter of P , together with their additive and subtractive triangles,[48] and the common sides, or parts of sides. To these common sides correspond triangles which are additive for P or P , and subtractive for the other (since P, P are situated on different sides of the common side) and which will therefore disappear when calculating the sum of the quantities S relative to these two polygons. Thus this sum is indeed the quantity S formed with polygon P . On the other hand, the quantity for P is obviously the sum of the analogous quantities for P and P , so that the equality of the quantities S and is true for this third polygon P if it is true for the first two.

We can now consider the proof finished, because the theorem has been proved when n = 1 (in which case it reduces to the preceding theorem) and, if it is true for some value of n, it will be true for the following value n + 1 (since a polygon composed of n + 1 triangles is the sum of a triangle and a polygon composed of n triangles).

Corollaries. The quantity S is independent of the choice of the point O, since the quantity does not depend on this choice.

Likewise, the quantity is independent of the decomposition of the polygon into triangles.

317. The common value of the numbers S and will be called the area of the polygon.

Two congruent polygons have the same area since they can be decomposed into pairs of congruent triangles; also, the preceding proof shows that, when two polygons are adjacent, the area of their sum is equal to the sum of the partial areas.

In other words, the areas thus defined possess properties I and II.

---

[48] We may have to divide a side of the polygon P into several segments, some of which will be shared with P , and some not, and to replace the triangle with vertex O and this segment as base with partial triangles whose bases are the smaller segments. This will not change the quantity S, since these partial triangles add up to the total triangle (by the preceding theorem). We can do the same with P and P .

318. It follows that it is impossible to decompose a polygon into parts which, assembled differently (but so that they are still adjacent to each other), form a polygon that lies inside the original one.

This is true because the new polygon would have the same area as the first.

This proposition is not proved by the theory given in the text, since the existence of areas is taken as a postulate.

319. We have not yet discussed the choice of the constant k. It is clear that changing this number amounts to changing all areas into proportional areas. We have already remarked (244) that such a change would not affect its two fundamental properties.

We can then determine k in such a way that the square with a side equal to the unit of length has unit area. Now this square is composed of two triangles, each of which has both a base and an altitude equal to the unit length. Its area is 2k, so that we choose $k = \frac{1}{2}$. The area of any triangle will then be half the product of its base and altitude. The areas determined in this way are then just those which we learned how to calculate in the text.[49]

---

[49] The arguments given in the text show that the method we have used earlier to calculate areas is the only one which has the preceding properties, while at the same time satisfying the condition that the square with unit side has unit area.

Appendix:
Malfatti's Problem

The principles established in the text (227 236) and in Note C, concerning tangent circles and circles isogonal to two given circles (that is, intersecting them at equal angles) allow us to present a solution to a famous problem, due to Malfatti, and stated as follows:

Given three lines (a_1), (a_2), (a_3) in a plane,[58] find three circles (x_1), (x_2), (x_3) each pair of which are tangent and, in addition, (x_1) is tangent to (a_2, a_3), (x_2) is tangent to (a_3, a_1), and (x_3) is tangent to (a_1, a_2).[59]

The solution was first given by Steiner, and we will follow an exposition by Schröter. It involves the property established in 228.

We have seen there that the circles which are tangent to two given circles C, C or, more generally, which are isogonal to C, C, are divided into two series which can be characterized (in the case where the inversions which change C into C have positive power) by saying that the circles of the first series are orthogonal to a certain circle, and those in the second series are orthogonal to an analogous circle $_1$.

The circles , $_1$ are, as we said, analogous to the bisectors of the angles formed by two lines, and we will call them the bisecting circles of C and C.

One of these bisectors reduces to a line when C and C are equal (225), and only in this case.

When the circles C, C are tangent, one series of isogonal circles is obviously formed by the circles passing through their point of contact. The corresponding bisecting circle is reduced to that point. In this case, one cannot define an inversion which transforms C into C, since the power of this inversion would have to be zero. In what follows, when we talk about circles isogonal to two tangent circles C, C, we do not refer to those just mentioned, but to the proper series, whose circles do not pass through the same point, and are preserved by an inversion (whose power is not zero).

If an inversion transforms two circles C, C into C_1, C_1, it also transforms the bisecting circles of C, C into those of C_1, C_1. Indeed, the definition of the bisecting circles is based solely on the notion of the angle of two circles, and this is not changed by inversion.

---

[58] We state the problem as if the three lines form a triangle with vertices A_1, A_2, A_3, which is the general case. The solution does not change if, for example, two of the lines are parallel.

[59] We suppose that the nine points of contact (those of the required circles with the given lines, and those of each pair of circles) are distinct. In other words, we do not consider the situation when, for instance, (a_1) is tangent at the point of contact of (x_2) and (x_3) (a situation which could, however, be treated with the same methods).

Let us now consider circles ($_1$), ($_2$), ($_3$) with centers $_1$, $_2$, $_3$ and pairwise tangent (externally, to be definite) at points $_1$, $_2$, $_3$ (see fig. 232). Join $_2$ $_3$, and let μ_1, $_1$ be the new points where this line intersects ($_2$), ($_3$), respectively.

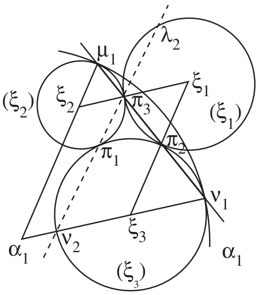

Figure 232

Through the points μ_1, $_1$ we can draw a new circle ($_1$), which is tangent to ($_2$), ($_3$) at these points, and whose center $_1$ is at the intersections of the radii μ_1 $_2$, $_1$ $_3$. The radius of this circle is the sum of the radii of the given circles.

To see this, observe that μ_1 $_2$ is parallel to $_1$ $_3$ (because $_3$ is a center of similarity for ($_1$), ($_2$)) and $_1$ $_3$ is parallel to $_1$ $_2$ (for an analogous reason). In parallelogram $_1$ $_2$ $_1$ $_3$, the equality of the opposite sides yields the indicated value for both $_1\mu_1$ and $_1$ $_1$.

Thus, if we also join points $_1$, $_3$ with a line which intersects ($_1$) again at $_2$ and ($_3$) at $_2$, the circle ($_2$) which is tangent at these points to ($_1$), ($_2$), respectively, is equal to ($_1$), since the preceding argument can be applied to it as well.

It is in fact be easy to see that the equality of the circles ($_1$), ($_2$) would still hold if the contacts of ($_1$), ($_2$), ($_3$) were not all exterior.[60]

We deduce immediately the following lemma, on which our subsequent reasoning will be based.

Lemma. If three circles (x_1), (x_2), (x_3) are pairwise tangent[61] at P_1, P_2, P_3, let (a_1) be a circle tangent to (x_2), (x_3) at m_1, n_1, and let (a_2) be a circle tangent to (x_1), (x_3) at $_2$, n_2, so that points m_1, n_1, P_2, P_3 are (227, 224)[62] on a circle (k_1), and the points $_2$, n_2, P_1, P_3 are on a circle (k_2).

Then the common point N_3 (other than P_3) of (k_1), (k_2) is on the bisecting[63] circle (g_3) of (a_1), (a_2).

---

[60] In this case, two of the circles ( ) would have to be tangent externally to each other, and internally to the third. Each circle ( ) would have a radius equal to the difference between the radius of the large circle and the sum of the radii of the small ones.

[61] Each point P is the point of contact of the circles (x) with indices different from its own.

[62] In order to apply the proposition of 224, we should generally make sure that (a_1), (x_1) belong to the same series of tangent circles to (x_2), (x_3), but in our situation there is only one proper series.

[63] Circle (x_3) belongs to one of two series of circles tangent to (a_1), (a_2); we are referring here to the bisecting circle corresponding to this series of circles.

Indeed, transform the figure by inversion, taking N_3 as the pole. Circles (x_1), (x_2), (x_3) will give us new circles ($_1$), ($_2$), ($_3$); (a_1), (a_2) will give circles ($_1$), ($_2$), while (k_1), (k_2) become two lines. We are led to the figure considered above, and we have just established that ($_1$), ($_2$) are equal. Their bisecting circle will thus be a line, so that the bisector of (a_1), (a_2) will pass through N_3. QED

Moreover, the circle through n_1, N_3, n_2 is orthogonal to (x_3), (a_1), (a_2), and (g_3).

Circle (k_1) intersects (a_1), (g_3) at equal angles, and likewise, (k_2) intersects (a_2), (g_3) at equal angles.

The angle made by circle (k_1) with (g_3) at N_3 is of the opposite sense from its angle with (a_1) at (n_1).

All of this is easily seen on a figure transformed by inversion with pole N_3, on which figure the points $_1$, $_2$ will be diametrically opposite on the circle ($_3$).

Having established these points, we can now attack the proposed problem.

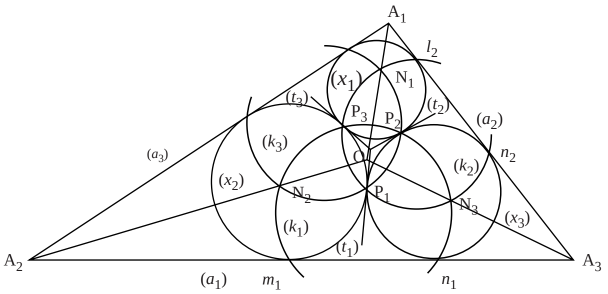

Figure 233

I. As above, denote by P_1, P_2, P_3 the points of contact of the required circles (x_1), (x_2), (x_3) (Fig. 233). We can apply the lemma just proved to these circles, with circles (a_1), (a_2) replaced by the given lines. We then know

1 . that there is a circle (k_1) passing through points P_2, P_3 and the points of contact m_1, n_1 of (x_2), (x_3) with (a_1); a circle (k_2) through P_3, P_1 and the points of contact of (x_3), (x_1) with (a_2); and a circle (k_3) through P_1, P_2 and the points of contact of (x_1), (x_2) with (a_3).

2 . that, for instance, (k_1), (k_2) intersect at a point N_3 (other than P_3) on the bisector (g_3) of the angle between (a_1) and (a_2), which here replaces the bisecting circle. (If, as we are now assuming, the circles (x) are all inside the triangle, we are dealing with the bisector of the interior angle.) Similarly, circles (k_2), (k_3) intersect at a point N_1 on the bisector (g_1) of the angle between (a_2) and (a_3), and circles (k_3), (k_1) intersect at a point N_2 on the bisector (g_2) of the angle between (a_3) and (a_1).

3 . that (k_1) intersects (a_1), (g_3) at equal angles.

We can observe immediately that, for an analogous reason, the angle made by circle (k_1) with (g_2) is equal to the angles made by the same circle with (a_1) or with (g_3).

It is also equal to the angle made by (k_1) with circle (x_2) at point m_1 (where this circle is tangent to (a_1)) or at the point P_3 (which is the same, but with the opposite orientation).[64]

II. Denote by (t_1), (t_2), (t_3) the common tangents to the required circles at the points of contact P_1, P_2, P_3, respectively. We see that line (t_3) intersects (k_1) at the same angle as (g_3) since this angle, measured at P_3, has the opposite sense from the analogous angle of (k_1) and (g_3) at N_3, as can easily be seen from what we have said so far.

Point P_3 is obviously symmetric to N_3 with respect to the line of centers of (k_1), (k_2). Thus (t_3) is symmetric to (g_3) with respect to the same line (since it forms the same angle with (k_1), but in the opposite sense).

For the same reason, (t_2) intersects (k_1) at the same angle, as it is symmetric to (g_2) with respect to the line of centers of (k_3), (k_1).

It is clear, however, that all the lines intersecting a given circle at a given angle are tangent to a second circle, concentric with the first. Therefore, the five lines (a_1), (g_2), (g_3), (t_2), (t_3) are tangent to a circle[65] (k_1) concentric with (k_1).

This last result is equivalent to a solution of the problem. Circle (k_1) can be considered to be known, since we know three of the five tangents (namely, (a_1), (g_2), (g_3)). Similar considerations apply to the analogous circles (k_2), (k_3) which are concentric to (k_2), (k_3), and we arrive at the following construction:

Let O be the center of a circle tangent to the three given lines, and let (g_1), (g_2), (g_3) be the lines joining the vertices of the triangle formed by these lines to O. We draw a circle (k_1) tangent to the lines (a_1), (g_2), (g_3), a circle[66] (k_2) tangent to the lines (a_2), (g_3), (g_1), and a circle (k_3) tangent to the lines (a_3), (g_1), (g_2).

Let (t_1) be the second common tangent of (k_2), (k_3), symmetric to (g_1) with respect to the line of the centers of these circles. Let (t_2) be the common tangent to (k_3), (k_1) symmetric to (g_2) with respect to the line of their centers. Let (t_3) be the common tangent to (k_1), (k_2) symmetric to (g_3) with respect to the line of their centers.

The first circle (x_1) is tangent[67] to lines (a_2), (a_3), (t_2), (t_3); likewise, (x_2) is tangent to (a_3), (a_1), (t_3), (t_1), and (x_3) is tangent to (a_1), (a_2), (t_1), (t_2).

---

[64] To determine the orientation of the angles under consideration, we rely on the fact that two circles (or a circle and a line) which have two common points form, at these two points, equal angles of opposite orientation, which is obvious, as these angles are symmetric relative to a line.

[65] In order not to make the figure too complicated, we have not drawn in circle (k_1) or the analogous circles (k_2), (k_3).

[66] There exist four circles tangent to (a_1), (g_2), (g_3). If one wants the circles (x) to be inside the given triangle, one must obviously choose the circle inscribed in the triangle formed by these lines. If not, any of these four circles can be chosen, but the other two analogous circles are then determined: indeed, we see (by performing another inversion relative to the pole N_3) that the chords N_3n_1, N_3n_2 must be symmetric with respect to (g_3), and the same must be true of the bisectors of the angle between (a_1) and (g_3) and the angle between (a_2) and (g_3), which pass through the centers of (k_1) and (k_2) respectively.

[67] Its center is on line (g_1) (and not on the bisector perpendicular to this line); one can show, by assigning directions to the lines (g), (t), that it is also on the bisector of the angle formed by (t_2), (t_3) which passes through the center of (k_1).

Lines (g_1), (g_2), (g_3) can be the bisectors of any of the angles formed by the given lines, provided that these bisectors intersect.[68]

It remains to prove that the construction indicated above does effectively produce circles solving the problem. We will not establish this fact, which was treated by Petersen.[69]

It is remarkable that the preceding solution extends to the case in which (a_1), (a_2), (a_3) are arbitrary circles, instead of being lines.[70]

In this case (g_1), (g_2), (g_3) will be the bisecting circles of $(a_2), (a_3)$; $(a_3), (a_1)$; $(a_1), (a_2)$, respectively.[71] Using this fact, all the reasoning involving only the circles (a_1), (a_2), (a_3), (g_1), (g_2), (g_3), (k_1), (k_2), (k_3) (whose definitions are not changed), that is, all the reasoning done until Part II, remain true without modification.[72]

In order to apply the results of this reasoning to actual situations, we must state what is meant by (t_1), (t_2), (t_3).

To do this, let (C) be the circle orthogonal to (a_1), (a_2), (a_3) (assuming, to be definite, that it exists).[73] We denote by (t_1) the circle orthogonal to (C), and tangent to (x_2) and (x_3) at their point of contact P_3.

Similarly, let (t_2), (t_3) be two circles orthogonal to (C), and each tangent to two of the given circles at their point of tangency.

---

[68] This follows from the fact that the points of contact of the required circles must be external, and the lines (a) must be common external tangents. (See an analogous remark later in this note for the case when (a_1), (a_2), (a_3) are replaced by circles.)

[69] Crelle's Journal, vol. 89, pp. 130–135. Clearly one must establish first that the lines (a_2), (a_3), (t_2), (t_3) are tangent to the same circle. The reader who has solved Exercise 422 will convince himself that this is indeed the case; that this is so even when O is any point, not necessarily the center of the inscribed circle; and that the lines (t_1), (t_2), (t_3) are concurrent.

On the other hand, the fact that these circles are tangent depends on the particular position of the point O (see Petersen's work). We must remark (limiting ourselves to the case in which the circles (x) are inside the triangle) that the existence of a solution is obvious by continuity. Indeed, draw an arbitrary circle (x_1) tangent to (a_2) , (a_3) and inside the triangle: there exists a circle (x_2) inside the triangle and tangent to (a_1), (a_3), (x_1), and a circle (x_3) tangent to (a_1), (a_2), (x_1).

These circles (x_2), (x_3) clearly intersect in two points when (x_1) is very small, and do not intersect at all when (x_1) is the inscribed circle in the triangle. Thus, for some value of the radius of (x_1), the circles (x_2), (x_3) will be tangent.

[70] The new problem would immediately reduce to the first if circles (a_1), (a_2), (a_3) had a common point S (an inversion with pole S would show this). But the solution must be considered differently if this is not the case.

[71] Among the six possible circles bisecting (a_1), (a_2), (a_3) in pairs, we must choose three for (g_1), (g_2), (g_3) which have (Exercise 276) the same radical axis. Assume, to be definite, that the required circles are tangent externally. Then circle (a_1) will have contacts of the same kind with (x_2), (x_3) as (x_3) itself , since there is only one proper series of common tangent circles to these two. Likewise, (a_2) has contacts of the same kind with (x_3), (x_1), and (a_3) with (x_1), (x_2). By considering the various kinds of contacts possible, we will be able to verify that the circles (g) satisfy the relation indicated.

The case where two of the circles are tangent internally can be reduced to the preceding one by inversion (and this discussion can thus be simplified).

[72] It follows that the bisecting circles in question exist whenever there is a solution to the problem. For instance, (g_1) must have its center at one of the centers of similarity of (a_2), (a_3), and must pass through N_3.

[73] This circle is reduced to one point in the case of footnote IV [i.e. when the three given circles have a common point. — transl.].

The reasoning developed above shows that circle (k_1) forms equal angles[74] with (x_2), (x_3), and with (a_1), (g_2), (g_3).

The last three are orthogonal to (C).

It follows (see Note C, especially 310) that any circle (k_1), having the same radical axis[75] as (k_1), (C), is also isogonal to (a_1), (g_2), (g_3), and that if it is tangent to one of them (311, construction) it will also be tangent to the others. Circle (t_3) is in fact the image[76] of (g_3) under the inversion which does not change (C), (k_1), or (k_2). The same is true if we replace (k_1), (k_2) by (k_1), (k_2).

Thus the construction is as follows:

Let (a_1), (a_2), (a_3) be given circles, and let (g_1), (g_2), (g_3) be bisecting circles of (a_2), (a_3); (a_3), (a_1); (a_1), (a_2) respectively, these circles being chosen so as to have the same radical axis. Let (C) be the circle orthogonal to the given circles

Determine circle (k_1) tangent to (a_1), (g_2), (g_3), circle (k_2) tangent to (a_2), (g_3), (g_1), and circle (k_3) tangent to (a_3), (g_1), (g_2)[77]; or, more generally[78], determine circle (k_1) isogonal to (a_1), (g_2), (g_3), circle (k_2) isogonal to (a_2), (g_3), (g_1), and circle (k_3) isogonal to (a_3), (g_1), (g_2).

Let (t_1) be the image of (g_1) under the inversion which does not change (C), (k_2), or (k_3); let (t_2) be the image of (g_2) under the inversion which does not change (C), (k_3), or (k_1); let (t_3) be the image of (g_3) under the inversion which does not change (C), (k_1), or (k_2).

Of the required circles, the first is tangent to (a_2), (a_3), (t_2), (t_3); the second is tangent to (a_3), (a_1), (t_3), (t_1); and the third is tangent to (a_1), (a_2), (t_1), (t_2).

It is easy to verify that what we have said remains true when the circle (C) does not exist, when the radical center I of (a_1), (a_2), (a_3) is interior to these circles. We just replace the words circle orthogonal to (C) by circle relative to which the power of I is the same as its power relative to (a_1), (a_2), (a_3) , and we say that a circle (k_1) has the same radical axis as (k_1), (C) if every circle orthogonal to (k_1), such that the power of I is the same as that with respect to (a_1), is also orthogonal to (k_1).

---

[74] With the same remark as before concerning the orientation of these equal angles.

[75] It is clear that, unlike the first case [where the (a) are lines transl.], the circle (k_1) is not generally concentric with (k_1).

[76] This follows as before from the fact that this image satisfies all the conditions defining (t_3), including its intersection with (g_1) and the size of the angle at that point, as well as concerning its orthogonality to C. The inversion involved here has as its pole the radical center of the circles under consideration.

[77] As before, we can take (k_1) to be any of the circles tangent to (a_1), (g_2), (g_3). Once this choice is made, it determines the series of circles isogonal to (a_2), (g_3), (g_1) to which (k_2), (k_2) belong.

[78] It is important to be aware of this generalization. It can indeed happen that the circle (k_1) does not exist (when the construction of 311 is impossible), even though our problem does have solutions.

LIVRE VII

DÉPLACEMENTS — SYMÉTRIES SIMILITUDE

CHAPITRE PREMIER

DÉPLACEMENTS

410. *Deux figures* F, F' *sont égales, si l'on peut trouver trois points non en ligne droite* A, B, C *de l'une, auxquels correspondent les points* A', B', C' *de l'autre, de manière que, si* M *est un point quelconque de* F *et* M' *son homologue dans* F', *la figure* $ABCM$ *soit égale à la figure* $A'B'C'M'$.

Supposons, en effet, qu'il en soit ainsi et transportons la figure F' de manière que le triangle $A'B'C'$ vienne sur le triangle ABC (qui lui est manifestement égal dans ces conditions).

Soient alors M et M' deux points correspondants des deux figures. En général, le point M' n'est pas dans le plan $A'B'C'$ et les droites $A'B'$, $A'C'$, $A'M'$ forment un trièdre égal, par hypothèse, à $A.BCM$. Lorsque $A'B'C'$ est superposé à ABC, ces deux trièdres coïncident (**380**, Rem.) et $A'M'$ prend la direction AM. Comme $A'M' = AM$, le point M' vient sur M.

La même conclusion subsiste si M' est dans le plan $A'B'C'$, en vertu de ce que nous savons (Pl., **50**, Rem. II) sur les figures planes égales.

Les figures F, F' ont donc été ainsi complètement superposées.

Le raisonnement montre en outre que *deux figures égales qui ont trois points homologues communs, non en ligne droite, coïncident.*

Il en résulte que *deux déplacements qui produisent le même effet sur trois points* A, B, C *non en ligne droite, sont identiques entre eux.*

C. Q. F. D.

Car les deux figures F′, F qui résultent d'une même figure quelconque F par ces deux déplacements, coïncident, comme ayant trois points homologues communs.

411. Rotations.

Considérons deux figures égales ayant *deux* points homologues communs A, B.

D'après la définition de la ligne droite (Pl., **5**), la droite AB a la même position dans les deux figures, et il en est de même d'un point quelconque *m* de cette droite, puisque le segment A*m* doit avoir la même grandeur et le même sens de part et d'autre.

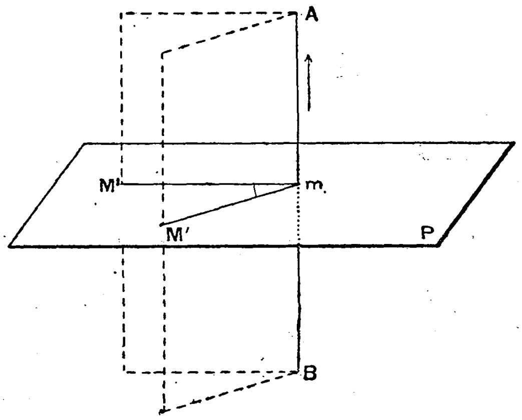

Fig. 316.

Ainsi *les deux figures ont en commun tous les points d'une droite.*

Considérons la portion de la figure située dans un plan quelconque perpendiculaire à AB, par exemple dans le plan P qui est perpendiculaire à AB au point *m* (*fig.* 316), et composée, par conséquent, de points M tels que M*m* soit perpendiculaire à AB. A ces points correspondront, dans la seconde figure donnée, des points jouissant de la même propriété (le point *m* restant le même) et, par conséquent, situés dans le même plan P.

Nous avons donc, dans ce plan, deux figures égales et de même sens (1), qui ont un point commun *m* et, par suite, se déduisent l'une de l'autre par une rotation autour de ce point (Pl., **100**). L'angle de cette rotation est l'angle plan du dièdre que forme un plan quelconque passant par AB dans la première figure avec le plan homologue de la seconde. *Cet angle de rotation est donc le même dans tous les plans* P.

Définition. — On donne, en géométrie de l'espace, le nom de *rotation* à l'opération par laquelle on déduit l'une de l'autre les deux figures dont il vient d'être parlé ; autrement dit, à l'opération qui consiste, étant donnée une droite AB (dite *axe de rotation*), et un angle (dit *angle de rotation*), à faire tourner chaque point de la figure primitive, dans le plan mené par ce point perpendiculairement à l'axe et autour du point de rencontre du plan en question avec l'axe, d'un angle égal à l'angle de rotation (*fig.* 316).

---

(1) Parce que deux droites issues de *m* forment, avec l'axe, un trièdre dont la disposition doit être la même dans les deux figures données.

On doit avoir choisi un sens sur l'axe et indiqué, une fois pour toutes, si les rotations effectuées sont directes ou rétrogrades par rapport au sens ainsi choisi (**349**).

Si l'on est libre de choisir à sa volonté le sens de l'axe, on peut évidemment toujours le prendre tel que la rotation soit directe.

Réciproquement, *deux figures déduites l'une de l'autre par une rotation, sont égales.*

Car, si M, M' en sont deux points correspondants, m leur projection (commune, en vertu de l'hypothèse) sur l'axe AB, on peut déplacer la première figure de manière à amener l'angle droit $\widehat{MmA}$ sur son égal $\widehat{M'mA}$. Ce déplacement, n'ayant pas changé les positions des points de AB, est, d'après ce qui précède, une rotation dont l'axe est AB et l'angle évidemment égal à $\widehat{MmM'}$. Cette rotation qui, par hypothèse, change la première figure en une figure égale, coïncide donc avec la rotation donnée, puisqu'elle a même axe et même angle.

412. Symétrie par rapport à une droite.

L'angle de rotation peut être de 180° : alors le point M' correspondant à un point quelconque M de la première figure sera le symétrique (Pl., **99**) de M par rapport à sa projection m sur l'axe (*fig.* 317).

On donne à la rotation de 180° autour d'une droite le nom de *symétrie* ou encore de *transposition* par rapport à cette droite.

Dans ce cas, il est inutile d'indiquer le sens de la rotation. La symétrie est *réciproque*, c'est-à-dire qu'en appliquant la même construction au point trouvé M', on retomberait sur le point M.

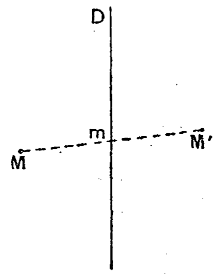

FIG. 317.

Il résulte de ce qui précède que *deux figures symétriques l'une de l'autre par rapport à une droite, sont égales entre elles.*

413. Translations.

Définition. — Si, par les différents points A, B, C, ... d'une figure F, on mène des droites AA′, BB′, CC′, ... toutes parallèles entre elles, de même sens et égales, les points A′, B′, C′, ... forment une figure F′ qui est dite (voir Pl., **51**) déduite de la première par la *translation* AA′ (*fig.* 318).

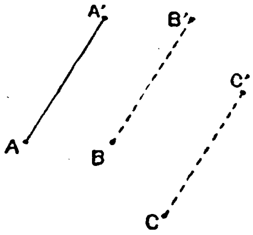

Fig. 318.

Cette nouvelle figure est égale à F.

En effet, si A et B sont deux points de F, il leur correspondra, dans F′, deux points A′ et B′, tels que A′B′ soit égal et parallèle à AB, avec le même sens.

A trois points A, B, C de F, correspondront trois points A′, B′, C′, tels que le triangle A′B′C′ soit égal à ABC. En particulier, l'angle $\widehat{B'A'C'}$, par exemple, est égal à $\widehat{BAC}$. De plus, le plan A′B′C′ est parallèle à ABC.

Soient alors A, B, C, M quatre points de F. Si ces points sont dans un même plan, la figure ABCM est (Pl., **50**) égale à celle que forment les points homologues A′, B′, C′, M′.

Si, au contraire, les quatre points A, B, C, M ne sont pas dans un même plan, le trièdre ABCM est égal au trièdre homologue A′B′C′M′ (**382** *bis*). Si l'on fait coïncider ces deux trièdres, comme A′B′, A′C′, A′M′ sont respectivement égaux à AB, AC, AM, les deux figures ABCM, A′B′C′M′ coïncident : d'où (**410**) l'égalité des figures F, F′.

Par exemple, *les projections d'une même figure sur deux plans parallèles sont deux figures égales.* Car elles se déduisent l'une de l'autre par une translation égale à la distance des deux plans et perpendiculaire à leur direction.

414. Déplacements hélicoïdaux.

Définition. — On nomme *déplacement hélicoïdal* (1) le déplacement résultant (2) d'une rotation R et d'une translation T, cette dernière étant parallèle à l'axe de la première.

L'ordre des deux opérations est indifférent (ce qui n'arriverait pas si la translation n'était pas parallèle à l'axe de rotation (3)). Autrement dit, si M′ est la nouvelle position que vient occuper le point M, après une rotation R d'un angle donné autour de l'axe D (*fig.* 319); M'_1, la nouvelle position que vient occuper le point M' par une translation déterminée T parallèle à D, on retomberait sur le même point M'_1 en faisant subir au point M la translation T, de manière à obtenir un point M_1, et faisant ensuite tourner ce point M_1 de l'angle donné autour de D.

---

(1) La raison de cette dénomination sera donnée plus loin, (**547**).

(2) Voir, pour le sens de ce mot, Pl., **103**, liv. II.

(3) Voir exercice 622.

Si, en effet, m est la projection commune des points M,M' sur l'axe; m_1, la projection du point M_1, la figure $M_1m_1M'_1$ se déduit évidemment de la figure MmM' par la translation MM_1. Elle est donc, comme celle-ci, un triangle isoscèle dont le plan est perpendiculaire à D et dont l'angle est celui de la rotation R : ce qui démontre l'exactitude de notre affirmation.

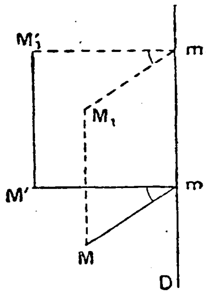

Fig. 319.

Le déplacement hélicoïdal comprend évidemment, comme cas particuliers, la rotation (lorsque la translation T est nulle) et la translation (lorsque la rotation R est nulle.)

Remarque. — Lorsqu'on se donne un déplacement hélicoïdal, un sens déterminé est par là même donné sur l'axe, à savoir le sens de la translation. On dira donc qu'un déplacement hélicoïdal est direct (ou encore *sinistrorsum*), ou bien au contraire qu'il est rétrograde (ou *dextrorsum*) suivant que la rotation est directe ou rétrograde par rapport au sens de la translation.

415. Nous avons vu que deux figures égales qui ont deux points communs (1) peuvent être amenées à coïncider par une rotation.

Deux figures égales qui ont un point commun peuvent être amenées à coïncider par deux rotations successives.

Soient, en effet, A le point commun; B,B' deux points homologues. On a $AB = AB'$ et, par conséquent, le point B' viendra coïncider avec B si l'on fait tourner la seconde figure autour d'une perpendiculaire au plan BAB', d'un angle égal à $\widehat{B'AB}$. Les deux figures ayant alors deux points communs, une seconde rotation amènera la coïncidence complète.

Deux figures égales quelconques peuvent être amenées à coïncider par une translation suivie de deux rotations. Car, si A,A' sont deux points homologues quelconques, la translation A'A imprimée à la seconde figure amène le point A' sur le point A, après quoi on est ramené au cas précédent.

Mais ces combinaisons de translations et de rotations peuvent être simplifiées et remplacées par un seul déplacement hélicoïdal.

A cet effet, nous procéderons comme en géométrie plane (Pl., **102-103**), en étudiant d'abord la composition des transpositions.

416. Deux symétries par rapport à la même droite se détruisent : nous savons (**412**) que, si M' est le symétrique du point M par rapport à la droite D, M'' le symétrique de M' par rapport à cette même droite, le point M'' coïncide avec le point M.

---

(1) C'est-à-dire telles que deux points coïncident avec leurs homologues.

Théorème. — *Deux transpositions successives, par rapport à deux axes différents, équivalent :*

1° *Si les deux axes sont parallèles, à une translation parallèle à la perpendiculaire commune aux deux axes et double de celle qui amènerait le premier axe sur le second;*

2° *Si les deux axes sont concourants, à une rotation autour de leur perpendiculaire commune, double de celle qui amènerait le premier axe sur le second;*

3° *Si les deux axes ne sont pas dans un même plan, à un déplacement hélicoïdal, ayant pour axe leur perpendiculaire commune et double de celui qui amènerait le premier axe sur le second.*

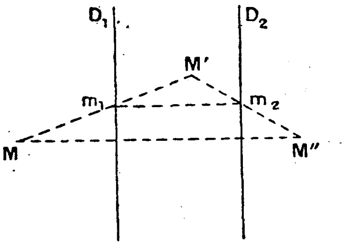

Fig. 320.

1° Soient les axes parallèles D_1, D_2 (*fig.* 320), M un point quelconque de la figure primitive, projeté en m_1 sur D_1 ; M′, son symétrique par rapport à D_1 ($m_1M' = Mm_1$), projeté en m_2 sur D_2 ; M″, le symétrique de M′ par rapport à D_2 ($m_2M'' = M'm_2$). Le plan mené par M perpendiculairement aux droites D_1, D_2 contient MM′ (qui est perpendiculaire à D_1) et M′M″ (qui est perpendiculaire à D_2). Donc m_1m_2 est une perpendiculaire commune aux deux axes et il est clair (Pl., **55**) que M″ se déduit de M par une translation parallèle à cette perpendiculaire commune et double de cette perpendiculaire commune.

2° Soient les deux axes D_1, D_2 (*fig.* 321) concourants en O ; P, leur plan ; Ox, la perpendiculaire à ce plan menée par le point O; et, comme tout à l'heure, M, M′, M″ trois points dont les deux premiers sont symétriques l'un de l'autre par rapport à D_1 (la droite qui les joint coupant D_1 en m_1), les deux derniers par rapport à D_2 (la droite qui les joint coupant D_2 en m_2).

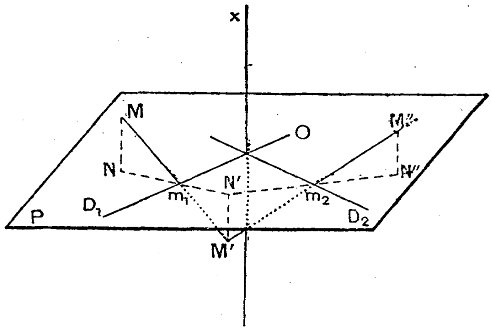

Fig. 321.

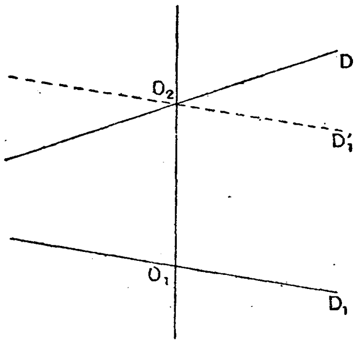

Fig. 322.

Le plan P étant son propre symétrique tant par rapport à D_1 que par rapport à D_2, si nous projetons les points M, M′, M″ en N, N′, N″ sur ce plan, les points N et N″ seront symétriques de N′ par rapport à D_1 et D_2 respectivement. N″ se déduira donc de N (Pl., **102**) par une rotation autour de Ox, d'angle égal au double de celui des deux axes.

Mais les droites NM, N″M″ sont égales, parallèles toutes deux à Ox et de même sens (contraire à celui de $N'M'$) : il est, dès lors, clair que la même rotation d'axe Ox qui amène N sur N'' amène aussi M sur M''.

3° Soient les deux axes D_1, D_2 (*fig.* 322), non situés dans un même plan; O_1O_2, leur perpendiculaire commune. Par le point O_2, menons la parallèle D'_1 à D_1. Entre les deux rotations de 180° que nous avons à composer, intercalons deux rotations successives de 180° autour de D_1' : ce qui est indifférent puisque ces deux rotations se détruisent.

Les deux symétries successives par rapport à D_1, D'_1, se composent en une translation parallèle à O_1O_2 et double de O_1O_2; les deux symétries relatives à D'_1, D_2, en une rotation autour de O_1O_2, double de celle qui amènerait D'_1 sur D_2 : le théorème est donc démontré.

Réciproque. — *Tout déplacement peut être décomposé en deux symétries par rapport à deux droites différentes.*

Ces deux droites doivent :

S'il s'agit d'une translation, être perpendiculaires à cette translation;

S'il s'agit d'une rotation ou d'un déplacement hélicoïdal, être perpendiculaires à l'axe et le rencontrer.

A ces conditions près, on peut choisir arbitrairement l'une des droites, l'autre étant alors déterminée.

Si, par exemple, c'est l'axe de la première symétrie qui est pris arbitrairement sous les conditions indiquées, le second axe se déduira du premier par une translation égale à la moitié de la translation et une rotation égale à la moitié de la rotation données. Ce second axe étant ainsi déterminé, les deux symétries produisent bien, en vertu du théorème précédent, un déplacement résultant identique au déplacement donné.

417. Théorème. — *Un nombre quelconque de déplacements hélicoïdaux ont pour déplacement résultant un déplacement hélicoïdal unique.*

S'il s'agit de rotations concourantes, le déplacement résultant est une rotation qui concourt avec les premières.

S'il s'agit de translations, le déplacement résultant est une translation.

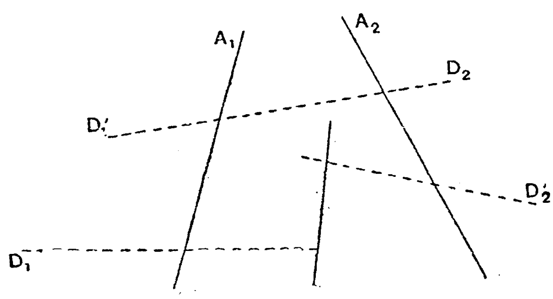

FIG. 323.

Il suffit évidemment[1] de démontrer le théorème pour deux déplacements : car pour en composer trois, on pourra composer les deux premiers, puis le déplacement résultant avec le troisième ; et ainsi de suite.

Soient donc deux déplacements hélicoïdaux[2] d'axes A_1, A_2 (*fig.* 323).

---

[1] Comparer Pl., **103**.

[2] Si l'un des déplacements donnés, le premier par exemple, est une translation, on prendra pour l'axe A, dans le raisonnement qui va suivre, une droite quelconque parallèle à cette translation.

Nous pourrons remplacer le premier par deux symétries d'axes D_1, D'_1, et cela, en prenant arbitrairement la seconde droite D'_1 parmi celles qui coupent à angle droit l'axe A_1. Nous pourrons de même remplacer le second déplacement par deux symétries d'axes D_2, D'_2, et cela, en prenant arbitrairement le premier axe D_2 parmi ceux qui coupent à angle droit A_2.

Nous ferons en sorte que D'_1 et D_2 coïncident : il suffira, pour cela de les faire coïncider toutes deux avec la perpendiculaire commune à A_1, A_2. Alors les symétries par rapport à ces deux axes se détruisent, et il reste les symétries par rapport à D_1, D'_2, lesquelles donnent bien un déplacement hélicoïdal unique.

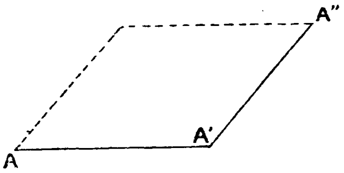

Fig. 323 *bis*.

Si les déplacements donnés sont des rotations et que les axes A_1, A_2 concourent en un point O, la droite D'_1 passera par ce même point et il en sera de même de D_1 et de D'_2. Le déplacement résultant sera donc une rotation d'axe passant par O.

Si les déplacements donnés sont des translations, les droites D'_1, D_1, D'_2 sont parallèles entre elles et le déplacement résultant est une translation.

Ce dernier fait est, d'ailleurs, évident *à priori*, et il est clair que la translation résultante est la diagonale d'un parallélogramme qui a pour côtés les deux composantes (*fig.* 323 *bis*).

C. Q. F. D.

418. Il suffit évidemment de combiner le théorème précédent avec les remarques du n° **415** pour arriver à l'énoncé que nous avions en vue :

Théorème. — *Deux figures égales peuvent toujours être amenées à coïncider :*

S'il y a un point commun, par une rotation ; dans le cas général, par un déplacement hélicoïdal.

EXERCICES

577. On fait tourner une figure invariable S autour d'un axe fixe D, l'angle de rotation étant quelconque; après quoi, on fait tourner une partie S' de la figure S autour d'un axe D' qui fait partie de S (le reste de la figure S restant fixe), l'angle de rotation étant également quelconque.

Montrer qu'on peut, en général, disposer des deux angles de rotation de manière à rendre une droite donnée de S' parallèle à une droite donnée arbitraire de l'espace (ou, ce qui revient au même, un plan arbitraire de S' parallèle à un plan donné arbitraire de l'espace). Quels sont les cas d'exception ?

578. On fait tourner une figure invariable S autour d'un axe fixe D, l'angle de rotation étant quelconque; après quoi, on fait tourner une partie S' de la figure S autour d'un axe D' qui fait partie de S, puis une partie S'' de S' autour d'un axe D'' qui fait partie de S', les deux angles de rotation étant également quelconques.

Montrer qu'on peut disposer des angles des trois rotations de manière que toutes les droites de la figure S'' deviennent parallèles aux droites correspondantes d'une figure donnée S''_0 égale à S''.

579. Trouver une rotation transformant respectivement deux points donnés en deux autres points donnés (la distance des deux premiers points étant, bien entendu, supposée égale à celle des deux autres).

Dans quels cas le problème est-il indéterminé ?

580. Construire l'axe de la rotation qui transforme deux demi-droites concourantes données OA, OB en deux demi-droites OA', OB' concourantes avec les premières (l'angle $\widehat{A'OB'}$ étant égal à $\widehat{AOB}$).

581. Étant admis que deux figures égales F, F' qui ont un point commun, dérivent l'une de l'autre par une rotation, en déduire que deux figures égales quelconques dérivent l'une de l'autre par un déplacement hélicoïdal.

(On montrera qu'il y a des droites de F qui sont parallèles à leurs homologues de F'. Soient alors P un plan de F perpendiculaire aux droites en question; P', son homologue; f, la partie de F située dans P; f', la partie correspondante de F'. On appliquera à f et à la projection de f' sur P le théorème du n° **102.** (Pl., liv. II.))

582. Quels sont les différents déplacements qui laissent inaltérée une droite donnée ?

583. Il y a une infinité de rotations qui transforment l'une dans l'autre deux droites données D, D'. Les axes de ces rotations ne sont autres que les droites appelées G_1, G_2 dans l'exercice 454.

Parmi ces rotations, il y en a deux dont l'angle est de 180°.

584. Tout déplacement hélicoïdal qui transforme l'une dans l'autre les deux droites données D, D' a son axe A parallèle à celui d'une des rotations considérées dans l'exercice précédent.

Quel est le lieu de l'axe A, lorsqu'en donne la direction de cet axe ?

Trouver ce lieu : 1° directement; 2° en utilisant la composition des déplacements et les deux exercices précédents. On prouvera que l'axe A rencontre toujours, à angle droit, l'une ou l'autre de deux droites fixes (suivant qu'il est parallèle à une droite G_1 ou à une droite G_2).

585. Trouver le lieu de l'axe d'un déplacement hélicoïdal, connaissant la direction de cet axe et deux points homologues.

586. Construire l'axe d'un déplacement hélicoïdal, connaissant un point de cet axe, la grandeur de la translation et deux points homologues.

587. Un déplacement donné quelconque peut, en général, être décomposé en deux rotations, dont une suivant une droite donnée quelconque. Quels sont les cas d'exception ?

588. On compose un déplacement hélicoïdal donné avec une quelconque des translations T parallèles à une direction donnée. Lieu de l'axe du nouveau déplacement ainsi obtenu, lorsqu'on fait varier la grandeur de la translation T. Montrer qu'en général il y a un et un seul de ces déplacements qui se réduit à une rotation.

589. On compose une rotation donnée avec une rotation donc l'axe est fixe et rencontre le premier, mais dont l'angle est variable. Lieu de l'axe de la rotation résultante.

590. Composer une rotation donnée avec une rotation d'axe donné rencontrant le premier mais d'angle inconnu, de manière que le déplacement résultant soit une transposition (ou plus généralement, une rotation d'angle donné).

591. Composer un déplacement hélicoïdal donné avec un déplacement inconnu, mais d'axe donné, de manière que le déplacement résultant soit une transposition.

592. Deux rotations (d'angles non nuls) dont les axes ne sont pas dans un même plan, ne se composent jamais suivant une rotation.

593. Lorsqu'un déplacement hélicoïdal ne se réduit ni à une translation, ni à une rotation, il n'existe aucun plan qui reste inaltéré par ce déplacement.

594. Mener, par un point donné, deux droites qu'un déplacement donné transforme l'une dans l'autre.

595. Étant donné un déplacement, trouver deux droites homologues entre elles, qui soient situées dans un même plan donné.

596. Construire un angle polyèdre, connaissant les bissectrices des faces.

Le problème peut-il être indéterminé?

Connaissant toutes les bissectrices, moins deux, trouver le lieu de ces dernières, de manière que l'indétermination ait lieu.

597. Déduire de la composition des rotations le lieu des symétriques d'un point donné, par rapport à toutes les droites qui passent par un point fixe et sont situées dans un plan fixe.

598. Décomposer une rotation R en deux rotations S, S′ dont les angles soient entre eux, l'axe de la rotation S étant, d'autre part donné et concourant avec celui de R. Quel est le lieu décrit par l'axe de la rotation S′ lorsque l'axe de la rotation S décrit un plan?

598 *bis*. Décomposer un déplacement hélicoïdal en deux déplacements hélicoïdaux S, S′ composés de translations égales entre elles et de rotations égales entre elles, tous deux dextrorsum ou tous deux sinistrorsum, l'axe du déplacement S étant donné.

599. Trouver deux déplacements hélicoïdaux d'axes donnés qui se composent suivant un déplacement d'axe également donné.

CHAPITRE II

SYMÉTRIES

419. Définitions. — Deux points M, M′ sont dits (comme en géométrie plane) *symétriques par rapport à un point* O (ou encore par rapport au *centre* O) (*fig.* 324) lorsque le point O est le milieu de la droite MM′.

Deux points M, M′ sont dits *symétriques par rapport à un plan* P (*fig.* 325), lorsque la droite qui les joint est perpendiculaire à ce plan et divisée par lui en deux parties égales.

Fig. 324.

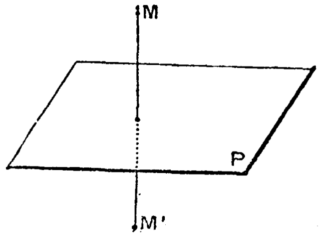

Fig. 325.

La *symétrique d'une figure* F, par rapport à un point ou à un plan, est la figure formée par les symétriques des différents points de F.

419 *bis*. Coïncident avec leurs symétriques par rapport à un point :

— le centre de symétrie ;

— les droites qui passent par ce point, et non d'autres droites : car toute droite qui coïncide avec sa symétrique doit contenir deux points symétriques l'une de l'autre, ce qui exige qu'elle passe par le centre ;

— les plans qui passent par le centre (et non d'autres plans, pour une raison tout analogue).

Coïncident avec leurs symétriques par rapport à un plan :

— les points du plan de symétrie, et non d'autres points ;

— les droites situées dans le plan de symétrie et celles qui lui sont perpendiculaires ;

— le plan de symétrie et les plans qui lui sont perpendiculaires.

420. Théorème. — *Deux figures symétriques d'une même troisième, par rapport à deux centres différents, sont égales entre elles.*

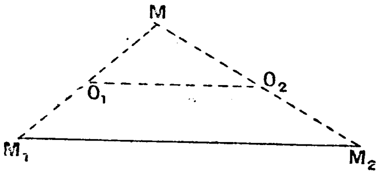

Fig. 326.

Si, en effet, M_1 et M_2 sont les symétriques de M par rapport aux deux centres O_1, O_2 (*fig.* 326), la droite M_1M_2 est (Pl., **55**) parallèle à O_1O_2 et double de O_1O_2.

Donc, les figures symétriques d'une même troisième, par rapport à O_1 et O_2 respectivement, se déduisent l'une de l'autre par une translation parallèle à O_1O_2 et double de O_1O_2.

Théorème. — *Deux figures symétriques d'une même troisième, l'une par rapport à un point, l'autre par rapport à un plan, sont égales entre elles.*

Il suffit, d'après le théorème précédent, de faire la démonstration pour une situation déterminée du centre de symétrie : elle sera, par cela même, faite pour toutes les autres positions de ce point.

Nous pouvons, par conséquent, supposer que le centre de symétrie O est situé dans le plan de symétrie P. Dans ces conditions, nous allons faire voir que *les symétriques d'une même figure* F, *l'une par rapport au point* O, *l'autre par rapport au plan* P, *se déduisent l'une de l'autre par une rotation de* 180° *autour d'une droite :* cette droite est la perpendiculaire Ox au plan P, menée par le point O.

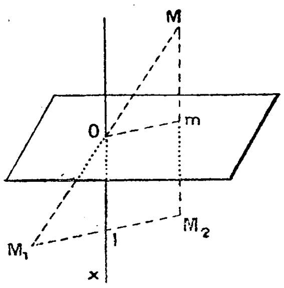

Fig. 327.

Soient, en effet, M un point quelconque de F (*fig.* 327) ; M_1, son symétrique par rapport à O ; M_2, son symétrique par rapport à P, de sorte que la droite MM_2, perpendiculaire au plan P, a son milieu m dans ce plan. La droite Ox, parallèle à MM_2 et menée par le milieu de MM_1, rencontre en son milieu le troisième côté M_1M_2 du triangle MM_1M_2.

D'ailleurs, M_1M_2 est parallèle à Om (qui joint les milieux de MM_1 et de MM_2) et, par suite, perpendiculaire à Ox. Donc, les points M_1, M_2 sont bien symétriques l'un de l'autre par rapport à Ox.

C. Q. F. D.

Corollaire. — *Deux figures symétriques d'une même troisième* F, *par rapport à deux plans différents, sont égales entre elles*, puisqu'elles sont égales à la symétrique de la figure F par rapport à un point quelconque de l'espace.

On peut d'ailleurs (exercice 600) constater directement que ces figures se déduisent l'une de l'autre par une rotation ou une translation convenable.

421. Théorème. — *Une figure plane est égale à sa symétrique par rapport à un point ou à un plan quelconque.*

Le théorème est évident lorsque le plan de symétrie coïncide avec le plan de la figure, puisque celle-ci coïncide alors avec sa symétrique. Il est dès lors vrai dans tous les cas, d'après le numéro précédent.

En particulier, *la figure symétrique d'un plan est un plan ;*

La figure symétrique d'une droite est une droite ; la figure symétrique d'un segment de droite est un segment de droite égal au premier ;

Deux angles symétriques l'un de l'autre sont égaux ;

La figure symétrique d'une circonférence est une circonférence ; etc.

421 *bis*. **Corollaires.** — I. *Une droite et un plan, perpendiculaires entre eux, ont pour symétriques une droite et un plan perpendiculaires entre eux :* cela résulte de la définition du plan perpendiculaire à une droite, puisqu'un angle droit a pour symétrique un angle droit.

II. *L'angle d'une droite et d'un plan est égal à l'angle de leurs symétriques :* cela résulte de la définition et du corollaire précédent. De même :

III. *Deux dièdres symétriques sont égaux.*

422. Théorème. — *Deux dièdres symétriques l'un de l'autre, par rapport à un point ou à un plan, sont de sens contraires* (*lorsque les sens choisis sur les arêtes se correspondent*).

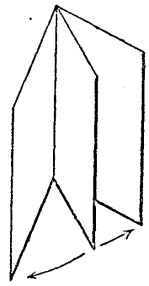

Fig. 328.

Si, en effet, le plan de symétrie est le plan de l'une des faces (*fig.* 328), les arêtes coïncident (et cela en direction *et sens*) pendant que les faces non communes sont de part et d'autre de la face commune.

Corollaire. — *Dans deux figures symétriques, les trièdres correspondants ont leurs dispositions inverses.*

REMARQUE. — Cette dernière proposition résulte d'ailleurs immédiatement du n° **372** : car si on prend pour centre de symétrie le sommet d'un des trièdres considérés, on retombe évidemment sur la construction des trièdres symétriques indiquée au n° **370**.

Les *trièdres symétriques* considérés en cet endroit satisfont donc bien à la définition générale des figures symétriques, telles que nous les considérons actuellement.

D'après ce qui précède — au lieu que deux figures symétriques par rapport à une droite sont superposables — deux figures symétriques par rapport à un point ou à un plan, tout en ayant tous leurs côtés, tous leurs angles, tous leurs dièdres égaux à chacun, *ne sont pas en général superposables*, parce que leur disposition est inverse.

423. Théorème. — *Deux polyèdres symétriques sont équivalents.*

Nous distinguerons deux cas :

1° *Les polyèdres considérés sont des pyramides.*

Ces pyramides ont leurs bases égales (**421**) ; leur hauteurs sont d'ailleurs symétriques l'une de l'autre (**421** *bis*, Coroll. I) et, par conséquent, égales : elles sont donc équivalentes ;

2° *Cas général.* Décomposons l'un des polyèdres donnés en pyramides. L'autre sera décomposable en pyramides, symétriques respectivement des premières. Ces pyramides étant équivalentes chacune à chacune, les polyèdres totaux le sont aussi.

C. Q. F. D.

424. On dit qu'une figure *admet pour axe de symétrie* la droite D, lorsqu'elle coïncide avec sa symétrique par rapport à D.

De même, une figure est dite *admettre un plan* ou *un centre de symétrie*, lorsqu'elle coïncide avec sa symétrique par rapport à ce plan ou à ce centre.

Une figure F qui a un plan P ou un centre C de symétrie (¹) est

---

(1) Il est clair que la même conclusion ne s'appliquerait pas au cas où, au lieu d'un centre ou d'un plan de symétrie, la figure F admettrait un *axe* de symétrie.

superposable à sa symétrique F′ par rapport à un point C′ ou à un plan P′ quelconque, puisque F et F′ peuvent être considérées comme symétriques d'une même figure (à savoir F elle-même) l'une par rapport à P ou à C, l'autre par rapport à P′ ou à C′.

Toutefois, il faut bien observer que, dans la superposition de F et de F′, ce ne sont pas, en général, les points homologues (c'est-à-dire symétriques l'un de l'autre par rapport à P′ ou à C′) que l'on arrive à faire coïncider. C'est, par exemple, ce qui se produit dans le cas du trièdre isoscèle (**383**) : un trièdre isoscèle est effectivement (voir exercice 480) une figure qui a un plan de symétrie.

EXERCICES

600. Deux figures sont symétriques d'une même troisième, par rapport à deux plans différents. Quel est le déplacement qui amène la première à coïncider avec la seconde ?

(Distinguer deux cas, suivant que les deux plans sont concourants ou parallèles).

601. Même question pour deux figures symétriques d'une même troisième, l'une par rapport à un plan, l'autre par rapport à un point non situé dans ce plan.

602. Une figure limitée en tous sens peut-elle avoir deux centres de symétrie ?

603. Tout plan mené par le point d'intersection des diagonales d'un parallépipède divise celui-ci en deux parties équivalentes.

604. *Symétrie oblique.* — Un point quelconque M étant considéré, soit M′ le point tel que la droite MM′ soit parallèle à une droite fixe D et divisée en deux parties égales par un plan P (sécant à D) : le point M′ est dit dériver de M par *symétrie oblique*.

Prouver que :

La figure obliquement symétrique d'une droite est une droite ;

La figure obliquement symétrique d'un plan est un plan.

Deux polyèdres obliquement symétriques l'un de l'autre sont équivalents. (On peut utiliser pour cela l'ex. 565.)

605. Même question lorsque le point M′ est défini, à l'aide du point M, par la condition que la droite MM′ soit parallèle à un plan fixe P et divisée en deux parties égales par une droite fixe D (sécante à P).

On démontrera que cette transformation peut se ramener à deux symétries obliques, telles qu'elles ont été définies à l'exercice précédent, ou encore à une symétrie oblique et une symétrie par rapport à un point.

606. Appliquer les conclusions de l'exercice précédent à l'exercice 568.

607. Si une figure F est égale à la symétrique, par rapport à un plan, d'une figure F′, les deux figures peuvent être amenées à coïncider par une rotation précédée ou suivie d'une symétrie par rapport à un plan perpendiculaire à l'axe de rotation ou par rapport à un point situé sur cet axe.

608. Inscrire, dans un angle polyèdre convexe donné, un angle polyèdre tel que la somme de ses faces soit minima. Cas du trièdre.

CHAPITRE III

HOMOTHÉTIE ET SIMILITUDE

425. Définition. — De même qu'en géométrie plane, nous nommerons *homothétique* d'un point quelconque M, par rapport à un point O, appelé *centre d'homothétie*, et à un nombre k, appelé *rapport d'homothétie* ou *de similitude*, le point M′ obtenu en joignant OM et portant sur cette droite, à partir du point O′, un segment donné par la relation

$$\frac{\mathrm{OM}'}{\mathrm{OM}} = k.$$

Pour achever de définir l'homothétie, on doit indiquer s'il faut prendre le segment OM′ dans le sens OM (homothétie *directe*) ou dans le sens opposé (homothétie *inverse*).

La symétrie par rapport à un point est, ainsi que nous l'avons noté (Pl., **140**, Rem.), un cas particulier d'homothétie inverse, le cas où le rapport de similitude est égal à 1.

426. Le théorème déjà énoncé en géométrie plane (n° **141**) :

Théorème. — *Dans deux figures homothétiques, la droite qui joint deux points quelconques de l'une des figures et celle qui joint les points homologues de l'autre sont toujours parallèles et dans le rapport de similitude; elle sont de même sens ou de sens contraires, suivant que l'homothétie est directe ou inverse*,

subsiste, avec sa démonstration, en géométrie de l'espace. Il en est de même des

Corollaires. — I. *La figure homothétique d'une droite est une droite parallèle à la première;*

d'où résulte, moyennant le n° **330** :

II. *La figure homothétique d'un plan est un plan parallèle au premier ;*

Il en est de même également des corollaires.

III. *Deux angles homothétiques l'un de l'autre sont égaux.*

La figure homothétique d'un triangle est un triangle semblable au premier

et (moyennant le corollaire II et le théorème du n° **393**)

IV. *La figure homothétique d'un polygone plan est un polygone semblable au premier;*

Plus généralement, *la figure homothétique d'une figure plane est une figure plane semblable à la première* (1).

V. *La figure homothétique d'une circonférence est une circonférence, les centres étant homothétiques l'un de l'autre et le rapport des rayons étant égal au rapport de similitude.*

Enfin les corollaires I et II donnent :

VI. *Une droite et un plan perpendiculaires ont pour homothétiques une droite et un plan perpendiculaires*

et, moyennant les n° **358** *bis*, **384** *bis* :

VII. *Dans deux figures homothétiques,*

Les dièdres homologues sont égaux;

Les angles polyèdres homologues sont égaux si l'homothétie est directe; symétriques, si l'homothétie est inverse.

427. La réciproque du théorème précédent :

Réciproque. — *Deux figures étant données, s'il existe deux points* O, O' *tels que la droite qui joint le point* O *à un point* M *quelconque de la première figure et celle qui joint le point* O' *au point* M' *homologue de la seconde soient constamment parallèles et dans un rapport donné* k (*toujours de même sens ou toujours de sens contraires*), *les deux figures sont homothétiques*,

subsiste également et se démontre comme en géométrie plane, moyennant la convention qui consiste à considérer, comme cas limite de deux figures homothétiques, deux figures égales qui se déduisent l'une de l'autre par une translation.

---

(1) Il peut sembler que cette proposition ne soit autre que la définition des figures semblables (Pl., **146**). Il n'en est rien : deux figures semblables sont en effet telles que l'une soit égale à une homothétique de l'autre *par rapport à un point de son plan* (seule espèce d'homothétie considérée en géométrie plane); au lieu que cette dernière restriction n'est point supposée dans l'énoncé actuel.

Il en résulte, comme en géométrie plane (**144**) :

Théorème. — *Deux figures homothétiques d'une même troisième sont homothétiques entre elles; le rapport d'homothétie est le quotient des rapports primitifs, et cette homothétie est directe ou inverse, suivant que les homothéties primitives sont de même nom ou de noms contraires.*

Les trois centres d'homothétie sont sur une même ligne droite (dite *axe d'homothétie*).

La démonstration de cette dernière partie de l'énoncé : *les trois centres sont en ligne droite*, peut toutefois être simplifiée lorsqu'on fait intervenir l'homothétie dans l'espace.

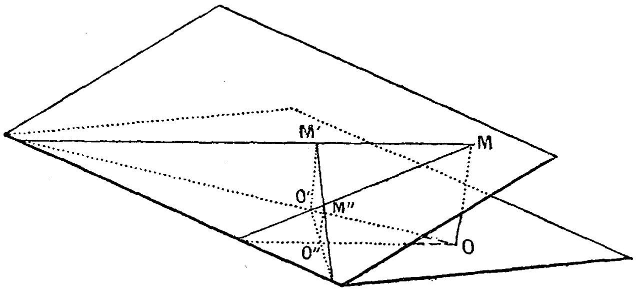

Fig. 329.

Soient, en effet, O un point de la première figure (*fig.* 329), O' et O'' ses homologues dans la seconde et dans la troisième; M, un point de la première figure, situé en dehors du plan $OO'O''$; M', M'' ses homologues. Le centre d'homothétie des deux premières figures est à l'intersection de OO', MM'; celui de la première et de la troisième, à l'intersection de OO'', MM''; celui des deux dernières, à l'intersection de $O'O''$, $M'M''$. Ces trois centres sont donc évidemment sur une même droite, à savoir l'intersection des plans $OO'O''$, $MM'M''$.

Remarque. — *Si les deux homothéties primitives sont de même nom, avec le même rapport de similitude, les deux figures homothétiques d'une même troisième se déduisent l'une de l'autre par translation.* C'est le cas limite auquel il a été fait allusion tout à l'heure.

428. Théorème. — *Lorsque quatre figures sont homothétiques entre elles, les six centres d'homothétie sont dans un même plan* (dit *plan d'homothétie*) *et forment un quadrilatère complet dont les côtés sont les quatre axes d'homothétie des figures prises trois à trois.*

Désignons par F_1, F_2, F_3, F_4 les quatre figures; par S_{12}, S_{13}, etc., les centres d'homothétie des figures F_1, F_2; F_1, F_3; etc. Les points S_{12}, S_{13}, S_{23} sont sur une même droite, l'axe d'homothétie des figures F_1, F_2, F_3. Le point S_{12} est d'ailleurs, avec les points S_{14} et S_{24}, sur une seconde droite, l'axe d'homothétie des figures F_1, F_2, F_4. Un plan passant par ces deux droites (et ce plan existe toujours (¹), puisque les deux droites ont un point commun) contiendra les deux autres axes d'homothétie : celui de F_1, F_3, F_4 (dont il contiendra les points S_{13}, S_{14}) et celui de F_2, F_3, F_4 (dont il contiendra les points S_{23}, S_{24}) : il contiendra donc les six centres, lesquels auront bien la disposition indiquée par l'énoncé.

429. Définition. — Deux figures sont dites *semblables* si l'une d'elles est égale à l'une des homothétiques *directes* de l'autre.

Cette définition concorde d'ailleurs (**426**, Coroll. IV), dans le cas des figures planes, avec celle qui a été donnée en géométrie plane.

Des différents corollaires du n° **426** résulte d'ailleurs :

Théorème. — *Deux polyèdres semblables ont leurs faces homologues semblables, avec le même rapport de similitude, et leurs angles polyèdres homologues égaux chacun à chacun.*

Nous allons démontrer la réciproque :

Réciproque. — *Si deux polyèdres ont leurs faces semblables chacune à chacune, avec le même rapport de similitude, leurs angles polyèdres égaux chacun à chacun, ces éléments étant pareillement assemblés* (²) *: ils sont semblables.*

Nous allons d'abord démontrer que *si deux polyèdres ont leurs faces égales et leurs angles polyèdres égaux chacun à chacun et pareillement assemblés, ils sont égaux.*

Pour cela, nous transporterons l'un des polyèdres sur l'autre, de manière qu'une de ses faces — soit, par exemple, la face F, dont

---

(1) Il peut ne pas être unique, si les deux axes d'homothétie qui le déterminent coïncident : les centres S_{12}, S_{13}, ... sont alors tous en ligne droite.

(2) C'est-à-dire que ces éléments se correspondent dans les deux polyèdres de manière qu'à deux faces du premier, contiguës suivant une arête, correspondent, dans le second, deux faces respectivement semblables aux premières et aussi contiguës entre elles; qu'à des faces formant un angle polyèdre, correspondent des faces (semblables aux premières) formant l'angle polyèdre égal au premier, etc.

les sommets sont A, B, C, D, E (*fig.* 330) — vienne coïncider avec la face homologue (et par conséquent égale) F′ (aux sommets A′, B′, C′, D′, E′) de l'autre.

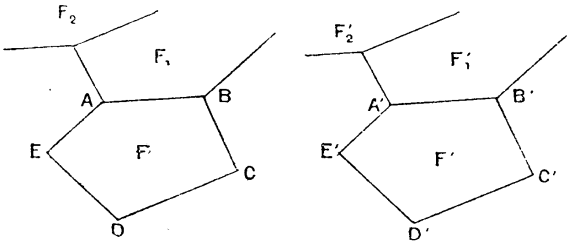

Fig. 330.

Alors l'angle polyèdre en A et l'angle polyèdre en A′, figures égales entre elles qui ont trois points communs non en ligne droite (puisque les faces F et F′ sont entièrement superposées), coïncident; et comme on peut raisonner de même pour chaque sommet de F, on voit que toute face F_1 du premier polyèdre, contiguë à F, coïncide avec son homologue.

Mais on peut recommencer le raisonnement précédent, en partant de F_1, et démontrer la même conclusion pour toute face F_2 contiguë à F_1, ; continuant ainsi de proche en proche, on peut manifestement montrer que la coïncidence est établie pour toutes les faces. Les deux polyèdres sont donc bien égaux.

Prenant alors, conformément à l'énoncé, deux polyèdres P, P′ qui ont toutes leurs faces semblables, avec le même rapport de similitude k, et leurs angles polyèdres égaux, ces éléments étant pareillement assemblés, nous considérerons le polyèdre P_1, homothétique direct de P avec k pour rapport d'homothétie. Ce polyèdre aura toutes ses faces égales et tous ses angles polyèdres égaux aux faces et aux angles polyèdres homologues de P′; il sera donc égal à P′, et les polyèdres P, P′ sont semblables.

C. Q. F. D.

430. Théorème. — *Deux polyèdres semblables peuvent être décomposés en pyramides semblables et pareillement assemblées.*

Il suffira, à cet effet, après avoir amené les deux solides dans la position où ils sont homothétiques, de décomposer l'un d'eux en pyramides (**395**) et l'autre, en pyramides homothétiques des premières.

On démontrerait d'ailleurs, par une marche analogue à celle qui a été suivie dans le plan (Pl., **149**) et à celle du n° précédent, que, *réciproquement, deux polyèdres, composés de pyramides semblables et pareillement assemblées sont semblables.*

431. Théorème. — *Le rapport des volumes de deux polyèdres semblables est égal au cube du rapport de similitude.*

Comme précédemment (**423**), nous distinguerons deux cas :

1° *Les polyèdres sont des pyramides.*

Soient B et H la base et la hauteur de la première pyramide ; B′ et H′, la base et la hauteur de la seconde ; k le rapport de similitude : on a (Pl., **257**)

$$B' = k^2B, \; H' = kH$$

et le rapport des volumes sera

$$\frac{\frac{1}{3}B'.H'}{\frac{1}{3}.B.H} = \frac{B'}{B}. \; \frac{H'}{H} = k^3.$$

2° *Cas général.* — On décomposera les polyèdres donnés en pyramides semblables et pareillement assemblées. Deux pyramides correspondantes quelconques étant dans le rapport k^3, leurs sommes sont, en vertu d'un théorème connu sur les proportions (¹), dans le même rapport.

C. Q. F. D.

EXERCICES

609. Si deux figures se correspondent point par point, de manière que la ligne joignant deux points quelconques de l'une soit parallèle à celle qui joint les points homologues de l'autre, elles sont homothétiques.

610. Si deux figures se correspondent point par point, de manière que A, B, C, étant trois points quelconques de l'une, A′, B′, C′ leurs homologues dans l'autre, l'angle $\widehat{B'A'C'}$ soit toujours égal à $\widehat{BAC}$, elles sont semblables, ou l'une est semblable à la symétrique de l'autre.

---

(1) Tannery, *Leçons d'Arithmétique*, n° **218**. Comparer Pl., **257**.

611. Deux figures semblables (mais non égales) peuvent être amenées à coïncider à l'aide d'une rotation, suivie d'une homothétie directe par rapport à un point situé sur l'axe de rotation.

Énoncé analogue pour deux figures dont l'une est semblable à la symétrique de l'autre.

612. Deux figures limitées en tout sens ne peuvent pas être homothétiques entre elles de plus de deux façons différentes.

613. Lieu du centre d'une homothétie dans laquelle les homologues de trois points donnés sont respectivement dans trois plans donnés.

614. Lieu du centre d'une homothétie dans laquelle le rapport de similitude est donné, sachant que l'homologue d'une droite donnée D rencontre une droite donnée D′.

615. Lieu des droites menées par un point donné et divisées dans un rapport donné par ce point et deux plans donnés ; par trois plans concourants donnés.

616. Prouver que l'on peut trouver, d'une infinité de façons, deux polyèdres, P, Q, tels que leurs volumes soient dans le même rapport que leurs surfaces. Déterminer Q, connaissant P et un polyèdre semblable à Q.

PROBLÈMES

PROPOSÉS SUR LE SEPTIÈME LIVRE

617. Deux tétraèdres sont égaux ou symétriques :

1° S'ils ont un dièdre égal compris entre faces égales chacune à chacune ;

2° S'ils ont un angle trièdre égal ou symétrique, compris entre arêtes égales chacune à chacune ;

3° S'ils ont une face égale adjacente à trois dièdres égaux chacun à chacun ;

4° S'ils ont une arête égale adjacente à deux trièdres égaux ou symétriques chacun à chacun ;

5° S'ils ont leurs six arêtes égales chacune à chacune.

Il est toutefois sous-entendu, dans tous ces énoncés, que les éléments égaux ou symétriques sont assemblés de la même façon.

618. Déduire des cas d'égalité énoncés à l'exercice précédent, des cas de similitude des tétraèdres.

619. Étant donnés une droite D et deux points A, B, trouver sur D le point M tel que $MA + MB$ soit minimum, et le point N tel que $NA - NB$ soit maximum.

620. Trouver, sur une droite donnée, le point tel que la somme de ses distances à deux droites parallèles données soit minima.

621. Que deviennent les énoncés des exercices 604 et 605 lorsque la droite MM′ est divisée par le plan P (ex. 604) ou la droite D (ex. 605) dans un rapport donné quelconque, et non en deux parties égales ?

622. Une rotation et une translation obliques entre elles se composent suivant un déplacement hélicoïdal dont l'axe est parallèle à celui de la rotation. Si l'on change l'ordre des deux opérations, on a deux mouvements dont les axes sont symétriques l'un de l'autre par rapport au plan qui passe par l'axe de la rotation et par la perpendiculaire commune menée à ce dernier et à la translation.

623. Plus généralement, en composant deux déplacements donnés dans un ordre déterminé, puis dans l'ordre inverse, on obtient deux déplacements dont les axes sont symétriques l'un de l'autre par rapport à la perpendiculaire commune aux deux axes primitifs (la grandeur de la rotation et celle de la translation résultantes étant d'ailleurs les mêmes dans les deux cas).

624. L'ordre dans lequel on compose deux déplacements n'est indifférent que si ces déplacements sont :

1° Ou deux déplacements de même axe;

2° Ou deux translations;

3° Ou deux rotations de 180° autour d'axes qui se coupent à angle droit.

625. Étant donnés trois plans P, Q, R passant par une même droite D et, dans l'un d'eux, une droite SA sécante à D en S, il existe, en général :

1° Un trièdre ayant une arête suivant SA et tels que P, Q, R soient les plans bissecteurs de ses dièdres ou de leurs suppléments (ex. 488). Discuter, suivant les cas, si c'est l'une ou l'autre de ces deux circonstances qui se présente. Lorsque, P, Q, R et S restant fixes, SA varie, le plan de la face opposée à SA passe par une droite fixe ;

2° Un trièdre tel que P, Q, R soient chacun perpendiculaire à une des deux faces, en passant par la bissectrice de cette face ou celle de son supplément, l'une de ces bissectrices étant SA. Discussion analogue à celle de 1°. Lieu des arêtes du trièdre lorsque SA varie, P, Q, R et S restant fixes;

3° Un trièdre tel que P, Q, R passent chacun par une de ses arêtes et la bissectrice de la face opposée ou de son supplément, l'une de ces bissectrices étant SA.

626. Étant données trois droites concourantes Sa, Sb, Sc d'un même plan, il existe, en général :

1° Un trièdre tel que Sa, Sb, Sc soient les droites dont il est question dans l'exercice 489, l'une des faces étant dans un plan donné P passant par Sa. Lieux des arêtes de ce trièdre lorsque P tourne autour de Sa;

2° Un trièdre tel que Sa, Sb, Sc soient les droites dont il est question dans l'exercice 491, l'un des plans bissecteurs mentionnés en cet endroit étant un plan donné P mené par Sa;

3° Un trièdre tel que Sa, Sb, Sc soient les droites dont il est question dans l'exercice 493, l'un des plans bissecteurs mentionnés en cet endroit étant un plan donné P passant par Sa.

627. (Généralisation de la 1^{re} partie de l'ex. précédent). Construire un angle polyèdre, connaissant les bissectrices des suppléments de ses faces. — Le problème est, en général, possible lorsque le nombre des faces est pair. Lorsque ce nombre est impair, le problème est, au contraire, impossible ou indéterminé. Quel est, dans ce dernier cas, le lieu d'une arête de l'angle polyèdre cherché ?

Lorsqu'on donne toutes les bissectrices moins une, quel est le lieu sur lequel doit se trouver cette dernière pour que le problème soit possible ?

628. Étant donnés trois plans P, Q, R passant par une même droite D et, dans l'un d'eux, une droite SA sécante à D en S, trouver un trièdre tel que P, Q et R passent chacun par une de ses arêtes et la bissectrice de la face opposée, l'une des arêtes étant SA. (Utiliser ex. 597.)

LIVRE VIII

LES CORPS RONDS

CHAPITRE PREMIER

DÉFINITIONS GÉNÉRALES — CYLINDRE

432. Parmi les surfaces qui ne sont pas planes, les plus simples sont les surfaces *cylindriques*, les surfaces *coniques* et les surfaces de *révolution*.

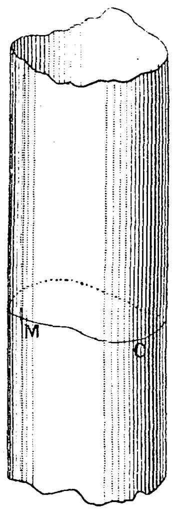

FIG. 331.

On nomme surface *cylindrique* (*fig*. 331), ou simplement *cylindre*, la surface engendrée par une droite, dite *génératrice*, qui se déplace en restant parallèle à une droite fixe.

Il est clair qu'on déterminera une surface cylindrique en se donnant : 1° la direction commune des génératrices ; 2° un point de chacune d'elles. On prend, en général, ces points de manière qu'ils varient continûment lorsque la génératrice varie continûment et forment une ligne (C, *fig*. 331), qui est dite la *directrice*.

Il est clair qu'on peut considérer comme directrice toute ligne tracée sur la surface et rencontrant toutes les génératrices. Il est souvent avantageux de prendre pour directrice une courbe plane.

Le plan est une surface cylindrique, à savoir celle qu'on obtient (**332**) en prenant pour directrice une droite.

433. Définition. — Une droite est dite *tangente à une surface*, en un point A de cette surface, lorsqu'elle est tangente en A à une ligne tracée sur la surface.

Théorème. — *Toutes les tangentes que l'on peut mener à une surface cylindrique, en un point de cette surface, sont dans un même plan.*

Ce plan est dit le *plan tangent au cylindre*, mené au point considéré.

Le plan tangent au cylindre en un point contient la génératrice qui passe par ce point et est le même tout le long de cette génératrice.

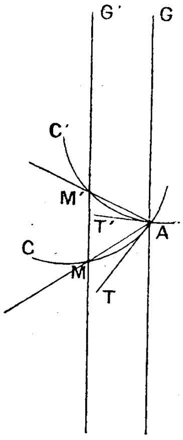

Fig. 332.

Soient A le point donné (*fig.* 332); G, la génératrice qui passe par ce point; C, une courbe tracée sur la surface par le point A et admettant une tangente AT, distincte (¹) de G; C', une autre courbe tracée par A sur la surface et admettant une tangente AT'. Soient maintenant M' un point de C', voisin de A; M, le point où la génératrice G' du point M' vient rencontrer la courbe C (²) : les deux droites AM, AM' sont, avec G, dans un même plan (le plan des deux génératrices G, G'). Donc leurs positions limites seront aussi (³) dans un même plan avec G : autrement dit, toutes les droites telles que AT' seront dans le même plan GAT.

Ce plan contient bien la droite G et est bien le même en tous les points de G (comme position limite (³) du plan GG').

434. *Une surface cylindrique peut être considérée comme le lieu des positions que vient occuper la directrice, lorsqu'on lui fait subir successivement les différentes translations parallèles aux génératrices.* Car, dans ces différentes translations, chaque point de la directrice se déplace évidemment sur la génératrice correspondante et décrit toute cette génératrice.

Les sections d'une surface cylindrique par des plans parallèles entre

---

(1) Nous ne considérerons pas le cas où il ne passerait pas, par le point A, de courbe ayant une tangente distincte de G. Ce cas, qui n'est pas théoriquement impossible, ne se présente pas dans les cylindres que l'on a à considérer habituellement.

(2) On démontre que ce point existe nécessairement lorsque la tangente AT est distincte de G.

(3) Nous admettons ici (voir Pl., **104**, note) les propositions suivantes : *Quand trois droites variables issues d'un même point sont dans un même plan, il en est de même de leurs positions limites (si celles-ci existent). — Quand une droite variable et un plan variable qui la contient tendent chacun vers une position limite, la position limite du plan contient la position limite de la droite.* Ces propositions se démontrent d'ailleurs aisément (V. Exercices 486 et 487).

eux (mais non parallèles aux génératrices) (*fig.* 333) *sont égales.* Car elles se déduisent l'une de l'autre par translation (**335**).

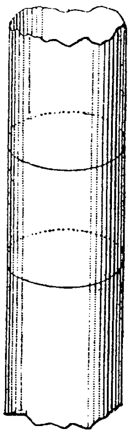

Fig. 333.

En particulier, on désigne sous le nom de *sections droites* du cylindre, les sections par des plans perpendiculaires aux génératrices. On voit que toutes les sections droites d'un même cylindre sont égales entre elles.

Dans le cas où le plan sécant est parallèle à la direction commune des génératrices, la section se compose évidemment d'une ou plusieurs de celles-ci.

435. On nomme plus spécialement *cylindre* le volume obtenu en coupant une surface cylindrique par deux plans parallèles (*fig.* 334) et limité, par conséquent, par une portion de surface cylindrique et deux aires planes égales entre elles (dites *bases*).

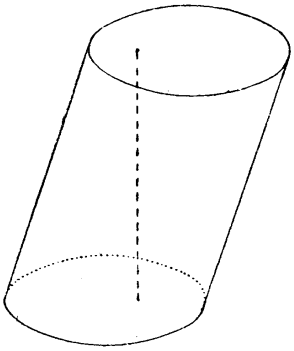

Fig. 334.

La *hauteur* du cylindre est la distance des plans des bases.

Un cylindre est dit *droit*, lorsque ses génératrices sont perpendiculaires aux plans des bases : autrement dit, lorsque celles-ci sont des sections droites.

436. On nomme surface *conique* (*fig.* 335) ou plus simplement *cône*, la surface engendrée par une droite (dite *génératrice*) qui se déplace en passant par un point fixe (dit *sommet* du cône).

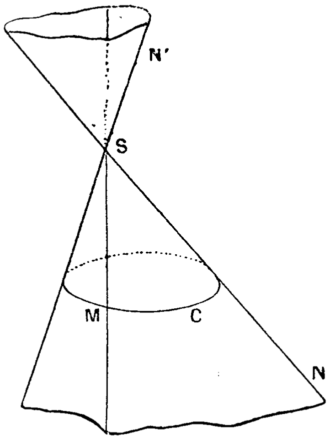

Fig. 335.

Il est clair qu'on déterminera une surface conique en se donnant : 1° le sommet; 2° un point de chaque génératrice. On prend, en général, ces points de manière qu'ils varient continûment et forment une ligne (C, *fig.* 335), qui est dite *directrice* ou *base* du cône. On peut considérer comme directrice toute ligne tracée sur la surface et rencontrant toutes les génératrices.

Le plan est une surface conique, à savoir celle qu'on obtient en prenant pour directrice une droite (**323**).

Théorème. — *Les tangentes que l'on peut mener à une surface conique, en un point autre que le sommet, sont toutes dans un même plan.*

Ce plan est dit le *plan tangent* au cône au point considéré.

Le plan tangent au cône contient la génératrice du point de contact et est le même en tous les points d'une même génératrice.

Même démonstration que pour le cylindre (**433**).

Une surface conique peut être considérée comme le lieu des positions que vient occuper la directrice, lorsqu'on lui fait subir successivement toutes les homothéties qui ont pour centre le sommet.

Lorsque la directrice est fermée, ses homothétiques directes forment une première portion ou *nappe* du cône, pendant que ses homothétiques inverses forment la seconde nappe.

Ces deux nappes sont alors séparées l'une de l'autre par le sommet (*fig.* 335).

Les sections d'un même cône par des plans parallèles sont semblables (**393**, Rem.).

La section d'un cône par un plan passant par le sommet se compose évidemment d'une ou plusieurs génératrices.

437. On appelle, plus spécialement, *cône*, le volume obtenu en coupant une nappe de surface conique par un plan, autrement dit, limité par une aire plane (dite *base*) et une portion de surface conique (*fig.* 336).

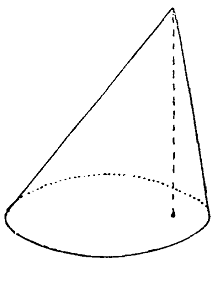

Fig. 336.

La *hauteur* du cône est la distance du sommet au plan de la base.

On nomme *tronc de cône* (*fig.* 337) le volume obtenu en coupant un cône par un plan parallèle à la base; autrement dit, limité par une portion de surface conique et deux aires planes semblables (dites *bases*). La *hauteur* du tronc du cône est la distance des plans des bases.

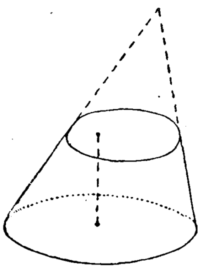

Fig. 337.

438. On nomme *surface de révolution*, la surface engendrée par une ligne C qui se déplace en tournant autour d'un axe fixe, l'angle de rotation prenant successivement toutes les valeurs possibles.

Dans ces conditions, un point quelconque M de C se déplacera, d'après ce que nous savons, dans le plan mené par ce point perpendiculairement à l'axe : il décrira dans ce plan, un cercle ayant son centre sur l'axe.

Ce cercle est dit un *parallèle* de la surface.

Comme il passe un parallèle par tout point de la surface, on voit qu'*une surface de révolution peut être considérée comme le lieu décrit par un cercle qui varie* (en changeant, en général, de rayon) *de manière que son centre décrive une droite, son plan restant perpendiculaire à cette droite.*

On achèvera de définir la surface en imposant au cercle variable la condition de rencontrer constamment la ligne donnée C. Comme, une fois l'axe donné, il suffit de se donner un point quelconque d'un parallèle pour le déterminer entièrement, on voit que *la ligne* C *peut être remplacée par n'importe quelle autre courbe tracée sur la surface et rencontrant tous les parallèles.*

On choisit, le plus souvent, pour la ligne C, la section de la surface par un plan quelconque passant par l'axe. Cette section MM′ (*fig.* 338), dite *méridienne* de la surface, est évidemment symétrique par rapport à l'axe, puisqu'elle contient les points diamétralement opposés de chaque parallèle. On pourra, par conséquent, se contenter d'en considérer une moitié, par exemple la partie située d'un seul et même côté de l'axe.

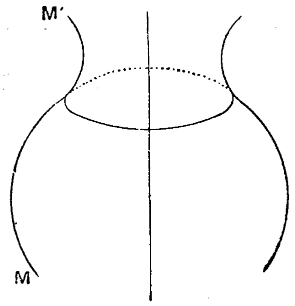

FIG. 338.

On nomme *méridiens* les diverses positions occupées par la méridienne, lorsque son plan tourne autour de l'axe. Par chaque point de la surface, il passe évidemment un méridien.

Une surface de révolution admet une infinité de plans de symétrie : elle est symétrique par rapport à tout plan passant par l'axe, car un parallèle quelconque jouit de cette propriété, en vertu du n° **419** *bis* et du n° **62** (Pl., liv. II).

On démontre qu'en un point quelconque d'une surface de révolution existe, en général, un *plan tangent*, c'est-à-dire que les tangentes que l'on peut mener aux différentes courbes tracées sur la surface par ce point, sont dans un même plan. Ce plan doit, d'après ce qui précède, coïncider avec son symétrique par rapport au plan méridien qui passe au point considéré, et, par suite, être perpendiculaire à ce dernier plan.

439. Après le plan, les surfaces cylindriques les plus simples sont celles qui ont pour directrices des cercles.

Parmi celles-là, on considère, en particulier, celle qui a pour section droite un cercle et qui est la *surface cylindrique de révolution :* cette surface est, en effet, celle qu'on obtient en faisant tourner une droite D autour d'un axe A qui lui est parallèle, car, dans ce mouvement, la droite reste constamment parallèle à A, pendant qu'un quelconque de ces points décrit un cercle dont le plan est perpendiculaire à A; et inversement, tout cylindre dont la section droite est un cercle peut être obtenu de cette manière, l'axe A étant la parallèle menée par le centre du cercle à la direction des génératrices.

En coupant la surface cylindrique de révolution par deux plans de sections droites, on obtient le *cylindre droit à base circulaire* ou *cylindre de révolution* (*fig.* 339), que l'on peut encore considérer comme la figure engendrée par un rectangle AA'DD' (*fig.* 339) tournant autour d'un de ses côtés.

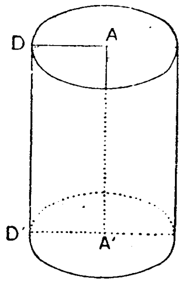

Fig. 339.

Un cylindre de révolution est manifestement défini quand on se donne le cercle de base et la hauteur (ainsi que le sens dans lequel elle doit être portée). Deux cylindres de révolution qui ont même rayon de base et même hauteur, sont égaux.

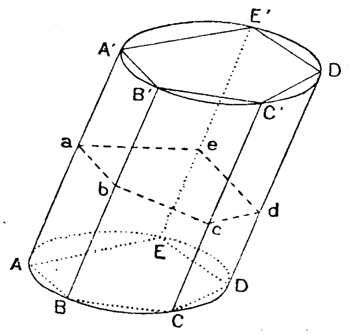

Fig. 340.

440. Surface latérale du cylindre.

Un cylindre étant donné (*fig.* 340), inscrivons dans la première courbe de base un polygone quelconque : ce polygone sera la base d'un prisme ABCDEA'B'C'D'E' (*fig.* 340) ayant pour arêtes des génératrices du cylindre et pour seconde base un polygone inscrit dans la seconde base de celui-ci : prisme qui sera dit *inscrit* au cylindre.

L'*aire latérale* du cylindre est, par définition, la limite vers laquelle tend l'aire latérale d'un prisme inscrit, lorsque le nombre des côtés du polygone de base augmente indéfiniment, de manière que chacun d'eux tende vers zéro.

Dans le cas du cylindre droit à base circulaire, nous allons prouver l'existence de cette limite et en trouver la valeur.

Théorème. — *L'aire latérale d'un cylindre droit à base circulaire est égale au produit du périmètre de la base par la hauteur.*

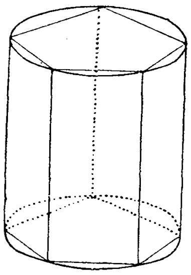

Fig. 341.

En effet, l'aire latérale du prisme inscrit (*fig.* 341) est égale (**388**), au périmètre de la section droite (qui se confond ici avec la base) multiplié par l'arête latérale.

Si l'on augmente indéfiniment le nombre des côtés du polygone de base, de manière que chacun d'eux tende vers zéro, le périmètre de ce polygone tend, ainsi que nous l'avons démontré (Pl., **176-177**), vers une limite, qui est la longueur de la circonférence de base du cylindre; l'arête du prisme étant d'ailleurs constamment égale à la hauteur du cylindre, le théorème est démontré (1).

Corollaire. — Soient R le rayon de base du cylindre, h sa hauteur. *L'aire latérale est* $2\pi Rh$, puisque la circonférence de base a pour longueur $2\pi R$.

Pour avoir l'*aire totale* du cylindre, il faudrait ajouter, bien entendu, les aires des deux cercles de bases. L'aire totale est donc $2\pi Rh + 2\pi R^2 = 2\pi R\,(h + R)$.

441. Volume du cylindre.

Le volume d'un cylindre est, par définition, la limite vers laquelle tend le volume d'un prisme inscrit, lorsque le nombre des côtés du polygone de base augmente indéfiniment, de manière que chacun d'eux tende vers zéro.

Dans le cas du cylindre à base circulaire, droit ou non, nous allons prouver l'existence de cette limite et en trouver la valeur.

---

(1) Le raisonnement s'applique à un cylindre quelconque, du moment que l'on a pu définir (Pl., **179**, note) la longueur de la courbe de section droite de ce cylindre : c'est-à-dire, du moment que le périmètre d'un polygone inscrit dans cette courbe et dont le nombre de côtés augmente indéfiniment tend vers une limite (voir fig. 340). La conclusion est évidemment la suivante : *L'aire latérale d'un cylindre quelconque est égale au périmètre de la section droite, multiplié par l'arête.*

Théorème. — *Le volume du cylindre à base circulaire est égal à la surface de base, multipliée par la hauteur.*

Le volume du prisme inscrit est, en effet, égal au produit de la surface de sa base par sa hauteur : cette dernière est commune au prisme et au cylindre, pendant que la surface de base du prisme a pour limite la surface de base du cylindre (1).

Corollaire. — Soient, comme précédemment, R le rayon du cylindre ; h sa hauteur. *Le volume est* $\pi R^2 h$.

Remarque. — Nous avons défini l'aire latérale et le volume d'un cylindre comme limites de l'aire latérale et du volume d'un prisme inscrit. Nous serions évidemment arrivés à la même limite en considérant l'aire latérale et le volume d'un prisme *circonscrit* (on désigne sous ce nom un prisme ayant pour bases des polygones circonscrits aux courbes de bases et dont les arêtes sont parallèles et égales aux génératrices du cylindre).

EXERCICES

629. Si une droite a plus de deux points communs avec une surface cylindrique à base circulaire, elle est une génératrice de la surface.

630. Trouver le lieu des milieux des cordes interceptées par une surface cylindrique à base circulaire sur des droites issues d'un point fixe.

631. Mener, par un point donné de l'espace, un plan tangent à un cylindre de révolution donné.

632. Lieu des centres des homothéties de rapport donné et telles que l'homologue d'une droite donnée rencontre un cercle donné.

633. Trouver le lieu des points de l'espace tels que leurs projections sur les côtés d'un triangle donné soient trois points en ligne droite.

634. Démontrer que les seules surfaces de révolution, qui soient en même temps des cylindres, sont les cylindres de révolution définis au n° **439**.

635. Calculer les dimensions du litre qui sert à mesurer les grains et du litre qui sert à mesurer les liquides, sachant que ces deux instruments ont tous deux la forme cylindrique, la hauteur étant, dans le premier, égale au diamètre de la base et, dans le second, double de ce diamètre.

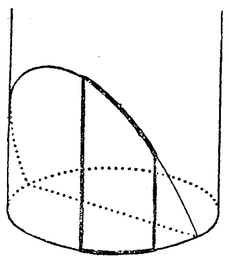
636. Quel est le rapport des volumes engendrés par un rectangle tournant successivement autour de deux côtés consécutifs ?

637. Étant donnés un cercle et deux diamètres rectangulaires, trouver un rectangle ayant deux côtés suivant ces diamètres, un sommet sur la circonférence et et qui, en tournant autour d'un de ses côtés, engendre un cylindre de surface totale donnée. Maximum de cette surface totale.

---

(1) Le raisonnement s'applique évidemment à un cylindre de base quelconque, en admettant toutefois que la définition (Pl., **260**, note) de l'aire d'une courbe fermée s'applique à la courbe de base de ce cylindre. Moyennant cette condition, on a donc le théorème suivant : *Le volume d'un cylindre quelconque est égal au produit de sa base par sa hauteur.*

638. Étant donné un cylindre droit à base circulaire, évaluer la portion de l'aire latérale comprise entre la base, un plan P passant par un diamètre de la base et deux génératrices quelconques (voir la figure ci-contre). Montrer que l'aire ainsi définie est *quarrable*, c'est-à-dire qu'on peut construire un rectangle équivalent (on suppose qu'on a tracé le cercle de base, marqué sur sa circonférence les pieds des deux génératrices, donné la longueur interceptée par le plan P sur l'une d'elles et la direction du diamètre commun aux deux plans).



(On imitera la méthode du n° **440**, en remplaçant d'abord la surface cylindrique par une surface prismatique inscrite).

639. En coupant une surface cylindrique à base circulaire par deux plans non parallèles entre eux (mais ne se coupant pas à l'intérieur de la surface), on obtient un solide (qu'on peut appeler *tronc de cylindre*). Montrer que l'aire latérale et le volume de ce solide sont les mêmes que ceux d'un cylindre limité par la même surface cylindrique et deux plans parallèles à la base du cylindre menés aux points où la parallèle aux génératrices menée par le centre de cette base rencontre les plans donnés.

CHAPITRE II

CONE — TRONC DE CONE

442. Parmi les cônes, on distingue ceux qui ont pour bases des cercles.

En particulier, un cône dont la base est un cercle et dont le sommet est sur la perpendiculaire élevé au plan du cercle par son centre, a reçu le nom de *cône droit à base circulaire* ou *cône de révolution*.

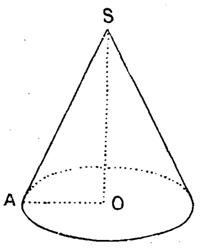


Fig. 342.

Ce cône (*fig.* 342), considéré comme surface conique illimitée, est, en effet la surface de révolution qui a pour méridienne une droite sécante à l'axe; considéré comme solide limité, c'est la figure engendrée par un triangle rectangle qui tourne autour d'un de ses côtés.

Un cône droit est évidemment déterminé lorsqu'on donne son cercle de base et sa hauteur, avec le sens dans lequel celle-ci doit être portée. Deux cônes droits de même rayon de base et de même hauteur soit égaux.

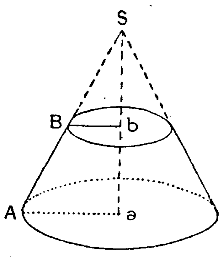

Fig. 343.

La longueur commune des génératrices d'un cône droit a reçu le nom d'*arête latérale* ou d'*apothème* du cône. On donne le nom d'*angle au sommet* du cône à l'angle que forment entre elles deux génératrices situées dans un même plan méridien, angle évidemment double de l'angle compris entre l'une d'elles et l'axe.

Il est clair que le *tronc de cône de révolution* peut s'obtenir en faisant tourner un trapèze rectangle AB*ab* (*fig.* 343) autour du côté perpendiculaire aux bases.

Remarque. — Si la génératrice est perpendiculaire à l'axe, la surface dégénère en un plan.

443. Aire latérale du cône de révolution.

Si, dans la base d'un cône quelconque, on inscrit un polygone quelconque, la pyramide qui a pour base ce polygone et dont le sommet est le même que celui du cône, est dite *inscrite* à celui-ci.

On nomme *aire latérale* du cône, la limite vers laquelle tend l'aire latérale d'une pyramide inscrite, lorsque le nombre des côtés du polygone de base augmente indéfiniment, de manière que chacun d'eux tende vers zéro.

Nous allons, dans le cas du cône de révolution, prouver l'existence de cette limite et en trouver la valeur.

Théorème. — *L'aire latérale du cône droit est égale au demi-produit de la circonférence de base par l'arête latérale.*

Dans le cône donné, de sommet S (*fig.* 344), inscrivons la pyramide SABCDE. L'aire latérale de cette pyramide est la somme des triangles SAB, SBC, SCD, ..., autrement dit, la somme des demi-produits obtenus en multipliant chacune des bases AB, BC, CD .... de ces triangles par la hauteur correspondante. Elle est donc égale (¹) à la demi-somme $\frac{AB + BC + \dots}{2}$, multipliée par une quantité a intermédiaire entre la plus grande et la plus petite des hauteurs.

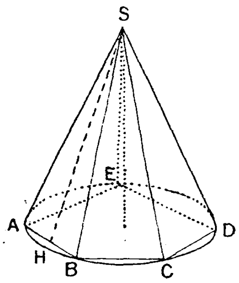

Fig. 344.

Lorsque le nombre des côtés du polygone de base augmente indéfiniment de manière que chacun d'eux tende vers zéro, la somme AB + BC + ... tend vers la longueur de la circonférence de base. Quant aux hauteurs, si nous considérons, par exemple, la hauteur SH (*fig.* 344) du triangle SAB, laquelle tombe au milieu H de AB, nous voyons, dans le triangle SAH, qu'elle est comprise entre SA et SA — AH, lequel est égal à $SA - \frac{AB}{2}$. Elle tend donc vers SA lorsque AB tend vers zéro et, lorsque le plus grand des côtés AB, BC, ... tend vers zéro, la plus grande et la plus petite des hauteurs considérées précédemment tendent vers l'arête latérale du cône. Il en est donc de même de a et le théorème est démontré (²).

---

(1) Tannery, *Leçons d'Arithmétique*, n° **212**, page 180.

(2) Contrairement à ce qui a été vu pour le cylindre, et à ce qu'on va voir plus loin pour le volume du cône, la démonstration relative à l'aire du cône de révolution n'est point valable

Corollaire. — Appelons maintenant a l'arête latérale du cône, et soit R le rayon de base. *L'aire latérale sera* $\frac{1}{2}\,2\pi R \times a = \pi R a$.

L'aire totale du cône s'obtiendra en ajoutant, à l'aire latérale, celle de la base, ce qui donnera $\pi R a + \pi R^2 = \pi R\,(a + R)$.

Remarque. — Si, au lieu de pyramides inscrites au cône, nous avions considéré des pyramides *circonscrites*, c'est-à-dire ayant pour bases des polygones circonscrits à la base du cône (le sommet restant le même), nous aurions constaté que les surfaces latérales de ces pyramides tendent vers la même limite que les surfaces latérales des pyramides inscrites. Le raisonnement précédent peut en effet se répéter dans ces nouvelles conditions, avec cette seule modification que, dans une pyramide circonscrite SA′B′C′D′,... (*fig.* 345), les hauteurs des triangles SA′B′, SB′C′,... sont constamment égales à l'apothème du cône, car elles tombent (**364**) aux points de contact des côtés A′B′, B′C′,... avec le cercle de base.

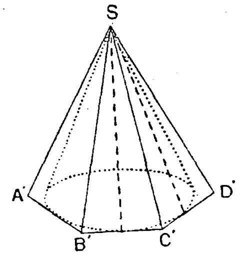

Fig. 345.

444. Volume du cône.

On nomme *volume* d'un cône quelconque, la limite vers laquelle tend le volume d'une pyramide inscrite, lorsque le nombre des côtés du polygone de base augmente indéfiniment de manière que chacun d'eux tende vers zéro.

Dans le cas du cône à base circulaire, nous allons prouver l'existence de cette limite et en trouver la valeur.

Théorème. — *Le volume d'un cône à base circulaire est égal au tiers du produit de la surface de base par la hauteur.*

Ce théorème se déduit immédiatement du théorème relatif au volume de la pyramide, en remarquant que l'aire du polygone qui sert de base à la pyramide tend, par définition, vers l'aire du cercle qui sert de base au cône, lorsqu'on augmente le nombre des côtés dans les conditions indiquées (¹).

Corollaire. — Soient R le rayon de base; h la hauteur. *Le volume est* $\frac{1}{3}\pi R^2 h$.

en dehors de ce cas spécial. Pour les autres espèces de cône (et en particulier pour le cône *oblique* à base circulaire), on peut démontrer l'existence de la limite, mais non en donner d'évaluation élémentaire, du moins en général.

(1) Le raisonnement et sa conclusion s'étendent évidemment à un cône quelconque, pourvu que l'on puisse définir l'aire de la base.

Remarque. — Il est clair qu'on serait arrivé au même résultat en substituant, aux pyramides inscrites, des pyramides circonscrites.

445. Aire latérale du tronc de cône de révolution.

Si, dans le cône dont fait partie un tronc de cône donné on inscrit une pyramide, le plan de base supérieure du tronc détache de cette pyramide un tronc de pyramide, qui est dit *inscrit* au tronc de cône.

On nomme *aire latérale* du tronc de cône, la limite vers laquelle tend l'aire latérale d'un tronc de pyramide inscrit, lorsque le nombre des côtés des polygones augmente indéfiniment, de manière que chacun de ces côtés tende vers zéro.

Cette définition est manifestement équivalente à la suivante : L'aire latérale d'un tronc de cône est la différence des aires des deux cônes qui font partie de la même surface conique que le tronc et qui ont bases respectives les deux bases de ce tronc.

Théorème. — *L'aire latérale d'un tronc de cône de révolution est égale à la demi-somme des deux circonférences de bases, multipliée par l'arête latérale.*

Soit le tronc de cône $ABA'B'$ (*fig.* 346), dont l'arête latérale est AA' et qui fait partie d'un cône SAB de sommet S. L'aire latérale de ce cône est la différence des aires latérales du cône SAB et du cône $SA'B'$ qui a pour base la petite base du tronc.

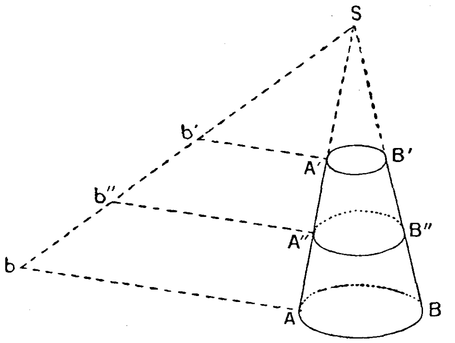

Fig. 346.

Par le point A, menons à SA une perpendiculaire Ab égale à la longueur de la circonférence de base AB, et joignons Sb. Si, par le point A', nous menons une parallèle $A'b'$ à Ab, jusqu'à rencontre en b' avec Sb, cette droite $A'b'$ sera égale à la longueur de la seconde circonférence de base $A'B'$. Car le rapport des deux circonférences de bases $A'B'$, AB, c'est-à-dire le rapport de leurs rayons, est égal à $\frac{SA'}{SA}$ ou à $\frac{A'b'}{Ab}$, et l'on a, d'autre part, circ. $AB = Ab$.

Dès lors, l'aire latérale du cône SAB est égale (**443**) à celle du triangle SAb et l'aire latérale du cône $SA'B'$, à celle du triangle $SA'b$. L'aire du tronc de cône donné équivaut donc à celle trapèze rectangle $AA'bb'$, laquelle a bien l'expression indiquée par l'énoncé.

Corollaires. — I. *Si* R, R′ *sont les rayons des bases; a, l'arête, l'aire latérale est* $\pi(R + R')a$.

II. *L'aire latérale d'un tronc de cône est égale au produit de l'arête par la circonférence obtenue en coupant le solide par un plan parallèle aux bases et équidistant de ces bases.*

Car un tel plan passe par le milieu A'' (*fig.* 346) de AA' : la longueur de la circonférence de section est (d'après un raisonnement tout semblable à celui qui a été fait tout à l'heure) égale à la droite $A''b''$ parallèle à Ab et limitée à Sb. Le produit de cette circonférence par l'arête AA' équivaut donc (Pl., **252** *bis*) à l'aire du trapèze $AA'bb'$.

C. Q. F. D.

Remarque. — On peut considérer le cylindre et le cône comme des cas limites du tronc de cône : le premier correspondant à l'hypothèse où le trapèze qui engendre le tronc de cône devient un rectangle (ses bases étant égales) ; le second, à l'hypothèse où ce trapèze se réduit à un triangle (une des bases étant nulle).

Les corollaires précédents continuent à s'appliquer et donnent bien : pour $R' = R$, l'aire du cylindre (**440**) ; pour $R' = 0$, l'aire du cône (**443**).

446. Volume du tronc de cône.

Le *volume du tronc de cône* est la limite vers laquelle tend le volume d'un tronc de pyramide inscrit, lorsque les côtés des polygones de bases tendent tous vers zéro. Il est évidemment égal à la différence des volumes de deux cônes, les mêmes dont il a été question dans le numéro précédent, à propos de l'aire latérale.

Théorème. — *Un tronc de cône à base circulaire est équivalent à la somme de trois cônes ayant pour hauteur commune la hauteur du tronc et, pour bases respectives, les deux bases de ce tronc et une moyenne proportionnelle entre ces deux bases.*

Car le tronc de pyramide inscrit est, d'après le théorème du n° **408**, équivalent à la somme de trois pyramides, qui tendent respectivement vers les trois cônes dont parle l'énoncé.

Corollaire. — *Si* R *et* R′ *sont les rayons des bases, h la hauteur, le volume est* $\frac{1}{3}\pi h\,(R^2 + R'^2 + RR')$.

Car les bases du tronc sont respectivement mesurées par πR^2 et $\pi R'^2$, dont la moyenne proportionnelle est $\sqrt{\pi R^2 \times \pi R'^2} = \pi RR'$.

EXERCICES

640. Si une droite a plus de deux points communs avec une surface conique à base circulaire, elle est une génératrice de la surface.

641. Montrer que les seules surfaces de révolution qui soient en même temps des cônes sont les cônes de révolution définis au n° **442**.

642. Mener, par un point donné, un plan tangent à un cône à base circulaire donné.

643. Si un cône de révolution est tangent aux deux faces d'un dièdre, les génératrices de contact font des angles égaux avec l'arête. Le plan mené par l'axe du cône et l'arête du dièdre fait des angles égaux avec les faces, et fait aussi des angles égaux avec les plans méridiens des génératrices de contact.

644. Quel est le lieu des axes des cônes de révolution tangents à deux plans donnés ?

645. Quel est le lieu des axes des cônes de révolution qui passent par deux droites concourantes données?

646. Lieu des points tels que le rapport de leurs distances à un point et à un plan passant par ce point soit constant.

647. Démontrer qu'un cône à base circulaire, mais quelconque d'ailleurs (c'est-à-dire, en général, non de révolution), admet toujours un plan de symétrie et que la surface conique dont il fait partie admet un axe de symétrie.

648. Faire passer un cône de révolution par trois droites données concourantes, mais non situées dans un même plan. Quel est le nombre des solutions?

Montrer que deux quelconques de cônes de révolution qui passent par les trois droites données ont une quatrième droite commune (laquelle peut être confondue avec l'une des trois premières). Construire la position de cette quatrième droite.

649. La condition pour qu'un angle polyèdre convexe à quatre faces soit inscriptible à un cône de révolution est que la somme de deux dièdres opposés soit égale à la somme des deux autres, ou sinon, qu'il en soit lorsqu'on remplace une ou plusieurs arêtes par leurs prolongements.

650. Quelle est la condition pour qu'un angle polyèdre à quatre faces soit inscriptible à deux cônes de révolution? — pour qu'il soit inscriptible à trois cônes de révolution? Dans ce dernier cas, les axes des trois cônes forment un trièdre trirectangle.

651. Trouver un cône (ou un cylindre) de révolution tangent à trois plans donnés. Quel est le nombre des solutions?

Deux cônes quelconques tangents aux trois plans donnés ont un quatrième plan tangent commun. Construire ce plan.

652. Quelles conditions doivent remplir les faces d'un angle polyèdre à quatre faces pour que cet angle soit circonscriptible à un cône de révolution? Dans quels cas l'angle polyèdre est-il conscriptible à plus d'un cône de révolution?

653. Parmi les génératrices d'un cône de révolution, quelle est celle qui fait le plus petit ou le plus grand angle avec une droite donnée?

654. L'angle au sommet d'un cône de révolution est plus grand que l'angle de deux génératrices non situées dans le même plan méridien.

655. On coupe un cône à base circulaire par un plan parallèle à la base, mais situé au delà du sommet et formant, par conséquent, avec la seconde nappe de la surface conique, un second cône homothétique, du premier. Évaluer le volume du solide (*tronc de cône de seconde espèce*) formé par l'ensemble des deux cônes, connaissant les rayons des deux cercles et la distance de leurs plans.

656. Inscrire, dans un cône de révolution donné, un cylindre de surface latérale donnée. Maximum de celle-ci.

657. On donne deux cônes de révolution égaux SAB, S'A'B', placés de façon que les plans des cercles de bases AB, A'B' sont parallèles et que le sommet de chacun des cônes est dans le plan du cercle de base de l'autre. On coupe ces deux cônes par un plan P parallèle aux plans des deux bases et situé entre ces plans; ce plan P coupe le premier cône suivant un cercle CD et le second cône suivant un cercle C'D'. On désigne par r, l, h, le rayon de la base, l'arête, la hauteur de chacun des cônes, par x la distance du sommet S au point de rencontre du plan P et de l'arête SA et par y la distance du sommet S au plan P.

1° Déterminer x de façon que le rapport de la somme des surfaces latérales des deux troncs de cône ABCD, A'B'C'D' et de la surface latérale du cône SAB soit égal à un nombre donné λ. Discuter.

2° Déterminer y de façon que le rapport de la somme des volumes des troncs de cônes ABCD, A'B'C'D' au volume du cône SAB soit égal à un nombre donné μ. Discuter.

CHAPITRE III

GÉNÉRALITÉS SUR LA SPHÈRE

447. Définition. — On nomme *sphère* (*fig.* 347), le lieu géométrique des points de l'espace situés à une distance donnée d'un point donné, appelé *centre* de la sphère.

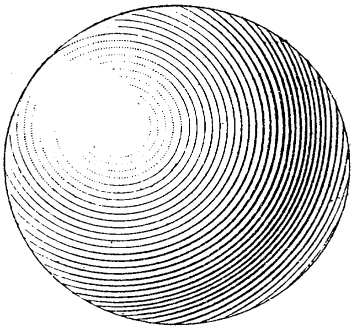

FIG. 347.

La droite qui joint le centre à un point de la surface est dite un *rayon*. Une droite qui joint deux points de la surface et qui, de plus, passe par le centre, est dite un *diamètre*. Il résulte de la définition que tous les rayons sont égaux entre eux et qu'un diamètre est double d'un rayon.

Un plan qui passe par le centre de la sphère est dit *plan diamétral*. La sphère sépare l'une de l'autre deux régions de l'espace : l'une, comprenant les points dont la distance au centre est moindre que le rayon, est dite *intérieure* à la sphère (¹) ; au contraire, les points dont la distance au centre est plus grande que le rayon sont dits *extérieurs* à la surface. On ne peut passer de l'une des deux régions à l'autre par un chemin continu sans traverser la surface.

La définition de la sphère, jointe à celle de la circonférence (Pl., **56**) montre évidemment que la section d'une sphère par un plan diamétral est une circonférence de même centre et de même rayon que la sphère : une telle circonférence est dite *grand cercle* de la sphère.

Théorème. — *La surface engendrée par la révolution d'une demi-circonférence autour de son diamètre est une sphère.*

---

(1) On donne également, dans le langage courant, le nom de *sphère* à la région située à l'intérieur de la surface : cette manière de parler n'introduit aucune confusion dans les raisonnements.

Réciproquement, *toute sphère peut être considérée comme engendrée de cette façon, l'axe étant un diamètre quelconque de la surface.*

1° Soit une demi-circonférence du centre O (*fig.* 348) tournant autour de son diamètre AB. La distance OM d'un point quelconque de la demi-circonférence au. centre O ne changera pas dans ce déplacement, de sorte que le point M sera constamment sur une sphère S ayant même centre et même rayon que la circonférence donnée.

Inversement, tout point M′ de la sphère ainsi obtenue est tel que la distance OM′ soit égale à OA. Il appartient donc à une circonférence, section de la sphère par le plan AM′B, et qui est une des positions que vient prendre la circonférence donnée dans son mouvement de révolution autour de l'axe;

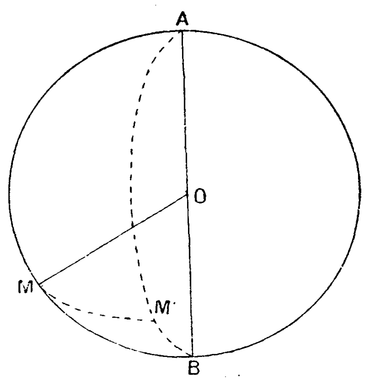

FIG. 348.

2° Soit AB un diamètre quelconque d'une sphère donnée O. Par AB, faisons passer un plan qui coupe la sphère suivant une circonférence de centre O. La sphère engendrée par la révolution d'une des moitiés de cette circonférence autour de l'axe AB coïncide manifestement avec la sphère donnée.

REMARQUE. — On voit que la *sphère est de révolution autour d'un quelconque de ses diamètres.*

Par conséquent (**438**), *la sphère admet tous ses plans diamétraux comme plans de symétrie.*

448. Intersection d'une droite et d'une sphère.

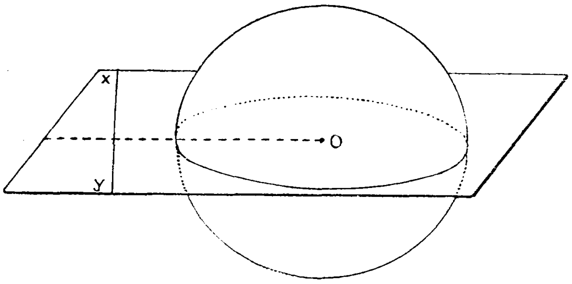

FIG. 349.

Pour étudier l'intersection d'une droite xy et d'une sphère S (*fig.* 349), faisons passer un plan par la droite xy et le centre O de la sphère. Tout point commun à la droite et à la sphère appartenant forcément au grand cercle, section de la sphère par ce plan, les conclusions du n° **58** (Pl., liv. II), nous permettent d'énoncer les propositions suivantes :

1° *Une droite ne rencontre pas une sphère, si la distance de cette droite au centre est plus grande que le rayon ;*

2° *Si cette distance est plus petite que le rayon, la droite et la sphère se coupent en deux points. La corde interceptée sur la droite est d'autant plus petite que la distance de la droite au centre est plus grande; le centre se projette au milieu de cette corde ;*

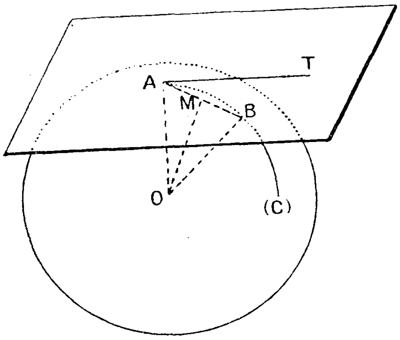

Fig. 350.

3° *Enfin, dans le cas intermédiaire où la distance de la droite au centre est égale au rayon, la droite n'a, avec la sphère, qu'un point commun.*

On dit alors qu'elle est *tangente* à la sphère (AT, *fig.* 350).

On voit qu'*une tangente à la sphère est perpendiculaire au rayon du point de contact*, et qu'inversement, *toute droite perpendiculaire à l'extrémité d'un rayon est tangente.*

449. La définition que nous venons de donner de la tangente à la sphère n'est pas celle que nous avons indiquée, d'une façon générale, pour la tangente à une surface quelconque (**433**). Nous allons faire voir que ces deux définitions sont entièrement équivalentes l'une à l'autre.

Par un point A de la sphère (*fig.* 350), soit tracée une courbe quelconque (C), que nous supposerons avoir une tangente AT. Nous avons à démontrer que AT est tangente à la sphère, au sens du numéro précédent.

Or la tangente AT est la limite d'une sécante AB, lorsque le point B tend vers le point A. Le point M, projection du centre AB, est le milieu de AB : il tend donc, dans les conditions dont nous venons de parler, vers le point A ; d'où résulte nécessairement la conséquence demandée.

Inversement, toute droite AT perpendiculaire à l'extrémité d'un rayon de la sphère est tangente au moins à une courbe tracée sur la surface, à savoir le grand cercle situé dans le plan OAT.

449 *bis*. De ce qui précède, résulte le théorème suivant :

Théorème. — *Le lieu des tangentes à la sphère en un de ses points est le plan perpendiculaire au rayon qui aboutit en ce point* (*fig.* 350).

Ce plan est dit *plan tangent à la sphère*, au point considéré.

Nous avons donc démontré, pour la sphère, un théorème analogue à celui qui avait été précédemment établi pour les cylindres (**433**) et pour les cônes (**436**).

Toutefois, nous avons à noter une différence importante : un plan tangent à la sphère n'a manifestement qu'*un seul* point de contact. Le cylindre et le cône présentaient, au contraire, cette particularité que le plan tangent était le même en *une infinité* de points (à savoir, tous les points d'une même génératrice).

450. Intersection d'une sphère et d'un plan.

Théorème. — *Si la distance d'un plan au centre d'une sphère est supérieure au rayon de celle-ci, les deux surfaces n'ont aucun point commun.*

Si la distance du plan au centre de la sphère est moindre que le rayon, les deux surfaces se coupent suivant un cercle, dont le centre est la projection du centre de la sphère sur le plan.

Enfin, dans le cas intermédiaire où il y a égalité, le plan n'a qu'un point commun avec la sphère; il est (**449** *bis*) *tangent à cette surface.*

Si, en effet, par la projection C du centre O de la sphère sur le plan considéré P, on mène, dans celui-ci, une série de droites (*fig.* 351, 352), la distance du centre à l'une quelconque d'entre elles est la même que celle du même point au plan.

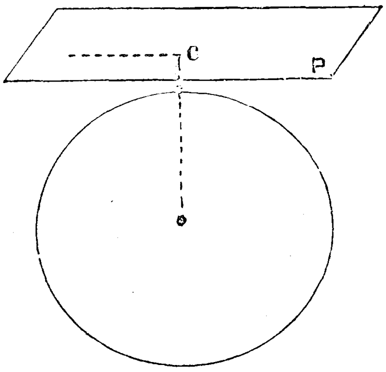

FIG. 351.

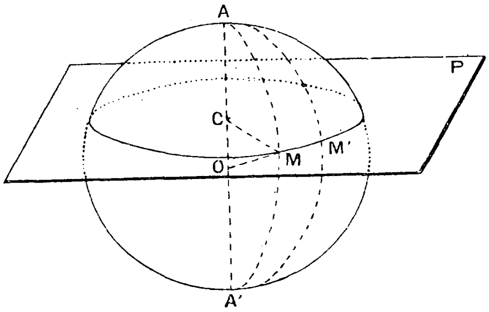

FIG. 352.

Si donc cette distance est plus grande que le rayon, aucune des droites ainsi menées ne coupe la sphère (**448**).

Si cette distance est égale au rayon, les droites en question sont tangentes.

Si elle est plus petite que le rayon, toutes ces droites coupent la sphère. Le lieu des points communs est, d'après la définition de la sphère et le théorème du n° **344**, une circonférence de centre C.

Ce dernier point résulte d'ailleurs de ce que le diamètre OC peut être considéré (**447**, Rem.), comme un axe de révolution de la sphère. Si, en effet, M est un point commun à celle-ci et au plan, ce point, en tournant autour de OC, engendre un cercle de centre C qui appartient à la fois à la sphère (engendrée par la révolution du demi-grand cercle AMA′ situé dans le plan OCM) et au plan P (engendré par la demi-droite CM ; **442**, Rem.).

Inversement, si M′ est un autre point quelconque commun à la sphère et au plan, le demi-grand cercle AMA′ peut être amené, par une rotation autour de OC, à coïncider avec le demi-grand cercle AM′A′, situé dans le plan OCM′. Le point M qui, dans ce mouvement, n'a pas cessé d'appartenir au plan P, se trouve alors amené à l'intersection de ce plan et du demi-grand cercle AM′A′, c'est-à-dire au point M′. Ce dernier est donc bien une des positions que vient prendre le point M en tournant autour de OC.

Corollaires. — I. *Une sphère de rayon* R *et un plan situé à une distance d du centre se coupent suivant un cercle dont le rayon r est donné par la formule*

$$r = \sqrt{R^2 - d^2}.$$

C'est ce qui se voit dans le triangle rectangle OCM (*fig.* 352), lequel a pour hypoténuse R et pour côtés de l'angle droit r, d.

La formule précédente justifie la dénomination de *grand cercle*, donnée plus haut à la section de la sphère par un plan passant par le centre, section dont le rayon est R. On voit en effet que toutes les autres sections de la sphère (lesquelles sont appelées *petits cercles*) ont un rayon inférieur à R.

II. *Toute sphère qui contient trois points d'un cercle, contient ce cercle tout entier.* Car le plan de ce cercle coupe la sphère suivant un cercle, forcément identique au premier (Pl., **57**).

III. *Le lieu des centres des sphères qui passent par un cercle donné est la droite* (dite *axe* du cercle) *perpendiculaire au plan du cercle en son centre.*

En effet, il résulte de ce que nous venons de voir que les centres des sphères qui contiennent le cercle donné sont tous sur la droite en question, et que, réciproquement, la sphère qui a pour centre un point quelconque de cette droite et qui passe par un point du cercle donné, contient ce cercle tout entier.

451. Théorème. — *Deux cercles qui ont deux points communs sans être situés dans un même plan, déterminent une sphère.*

Soient les deux cercles C, C' (*fig.* 353) dont les plans sont P, P' et qui ont les deux points communs A, B.

Toute sphère passant par le cercle C aura son centre sur la perpendiculaire Cx, élevée par le centre de ce cercle au plan P, et réciproquement, toute sphère ayant son centre sur cette droite et passant par A contiendra tout le cercle C. En particulier, il résulte tout d'abord de là et du n° **340** que la droite Cx est dans le plan perpendiculaire au milieu de AB.

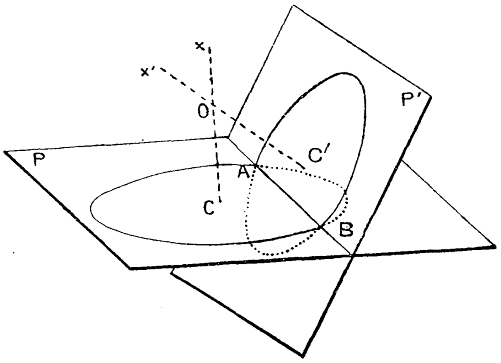

FIG. 353.

De même, toute sphère passant par le cercle C aura son centre sur la perpendiculaire $C'x'$, élevée par le centre de ce cercle au plan P' ; et, réciproquement, toute sphère ayant son centre sur cette droite et passant par le point A, contiendra tout le cercle C'. En particulier, cette droite est dans le plan perpendiculaire au milieu de AB.

Les deux droites Cx, $C'x'$ sont dans un même plan ; elles ne sont ni parallèles ni confondues (sans quoi les plans P, P', qui leur sont respectivement perpendiculaires, seraient eux-mêmes parallèles ou confondus, ce qui n'est pas). Elles se coupent donc en un point unique O.

La sphère de centre O et de rayon OA répond, et répond seule, à la question.

REMARQUES. — I. On verrait de même que *deux cercles, qui sont tangents entre eux sans être dans un même plan* (*fig.* 354), *déterminent une sphère.*

Il faudrait seulement, dans la démonstration précédente, remplacer le plan perpendiculaire au milieu de AB par le plan mené au point de contact, perpendiculairement à la tangente commune.

II. Si les deux cercles donnés étaient dans un même plan, ce serait ce plan qui remplacerait la sphère. Le plan est un cas-limite de la sphère, comme la droite est un cas-limite du cercle (Pl., **90**, Rem.).

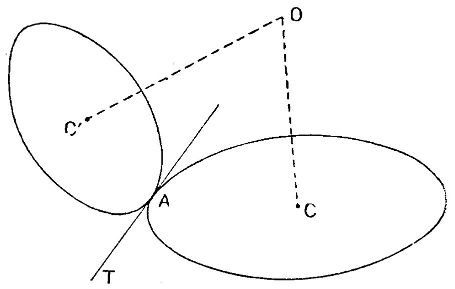

Fig. 354.

Théorème. — *Un cercle et un point extérieur à son plan déterminent une sphère.*

Quatre points, non situés dans un même plan, déterminent une sphère.

1° La condition, imposée à la sphère cherchée de passer par un cercle et un point extérieur à son plan, peut être remplacée (**450**, Coroll. II) par celle de contenir deux cercles qui ont deux points communs : à savoir, le cercle donné et celui qu'on peut mener par deux points de ce cercle et le point donné ;

2° De même, la condition, imposée à une sphère, de passer par quatre points donnés A,B,C,D, peut être remplacée par celle de contenir deux cercles qui se coupent en deux points : le cercle ABC et le cercle ABD.

Corollaire. — *Une sphère ne peut avoir deux centres, ni, par suite, deux rayons différents.*

452. Cône et cylindre circonscrits à la sphère.

Théorème. — *Le lieu des tangentes que l'on peut mener à une sphère par un point extérieur est un cône de révolution.*

Ces tangentes sont toutes égales entre elles.

Le lieu de leurs points de contact est un petit cercle de la sphère.

Les plans tangents au cône, lieu des tangentes, sont tangents à la sphère. Ce sont les seuls plans jouissant de cette propriété qu'on puisse mener par le point donné.

Soient O le centre de la sphère donnée (*fig.* 355), S le point donné. Soit T le point de contact d'une tangente menée par S à l'un quelconque des grands cercles dont les plans passent par OS. Si nous faisons tourner la droite ST autour de l'axe OS, elle ne cessera pas d'être tangente à la sphère, puisque celle-ci est de révolution autour de OS.

Les tangentes ainsi obtenues (à savoir les positions successives de ST) et qui satisfont évidemment aux conditions de l'énoncé, sont d'ailleurs les seules que l'on puisse mener du point S à la sphère : car une telle tangente est, d'après la démonstration du n° **449**, tangente au grand cercle situé dans le plan qui passe par son point de contact et les points O, S.

En chacune des positions du point T, le cône et la sphère ont même plan tangent, à savoir celui qui est déterminé par la droite ST et la tangente T*t* au cercle lieu du point T.

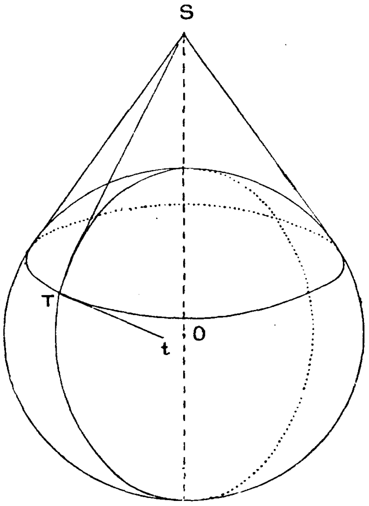

FIG. 355.

Nous obtenons ainsi une série de plans tangents menés du point S à la sphère : ce sont d'ailleurs les seuls, car, si le plan tangent en un point T passe par le point S, la droite ST est tangente.

REMARQUE. — On dit que le cône dont nous venons de parler est *circonscrit* à la sphère, et celle-ci *inscrite* au cône.

Inversement, *le long d'un petit cercle quelconque, on peut inscrire un cône à la sphère :* le sommet de ce cône sera le point où le plan tangent en un point quelconque du cercle coupe le diamètre perpendiculaire au plan de ce cercle.

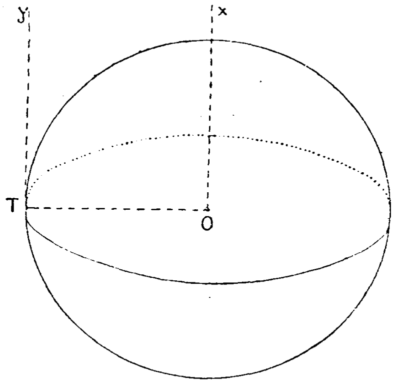

FIG. 356.

Théorème. — *Le lieu des tangentes menées à une sphère, parallèlement à une droite donnée, est un cylindre de révolution. Les plans tangents à ce cylindre sont tangents à la sphère. Ce sont les seuls plans qui jouissent de cette propriété, tout en étant parallèles à la droite donnée. Le lieu de leurs points de contact est le grand cercle dont le plan est perpendiculaire à la droite donnée.*

Soit Ox (*fig.* 356) la parallèle à la droite donnée, menée par le centre de la sphère. Soit Ty une tangente menée, parallèlement à cette droite, à un grand cercle dont le plan passe par Ox. On pourra, comme tout à l'heure, faire tourner cette droite Ty autour de Ox, sans qu'elle cesse d'être tangente à la sphère. Elle décrira, dans ces conditions, un cylindre de révolution et le point T décrira un grand cercle, car le rayon OT, perpendiculaire à la tangente, décrira le plan mené par O perpendiculairement à la direction donnée.

On verrait, comme plus haut, que les seules tangentes à la sphère parallèles à Ox, sont les génératrices du cylindre dont nous venons de parler et que ce cylindre est *circonscrit* à la sphère, c'est-à-dire tangent (¹) à cette surface en tous les points du cercle que décrit le point T.

Inversement, *le long d'un grand cercle quelconque, on peut circonscrire à la sphère un cylindre*, celui qui a pour section droite le grand cercle.

452 *bis*. *Par une droite entièrement extérieure à une sphère, on peut mener deux plans tangents à cette sphère.*

Soient D la droite donnée (*fig.* 357) ; C, le cercle de contact du cône circonscrit à la sphère, ayant pour sommet un point P de cette droite. Le plan du cercle C coupe D en un point I, extérieur à C (puisqu'il est extérieur à la sphère). Du point I, on peut mener deux tangentes IT, IT′ au cercle C. Le plan tangent à la sphère au point T n'est autre (n° précédent) que le plan TIP.

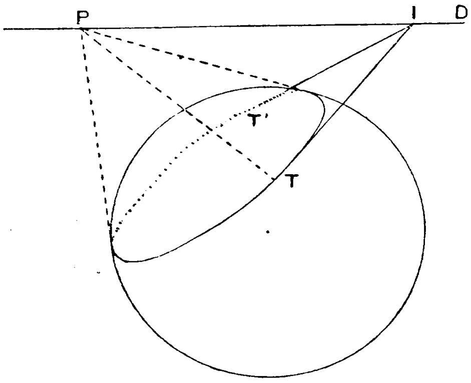

Fig. 357.

Inversement, tout plan tangent à la sphère passant par P doit (n° précédent) être tangent au cône dont il vient d'être question. S'il passe également par I, il coïncide avec l'un des deux que nous venons d'obtenir.

On peut mener à une sphère deux plans tangents parallèles à un plan donné. Leurs points de contact sont les extrémités du diamètre perpendiculaire au plan donné.

453. Intersection de deux sphères.

Théorème. — *Si deux sphères distinctes ont un point commun en dehors de la ligne des centres, leur intersection est un cercle, dont*

---

(1) Par analogie avec la définition donnée en géométrie plane, on dit que deux surfaces sont *tangentes* en un de leurs points communs, lorsqu'elles ont même plan tangent en ce point.

le plan est perpendiculaire à cette ligne et le centre, situé sur cette ligne.

Soient, en effet, O, O′ deux sphères qui ont en commun un point A, situé en dehors de la ligne OO′. Le point A, en tournant autour de OO′, engendrera un cercle qui appartiendra à la fois aux deux surfaces. Celles-ci n'ont d'ailleurs aucun point commun en dehors de ce cercle, en vertu du n° **451**.

453 *bis*. La situation respective de deux sphères dépend de l'ordre de grandeur dans lequel sont rangées la distance OO′ des centres, la somme R + R′ des rayons et la différence R — R′ de ces mêmes rayons. Cette dépendance est indiquée par le théorème suivant :

Théorème. — *Deux sphères sont :*

1° *Extérieures* (*fig.* 358), *si la distance des centres est supérieure à la somme des rayons ;*

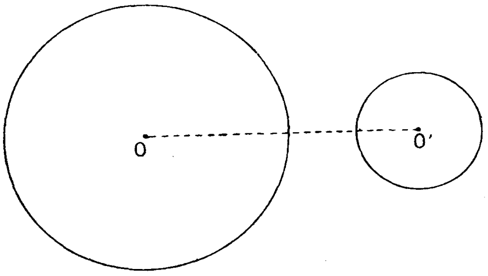

FIG. 358.

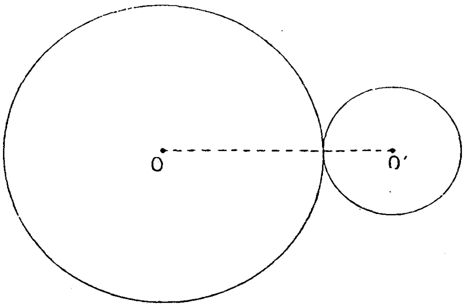

FIG. 359.

2° *Tangentes extérieurement* (*fig.* 359), *si la distance des centres est égale à la somme des rayons ;*

3° *Sécantes suivant un cercle* (*fig.* 360), *si la distance des centres est comprise entre la somme des rayons et leur différence ;*

4° *Tangentes intérieurement* (*fig.* 361), *si la distance des centres est égale à la différence des rayons.*

5° *Intérieures* (*fig.* 362), *si la distance des centres est plus petite que la différence des rayons.*

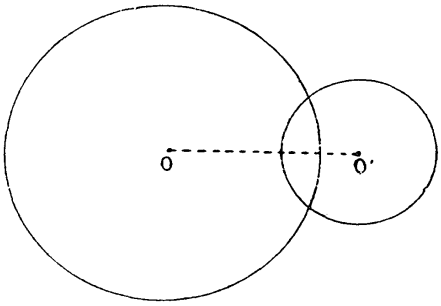

FIG. 360.

La démonstration est identiquement la même qu'en géométrie plane (Pl., **66**) sauf en 3°, où il suffit de remarquer qu'en coupant la figure par un plan quelconque passant par la ligne des centres, on obtient, dans les deux sphères, deux grands cercles sécants entre eux, de sorte que ces surfaces ont un point commun en dehors de la ligne des centres : après quoi, on est ramené au numéro précédent.

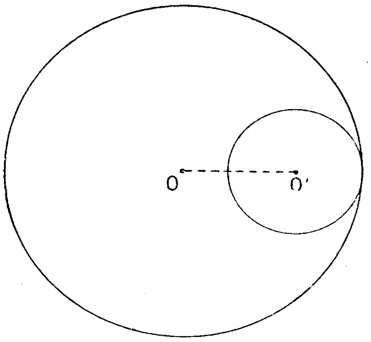

Fig. 361.

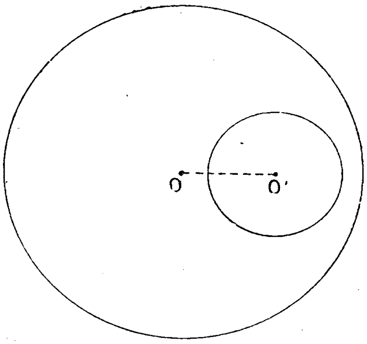

Fig. 362.

454. Intersection de trois sphères.

Si trois sphères ont un point commun en dehors du plan qui contient les trois centres, elles en ont un second, symétrique du premier par rapport à ce plan, puisque celui-ci est un plan de symétrie commun des trois surfaces.

D'après cela trois sphères peuvent :

Soit n'avoir aucun point commun ;

Soit avoir un seul point commun situé dans le plan des centres (les trois plans tangents se coupant suivant une ligne droite, perpendiculaire au plan des centres) ;

Soit avoir deux points communs ;

Soit avoir en commun trois points *et, par suite, un cercle entier.*

455. Puissance d'un point par rapport à une sphère.

Théorème. — *Si, par un point donné de l'espace, on mène différentes sécantes à une sphère, le produit des segments issus du point donné et aboutissant respectivement aux deux points d'intersection de chacune d'elles avec la surface est le même pour toutes les sécantes.*

Soient A le point donné (*fig.* 363) ; ABB′, ACC′, deux quelconques des sécantes. Le plan de ces deux droites coupe la sphère suivant un cercle, lequel donne bien

$$AB \cdot AB' = AC \cdot AC'.$$

Le produit dont il est question dans l'énoncé ne dépend donc que de la sphère et de la position du point donné A.

Ce produit, précédé du signe + si le point A est extérieur, du signe — si ce point est intérieur, est dit la *puissance* du point par rapport à la sphère.

La démonstration précédente montre que *si, par un point donné, on mène différents plans coupant une sphère donnée suivant des cercles,*

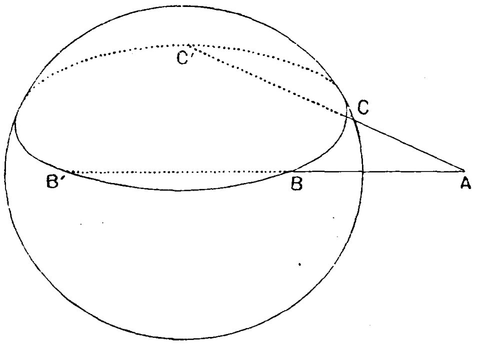

Fig. 363.

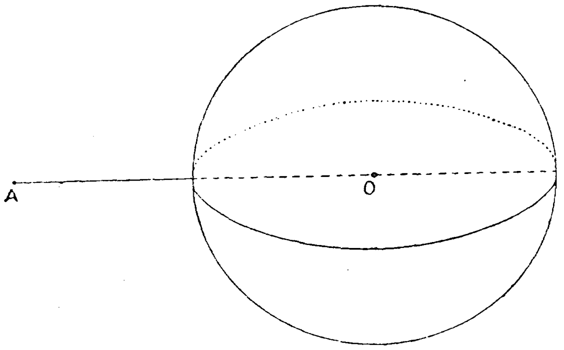

Fig. 364.

le point donné a, par rapport à tous ces cercles, la même puissance, à savoir la puissance de ce point par rapport à la sphère.

Considérons, en particulier, un plan passant par le point donné et coupant la sphère suivant un grand cercle : nous voyons immédiatement (*fig.* 364) que, comme pour le cercle en géométrie plane, *la puissance d'un point par rapport à une sphère est représentée par l'expression* $d^2 - R^2$, *où* R *est le rayon de la sphère, d la distance du point au centre* (1).

Dans le cas du point extérieur, la puissance est égale au carré de la tangente.

456. On appelle *angle de deux surfaces*, en un de leurs points communs, l'angle dièdre formé par les deux plans tangents.

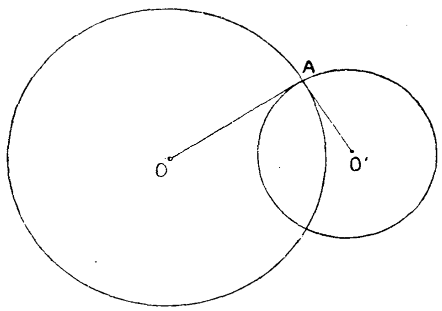

Fig. 365.

D'après cela, l'angle de deux sphères est (**378**) égal à l'angle des rayons qui aboutissent au point commun, ou à son supplément. Si les deux sphères se coupent orthogonalement, ces deux rayons sont perpendiculaires entre eux.

---

(1) Comparer Pl., **134**.

Lorsque deux sphères sont orthogonales, le carré du rayon de chacune d'elles est égal à la puissance de son centre par rapport à l'autre (¹). Car le rayon de la première sphère qui aboutit en un point commun est tangent à la seconde sphère (*fig.* 365). Réciproquement, *si le carré du rayon d'une sphère est égal à la puissance de son centre par rapport à une sphère, ces deux sphères se coupent à angle droit.*

457. Plan radical de deux sphères.

Théorème. — *Le lieu des points qui ont même point par rapport à deux sphères, est un plan perpendiculaire à la ligne des centres.*

Ce plan est dit *plan radical* des deux sphères considérées.

Démonstration. — Un plan quelconque P, mené par la ligne des centres des deux sphères données, les coupe suivant deux grands cercles C,C′ (*fig.* 366). La portion du lieu cherché, située dans le plan P, se compose de l'axe radical de ces deux cercles.

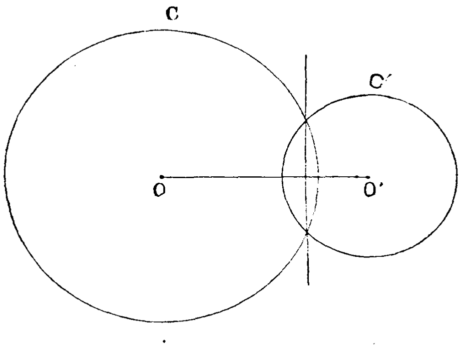

Fig. 366.

Lorsque le plan P tourne autour de la ligne des centres, l'axe radical qui vient d'être considéré engendre un plan, lequel constitue le lieu cherché.

Lorsque les deux sphères se coupent, le plan radical n'est autre que le plan du cercle *c* d'intersection, car tout point situé dans ce plan a pour puissance, tant par rapport à l'une que par rapport à l'autre sphère, sa puissance par rapport au cercle *c*. Ce qui précède montre que les points de ce plan sont les seuls à avoir même puissance par rapport aux deux sphères ; le même fait peut d'ailleurs se reconnaître directement (Comparer Pl., **137**).

Le plan radical ou, du moins, la portion de ce plan extérieure aux deux sphères (dans le cas où celles-ci se coupent) est (²) le lieu des centres des sphères orthogonales à la fois aux deux premières.

---

(1) Comparer Pl., **135**.
(2) Comparer Pl., **138**.

Si les sphères données sont concentriques, le plan radical est rejeté à l'infini(1).

458. Théorème. — *Les plans radicaux de trois sphères prises deux à deux se coupent suivant une même droite (sauf dans le cas où les trois centres sont en ligne droite et où les trois plans radicaux sont parallèles entre eux ou tous confondus).*

En effet, si S, S′, S″ sont les trois sphères considérées dont les centres ne sont pas en ligne droite, le plan radical de S et de S′ coupe le plan radical de S et de S″ suivant une droite, laquelle est le lieu des points qui ont même puissance par rapport aux trois sphères et se trouve, par conséquent, située dans le plan radical de S′ et de S″.

La droite dont nous venons de démontrer l'existence se nomme *axe radical* des trois sphères. Elle n'est d'ailleurs autre que la perpendiculaire au plan des trois centres, menée par le centre radical des grands cercles suivant lequel ce plan coupe les sphères données.

L'axe radical (ou du moins sa partie extérieure aux trois sphères), est le lieu des centres des sphères qui coupent les premières orthogonalement.

Si les trois centres sont en ligne droite, les trois plans sont tous perpendiculaires à cette droite.

Si le plan radical de S, S′ coïncide avec le plan radical de S, S″, il sera aussi le plan radical de S′, S″, puisque tous les points de ce plan auront même puissance par rapport aux trois sphères.

Théorème. — *Les six plans radicaux de quatre sphères prises deux à deux (ou les quatre axes radicaux de ces quatre sphères prises trois à trois) se coupent en un même point* (dit *centre radical* des quatre sphères), *sauf le cas où les quatre centres sont dans un même plan, les plans radicaux étant alors parallèles à une même droite.*

Car si les plans radicaux de S avec S′, de S avec S″, de S avec S‴ se coupent en un point I, ce point aura même puissance par rapport aux quatre sphères S, S′, S″, S‴ et appartiendra, par suite, aux autres plans radicaux.

Il sera (s'il est extérieur aux quatre sphères) le centre d'une sphère qui les coupera toutes quatre orthogonalement.

---

(1) Comparer Pl., **136**, Rem. II.

459. Sphères homothétiques.

La figure homothétique d'une sphère est une sphère, le rapport des rayons étant égal au rapport d'homothétie et les deux centres se correspondant.

Si, en effet, O est le centre de la sphère donnée, O′ son homothétique ; M un point quelconque de ladite sphère, M′ son homologue, le segment O′M′ est, avec OM, dans un rapport égal au rapport d'homothétie (**426**) : ce segment est donc bien constant.

460. Réciproquement, *deux sphères quelconques sont deux figures homothétiques, et cela de deux façons différentes* (¹) : *l'homothétie étant directe dans un cas, inverse dans l'autre.*

En effet, si O, O′ sont les centres des deux sphères; OM, O′M′ deux rayons parallèles et de même sens, mais quelconques d'ailleurs (le point M prenant successivement toutes les positions possibles sur la première sphère), les segments OM, O′M′ satisfont aux conditions énumérées dans l'hypothèse du nº **427**.

La même conclusion subsisterait si OM, O′M étaient des rayons parallèles et de sens contraires : le théorème est donc démontré.

Le théorème résulte encore, d'ailleurs, de ce que les grands cercles obtenus en coupant les sphères par un plan passant par la ligne des centres sont homothétiques entre eux, le centre et le rapport d'homothétie étant indépendants du choix du plan sécant.

Remarque. — *Deux sphères ne peuvent être homothétiques de plus de deux façons différentes.* Car, d'après le numéro précédent, dans toute homothétie qui transforme la première sphère en la seconde, les centres se correspondent et le rapport d'homothétie est égal au rapport des rayons. Or il n'y a que deux points qui divisent la ligne des centres dans un rapport égal à celui des rayons (²).

On nomme, comme en géométrie plane, *centre de similitude externe* et *centre de similitude interne*, les centres des deux homothéties dont l'existence vient d'être constatée.

461. La propriété qui appartient aux sphères, d'être homothétiques de deux manières différentes, leur est commune avec toutes les figures douées de centres de symétrie.

---

(1) Toutefois, il importe de remarquer que deux sphères égales ne peuvent être considérées comme homothétiques que moyennant l'extension donnée à ce mot au nº **427**.

(2) Voir aussi exercice 612.

Soient, en effet, F une figure quelconque; F_1, sa symétrique par rapport à un point O. Toute homothétique F' de F sera (**427**) homothétique de F_1, le centre d'homothétie étant en général différent du premier et les homothéties étant de noms contraires.

Si maintenant la figure F admet le point O comme centre de symétrie, elle coïncide avec F_1 : elle est, par conséquent, homothétique à F' de deux manières différentes.

Les deux homologues M, M_1 (*fig.* 367) d'un même point M' de F' sont toujours symétriques l'un de l'autre par rapport au point O. On choisira entre les deux homothéties en indiquant lequel de ces deux points on fait correspondre au point M'.

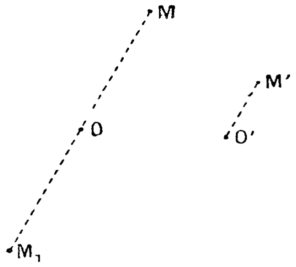

FIG. 367.

462. *Trois sphères ont quatre axes d'homothétie,* comme trois cercles en géométrie plane.

Ces quatre axes d'homothétie sont, en effet, les mêmes que ceux des grands cercles déterminés par le plan des trois centres.

Quatre sphères ont huit plans d'homothétie (**428**). Car, ayant pris un point M sur la première sphère O, et menant, dans les trois autres O', O'', O''', les diamètres $M'M'_1$, $M''M''_1$, $M'''M'''_1$ parallèles au rayon OM, on pourra choisir, parmi les extrémités de chacun de ces diamètres, le point qui sera l'homologue du point M dans l'homothétie correspondante. Une fois choisis ainsi les trois homologues du point M, on aura un plan d'homothétie bien déterminé. Or ce triple choix peut se faire de huit façons différentes : car on peut d'abord choisir entre les points M'_1, M'_1, ainsi qu'entre les points M'', M''_1, ce qui peut se faire de quatre manières, et à chacune des quatre combinaisons ainsi obtenues en correspondent deux, différentes entre elles par le choix fait entre M''' et M'''_1.

Chaque axe d'homothétie des trois premières sphères, correspondant au choix fait entre M' et M'_1 d'une part, M'' et M''_1 de l'autre, *est contenu dans deux plans d'homothétie; chaque centre d'homothétie, dans quatre.*

463. Plans tangents communs à deux sphères.

Tout plan tangent commun à deux sphères passe par un centre de similitude : le centre de similitude externe, si le plan tangent est *extérieur* (*c'est-à-dire laisse les deux sphères d'un même côté*); *le centre de similitude interne, si le plan tangent est intérieur* (*c'est-à-dire laisse les deux sphères de part et d'autre*).

Cela résulte de ce que les rayons OA, O'A' (*fig.* 368) qui aboutissent aux deux points de contact, sont parallèles entre eux, comme étant tous deux perpendiculaires au plan tangent commun.

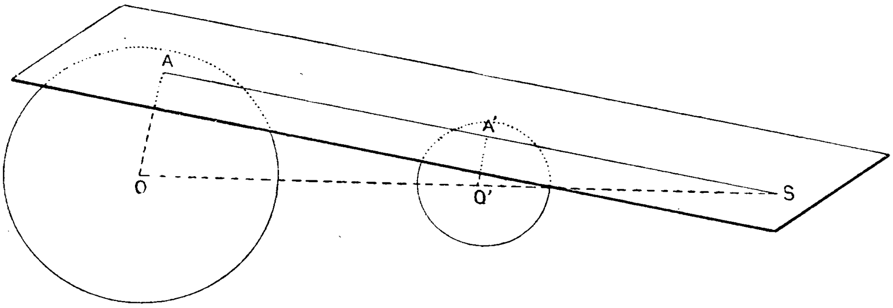

FIG. 368.

Réciproquement, tout plan tangent à l'une des sphères, mené par un des centres de similitude, est tangent à l'autre sphère, en raison de l'homothétie des deux figures par rapport à ce point.

Les plans tangents communs à deux sphères sont donc les plans tangents à l'un ou à l'autre des deux cônes circonscrits à l'une d'elles et ayant pour sommets les centres de similitude, si ces cônes existent.

Si on se reporte aux raisonnements du n° **452**, on voit immédiatement que l'un quelconque de ces deux cônes a pour méridienne une tangente commune menée, par le centre de similitude correspondant, aux grands cercles C, C' déterminés, dans les deux sphères données, par un plan passant par la ligne des centres. Les deux cônes existeront donc si les deux sphères sont extérieures; un seul d'entre eux, si les sphères se coupent; aucun, si elles sont intérieures l'une à l'autre.

464. Plans tangents communs à trois sphères.

Tout plan tangent commun à trois sphères passe par un de leurs axes de similitude : il doit, en effet (n° précéd.), passer par un centre de similitude de la première et de la seconde sphère donnée et par un centre de similitude de la première et de la troisième.

Inversement, tout plan, tangent à l'une des sphères et passant par un de leurs axes de similitude, est tangent aux deux autres sphères.

D'après cela, à chaque axe de similitude des trois sphères, pourvu qu'il soit sans point commun avec ces sphères, correspondent deux plans tangents communs passant par cet axe. Si aucun des quatre axes de similitude ne coupe les sphères, il y aura huit plans tangents communs. Si cette condition n'est pas remplie, le nombre des plans tangents s'abaisse de deux ou plusieurs unités : il peut n'y avoir aucun plan tangent commun (par exemple si deux des sphères données sont intérieures l'une à l'autre).

EXERCICES

658. Une surface telle que le cercle qui passe par trois quelconques de ses points y soit contenu tout entier, est une sphère (ou un plan).

659. Si des cercles, en nombre quelconque, sont tels que deux quelconques d'entre eux se coupent en deux points :

Ou bien tous ces cercles ont deux points communs ;

Ou bien ils appartiennent tous à une même sphère.

660. Quelle est la surface engendrée par une circonférence, lorsqu'elle tourne autour d'un axe qui se projette sur son plan suivant un de ses diamètres ?

661. Lieu des projections d'un point donné sur les plans qui passent par un point fixe.

661 *bis*. Lieu des centres des sections faites dans une sphère par des plans qui passent par un point fixe ou par une droite fixe.

662. Le centre d'une sphère est fixe, pendant que son rayon varie. Lieu du cercle de contact du cône circonscrit à cette sphère, ayant pour sommet un point donné.

663. Lieu des points d'où l'on peut mener à une sphère trois tangentes formant un trièdre trirectangle.

664. Lieu des points d'où l'on peut mener à une sphère trois plans tangents formant un trièdre trirectangle.

665. Le lieu des points tels que le rapport de leurs distances à deux points donnés soit constant, est une sphère.

666. Le lieu des points tels que leurs distances à trois points donnés soient proportionnelles à trois nombres donnés, est un cercle orthogonal à toutes les sphères qui passent par les trois points donnés.

667. Lieu des points tels que les cônes circonscrits à deux sphères données et ayant ces points pour sommets soient égaux.

Même problème, lorsqu'il y a trois sphères données.

668. Lieu des points tels que la somme des carrés de leurs distances à deux points donnés, multipliés respectivement par des coefficients donnés, soit constante.

669. Lieu des points dont les puissances par rapport à deux sphères données soient entre elles comme deux nombres donnés.

Même problème, lorsqu'il y a trois sphères données et trois nombres donnés.

670. Lieu des extrémités d'un segment égal et parallèle à un segment fixe, sachant que ces extrémités sont respectivement sur deux sphères données.

672. Trouver un triangle se déduisant par une translation d'un triangle donné et ayant ses sommets sur trois sphères données.

673. Un plan fixe quelconque est coupé par des sphères qui passent par un même cercle suivant des cercles ayant même axe radical.

674. Trouver une sphère, connaissant un cercle et le plan tangent en un point de ce cercle.

675. Plus généralement, trouver une sphère qui passe par un cercle donné et soit tangente à un plan ou à une sphère donnée.

676. Faire passer, par un cercle donné, une sphère orthogonale à une sphère donnée.

677. Trouver une sphère ayant son centre sur une droite donnée, tangente à une droite donnée et passant par un point donné.

678. Trouver une sphère ayant son centre sur une droite donnée, tangente à une droite donnée et à un plan donné.

679. Trouver une sphère passant par un cercle donné et tangente à un autre cercle donné. Discussion.

680. Trouver une sphère coupant à angle droit deux cercles donnés (1). Cas d'impossibilité.

681. Une sphère varie en passant par un cercle fixe C. Lieu du cercle de contact du cône circonscrit à la sphère, ayant pour sommet un point donné du plan de C. — Lieu des points de contact des plans tangents menés à la sphère par une droite donnée du plan de C. — Lieu de la droite d'intersection des plans tangents en deux points du cercle.

Qu'arrive-t-il lorsqu'une sphère varie en passant par deux points fixes A, B et restant tangente à une droite fixe qui rencontre AB prolongée?

682. Une sphère variable passe par deux points fixes, et est tangente à un plan fixe ou à une sphère fixe. Lieu du point de contact.

682 *bis*. Trouver une sphère passant par deux points donnés et tangente à deux plans donnés.

683. Une sphère variable est tangente à deux droites fixes et a son centre dans le plan mené parallèlement à ces deux droites, à égale distance de l'une et de l'autre. Trouver le lieu de ce centre.

684. Il existe, en général, une sphère et une seule tangente aux côtés d'un quadrilatère gauche. Mais si la somme de deux côtés est égale à celle des deux autres, le nombre des sphères tangentes aux quatre côtés est infini. Trouver, dans ces conditions, le lieu des centres des sphères. Quelle est celle dont le rayon est le plus petit ?

Déduire de là la solution de l'exercice 558.

---

(1) Une sphère et un cercle se coupent à angle droit lorsque la tangente au cercle, menée par un point commun, est perpendiculaire au plan tangent à la sphère au même point.

684 *bis*. Quelles sont les conditions pour qu'il existe une sphère tangente aux six arêtes d'un tétraèdre?

685. Inscrire ou ex-inscrire une sphère à un tétraèdre.

686. Une sphère varie en restant tangente à un plan fixe en un point fixe. Lieu des points de contact des plans tangents parallèles à un plan donné.

687. Si un cercle variable rencontre deux cercles fixes chacun en deux points, son plan passe par un point fixe.

688. Trouver un cercle qui divise deux cercles donnés en deux parties égales.

688 *bis*. Trouver un cercle qui soit divisé par deux cercles donnés en deux parties égales.

689. Trouver un cercle tangent à deux cercles donnés.

690. Si deux sphères n'ont aucun point commun, il existe deux points (*points limites*) tels que les sphères réduites à ces points, aient, avec les sphères données, même plan radical. Toute sphère orthogonale aux deux premières passe par les points limites.

691. Si trois sphères qui n'ont pas même plan radical n'ont aucun point commun, les sphères qui leur sont orthogonales passent par un cercle fixe. Ce cercle est le lieu des points tels que les sphères réduites à ces points aient, avec les sphères données, même axe radical.

La sphère orthogonale à quatre sphères données (si elle existe) est le lieu des points tels que les sphères réduites à ces points aient, avec les sphères données, même centre radical.

Quel est le lieu des points limites de deux sphères dont chacune varie en passant par un cercle fixe?

692. Autour d'un point fixe comme sommet, on fait tourner un trièdre trirectangle dont les arêtes rencontrent une sphère donnée. Montrer :

1° Que la somme des carrés des cordes interceptées par la sphère sur les trois arêtes reste constante;

2° Qu'il en est de même de la somme des carrés des six segments qui vont du sommet aux points d'intersection des arêtes avec la sphère;

3° Que la somme des aires des cercles d'intersection de la sphère avec les trois faces est également constante.

693. Dans les mêmes conditions, si l'on fait passer un plan par trois des points d'intersection considérés à l'exercice précédent, le lieu de la projection du sommet du trièdre sur ce plan est une sphère (ex. 513, 1° et Pl., ex. 70).

Si le sommet du trièdre est sur la sphère, le plan en question passe par un point fixe, lequel est le centre de gravité du triangle formé par les trois points d'intersection des arêtes avec la sphère.

694. On peut choisir trois sphères de manière que leurs huit plans tangents communs (**464**) existent. (Il suffira, les centres étant choisis, de prendre les rayons suffisamment petits.)

CHAPITRE IV

GÉOMÉTRIE SPHÉRIQUE — TRIANGLES SPHÉRIQUES

465. *Par deux points de la sphère, il passe un grand cercle ; et un seul, sauf si ces deux points sont diamétralement opposés.*

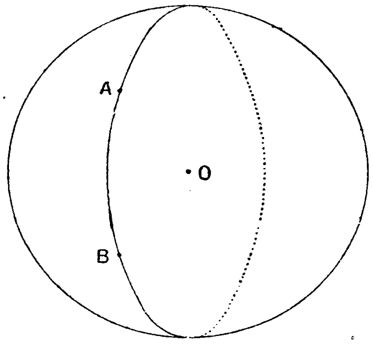

Fig. 369.

Car par deux points A, B (*fig.* 369) de la surface et le centre O passe un plan, lequel est unique si A et B ne sont pas en ligne droite avec le centre.

Remarques I. — La propriété que nous venons de constater établit une analogie entre les grands cercles de la sphère et les lignes droites en géométrie plane. Mais cette analogie n'est pas complète, puisqu'il y a exception pour les points diamétralement opposés.

II. Les points A et B divisent le grand cercle qui les contient en deux arcs. Lorsqu'on parle de *l'arc de grand cercle* qui joint A et B, on a plus spécialement en vue celui des deux qui est plus petit qu'une demi-circonférence.

466. Le diamètre perpendiculaire au plan d'un cercle de la sphère coupe la surface en deux points, qu'on nomme les *pôles* de ce cercle (*fig.* 370).

Chacun d'eux est également distant de tous les points du cercle. Si celui-ci est un grand cercle, la distance d'un quelconque de ses points au pôle est égale à la corde d'un quadrant, ainsi qu'on le reconnaît immédiatement à l'inspection de la figure 371.

Inversement, le lieu des points d'une sphère situés à une distance constante (moindre que le diamètre) d'un point de cette surface, est un cercle ayant ce point pour pôle.

D'après cela, on voit qu'on peut décrire un cercle sur une sphère comme sur un plan, à l'aide d'un compas dont l'une des pointes est placée en l'un des deux pôles de ce cercle. Toutefois, il est nécessaire (surtout si l'ouverture est un peu grande) d'employer un compas (dit compas *sphérique*) à branches courbes et non droites.

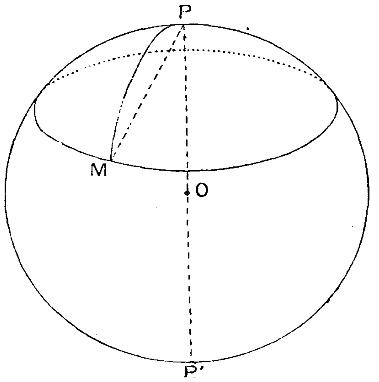

FIG. 370.

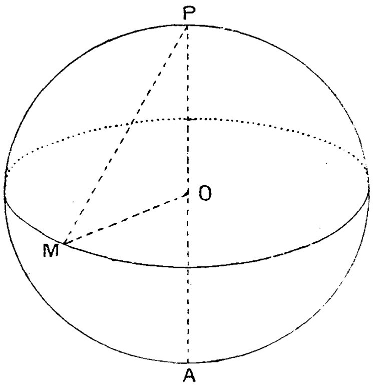

FIG. 371.

L'arc de grand cercle qui joint le pôle d'un cercle de la sphère à un point quelconque de ce cercle a également la même grandeur, quel que soit ce point. On lui donne le nom de *rayon sphérique* du cercle. Le rayon sphérique d'un grand cercle est égal à un quadrant.

Un cercle quelconque divise la sphère en deux régions, dites *calottes sphériques*, situées de part et d'autre du plan de ce cercle. Chacune de ces calottes comprend un des pôles et est formée par les points dont la distance à ce pôle est plus petite que la distance de ce même pôle aux points du cercle.

S'il s'agit d'un petit cercle, on donne souvent le nom de région *intérieure* à ce petit cercle, à la plus petite des deux calottes sphériques, celle dont le rayon sphérique est inférieur à un quadrant. Cette région intérieure est évidemment celle qui est située du côté du plan du cercle où n'est pas le centre de la sphère.

467. Angle de deux grands cercles.

Théorème. — *L'angle* (Pl., **60** *bis*) *de deux demi-grands cercles, terminés à leur diamètre commun, est égal à l'angle des demi-plans qui les contiennent. Il a pour mesure l'arc intercepté, entre eux, sur le grand cercle qui a pour pôles leurs points communs.*

Soient les deux demi-grands cercles AMA′, ANA′ (*fig.* 372), qui se coupent en A, A′.

Soient Ax, Ay les tangentes à ces courbes au point A. Ces tangentes, étant toutes deux perpendiculaires à AA′, déterminent l'angle plan du dièdre M-AA′-N.

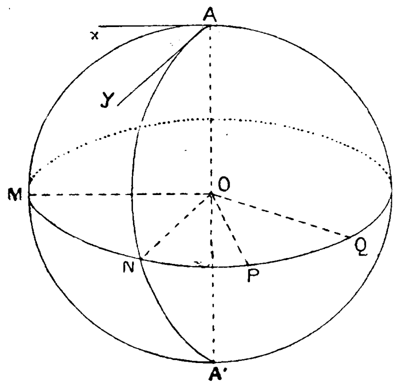

Fig. 372.

D'autre part, le grand cercle qui a pour pôles A, A′, a son plan perpendiculaire à AA′. Ce plan coupe les demi-plans AA′M, AA′N suivant deux droites OM, ON qui forment également entre elles l'angle plan du dièdre M-AA′-N. Mais cet angle est précisément l'angle au centre correspondant à l'arc de grand cercle MN : ce qui démontre la seconde partie du théorème.

468. Une autre expression de l'angle de deux grands cercles est encore donnée par le théorème suivant :

Théorème. — *L'angle de deux demi-grands cercles est mesuré par l'arc de grand cercle qui joint leurs pôles, ou par son supplément.*

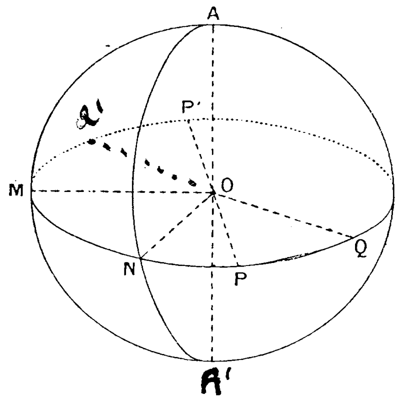

Fig. 373.

Soient, comme tout à l'heure, AMA′, ANA′ (*fig.* 373) deux demi-grands cercles qui coupent en M, N le grand cercle dont le plan est perpendiculaire à AA′. Ce dernier grand cercle contient les pôles P, P′, Q, Q′ des deux premiers : car les diamètres PP′, QQ′, respectivement perpendiculaires à AMA′, ANA′, sont tous deux perpendiculaires à AA′. De plus PP′, QQ′ sont respectivement perpendiculaires aux rayons OM, ON de la sphère : leur angle est donc égal à $\widehat{MON}$ ou à son supplément.

Remarque. — Chacun des deux grands cercles considérés ayant deux pôles, l'arc de grand cercle qui joint un pôle de l'un à un pôle de l'autre peut être choisi de quatre façons différentes.

Supposons que les pôles P, Q (*fig.* 373) soient tels que les trièdres O·AMP, O·ANQ aient même disposition. Alors ces deux trièdres, étant trirectangles, sont égaux et, comme ils ont l'arête OA commune, ils se déduisent l'un de l'autre par rotation autour de cette droite. Ceci revient à dire que les angles $\widehat{MON}$ (angle des deux demi-grands cercles) et $\widehat{POQ}$ sont égaux.

D'ailleurs, si l'on remplace le pôle P par son opposé P′ (*fig.* 373), la disposition du trièdre O·AMP change évidemment. Comme l'angle $\widehat{MOP'}$ est supplémentaire de $\widehat{MOP}$, on voit que l'*arc de grand cercle qui joint les deux pôles a même mesure que l'angle des deux demi-grands cercles ou que son supplément, suivant que les trièdres* O·AMP, O·ANQ *ont ou non même disposition.*

La disposition du trièdre O·AMP dépend d'ailleurs du sens de rotation de l'angle $\widehat{AOM}$, vu du point P. Donc *l'angle de deux demi-grands cercles, en un de leurs points communs, est égal à l'arc de grand cercle qui joint leurs pôles, si l'on choisit ceux-ci de telle manière que chacun des deux demi-grands cercles, vu de son pôle, paraisse tourner dans le sens direct, quand on le suit à partir du point commun considéré.*

469. Théorème. — *Le lieu des points d'une sphère également distants de deux points donnés sur cette surface, est le grand cercle perpendiculaire au milieu de celui qui joint les deux points donnés.*

Soient A, B, les deux points donnés (*fig.* 374). Le plan perpendiculaire au milieu de AB passe par le centre O de la sphère (puisque OA = OB) et coupe, par conséquent, la surface suivant un grand cercle, qui est le lieu cherché (**340**). Celui-ci passe d'ailleurs par le milieu de l'arc de grand cercle AB (point équidistant de A et de B); de plus, en vertu du n° **467**, il est perpendiculaire à cet arc; car leurs deux plans sont évidemment perpendiculaires entre eux.

Remarque. — Le lieu précédent divise la surface en deux hémisphères qui contiennent (**340**, Remarque) l'un les points plus rapprochés de A que de B, l'autre les points plus rapprochés de B que de A.

470. Problème. — *Trouver le rayon d'une sphère solide, à l'aide de constructions effectuées sur la surface et de constructions planes.*

Première solution. — Prenant deux points quelconques A, B sur la surface (*fig.* 374), traçons, avec une même ouverture de compas, deux cercles ayant ces deux points comme pôles respectifs. Un point M, commun à ces deux cercles, étant également distant de A et de B, appartiendra au grand cercle obtenu au n° précédent. En répétant la même construction avec d'autres ouvertures de compas, on aura deux autres points N, P du même grand cercle. Relevant alors au compas les distances MN, NP, PM, on pourra construire, sur un plan (*fig.* 375), un triangle égal à MNP, et le cercle circonscrit à ce triangle aura, pour rayon, le rayon cherché.

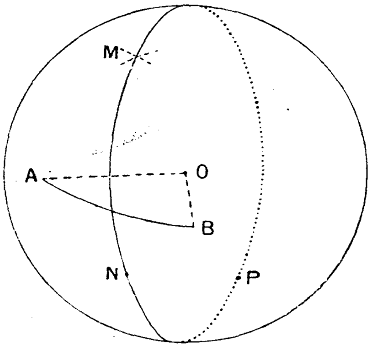

FIG. 374.

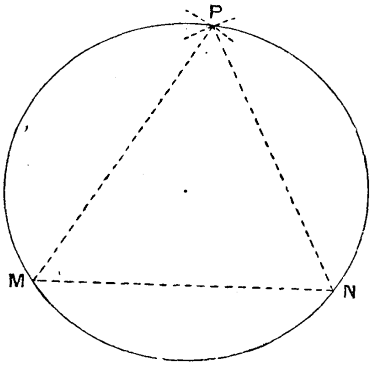

FIG. 375.

Deuxième solution. — D'un point quelconque C de la sphère comme pôle, avec une ouverture de compas déterminée, décrivons un cercle, sur lequel nous prendrons trois points M, N, P. Nous pourrons, comme il vient d'être expliqué, déterminer le rayon de ce cercle en construisant un triangle égal à MNP.

Or la connaissance de ce rayon et de celle de la distance CM (égale à l'ouverture de compas initiale) permettent de trouver le rayon de

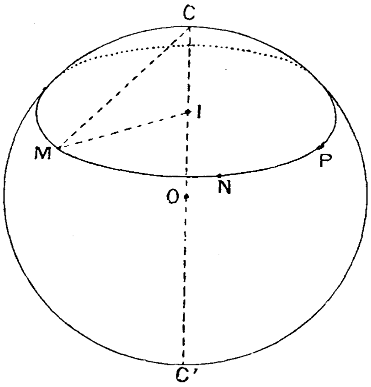

FIG. 376.

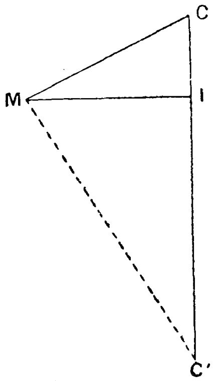

FIG. 376 *bis*.

la sphère; car, si I est le centre du cercle MNP (*fig.* 376), le triangle CIM est rectangle et peut être construit sur un plan (puisqu'on en connaît l'hypoténuse CM et un côté MI) : prolongeant alors (*fig.* 376 *bis*) le côté CI et menant, en M, la perpendiculaire à CM jusqu'à rencontre en C′ avec CI prolongé, la longueur CC′ sera le diamètre de la sphère.

470 *bis.* **Problème.** — *Joindre deux points donnés d'une sphère solide par un arc de grand cercle.*

De chacun des points donnés comme pôle, décrivons un grand cercle (ce que nous savons faire après la résolution du problème précédent). Ces deux grands cercles se coupent en deux points, qui sont manifestement les pôles du grand cercle cherché.

Remarque. — Il est clair que la solution de ce problème, combinée avec la deuxième solution du problème précédent, permet de *tracer le grand cercle perpendiculaire au milieu de l'arc de grand cercle qui joint deux points donnés* (**462**).

471. Polygones sphériques.

On donne le nom de *polygone sphérique* à toute portion de sphère limitée par des arcs de grands cercles (appelés *côtés* du polygone), plus petits qu'une demi-conférence, limités à leurs intersections successives.

Un polygone sphérique est dit *convexe* (*fig.* 377) lorsqu'il est situé d'un seul côté par rapport à chacun des grands cercles dont font partie ses côtés; *concave* (*fig.* 378), dans le cas contraire.

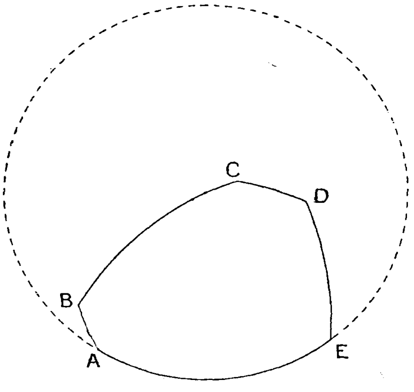

Fig. 377.

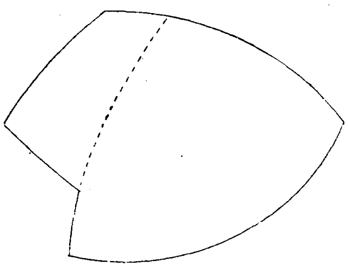

Fig. 378.

Les polygones sphériques se classent, comme les polygones plans, d'après le nombre de leurs côtés, le plus simple (1) étant le *triangle sphérique* (*fig.* 379).

Un triangle sphérique est toujours un polygone convexe. Car, dans le triangle ABC (*fig.* 379), si l'arc de grand cercle AC n'était pas tout entier du même côté par rapport au grand cercle AB, il couperait ce dernier en un point (autre que A) situé entre A et C et serait, par conséquent, plus grand qu'une demi-circonférence, contrairement à la définition.

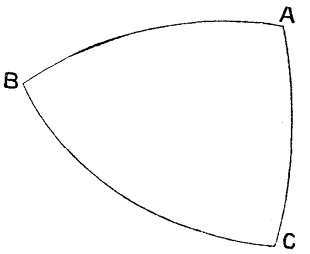

Fig. 379.

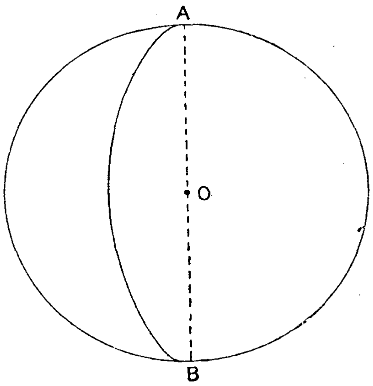

Fig. 380.

Relations entre les polygones sphériques et les angles polyèdres.

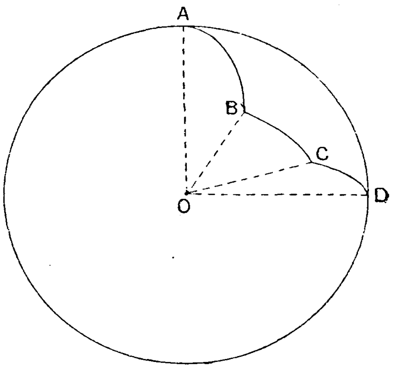

Fig. 381.

A tout polygone sphérique correspond un angle polyèdre, ayant pour sommet le centre de la sphère et pour arêtes les droites qui joignent ce centre aux différents sommets (*fig.* 381).

Les faces $\widehat{AOB}$, $\widehat{BOC}$, etc. (*fig.* 381) *de cet angle polyèdre sont les angles au centre correspondant aux côtés* AB, BC, etc., *du polygone.*

Les dièdres de l'angle polyèdre ont, d'après le théorème du n° **469**, *leurs rectilignes égaux aux angles du polygone.*

Inversement, tout angle polyèdre ayant pour sommet le centre d'une sphère coupe celle-ci suivant un polygone sphérique ayant, avec l'angle polyèdre, les relations que nous venons d'indiquer.

---

(1) Deux demi-grands cercles terminés au même diamètre comprennent entre eux une figure (fig. 380), dite *fuseau sphérique* (Compléments, n° **693**), qui peut évidemment être considérée comme un *biangle.* Seulement les côtés de cette sorte de polygone sont *égaux* et non *inférieurs* à une demi-circonférence.

471 *bis*. D'après cela, on voit que, de toute propriété relative aux faces et aux dièdres d'un angle polyèdre, on peut déduire une propriété relative aux côtés et aux angles du polygone sphérique correspondant, et inversement.

Par exemple, le théorème du n° **373** nous donnera le suivant : *Un côté quelconque d'un polygone sphérique est plus petit que la somme des autres* (d'où résulte : *un côté quelconque d'un triangle sphérique est plus grand que la différence des deux autres*).

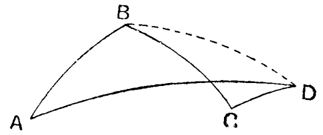

Fig. 382.

On voit dès lors, comme en géométrie plane (Pl., **26**), que *l'arc de grand cercle* (*moindre qu'une demi-circonférence*) *qui joint deux points est plus court que toute ligne polygonale sphérique terminée aux mêmes extrémités* (*fig.* 382) (1).

Cet arc de grand cercle est dit mesurer la *distance sphérique* des deux points donnés.

En nous bornant au cas d'un triangle sphérique, le théorème du n° **375** nous montre qu'inversement, trois arcs de grands cercles, moindres qu'une demi-circonférence et dont chacun est moindre que la somme des deux autres, tandis que la somme des trois est inférieure à une circonférence entière, sont égaux aux côtés d'un même triangle sphérique.

472. *Quand un polygone sphérique convexe est intérieur à un polygone sphérique quelconque* (*un ou plusieurs sommets ou côtés pouvant être communs*) (*fig.* 383, 383 *bis*), *le périmètre du*

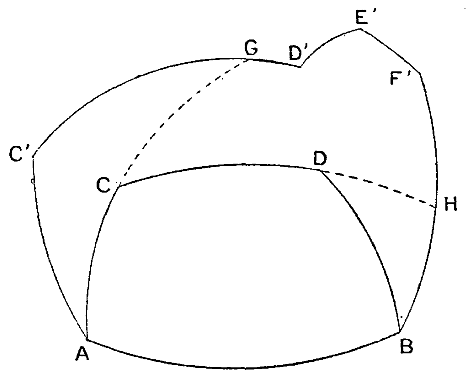

Fig. 383.

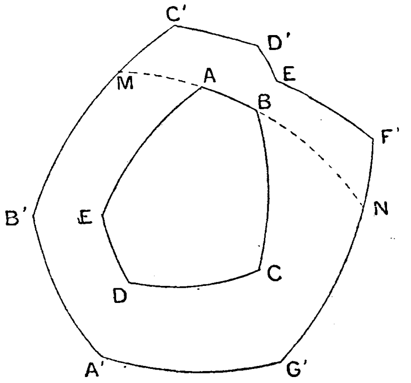

Fig. 383 *bis*.

---

(1). La figure montre la construction à effectuer.

polygone enveloppé est inférieur à celui du polygone enveloppant.

Cet énoncé est, d'après ce que nous venons de dire, identique à celui du n° **373** *bis*, un polygone sphérique étant manifestement convexe ou concave en même temps que l'angle polyèdre correspondant. Mais on peut refaire le raisonnement sur la figure sphérique : c'est ce que montrent les figures 383, 383 *bis*, où, pour plus de facilité, les notations ont été prises conformes à celles de la Géométrie plane (Pl., **27**).

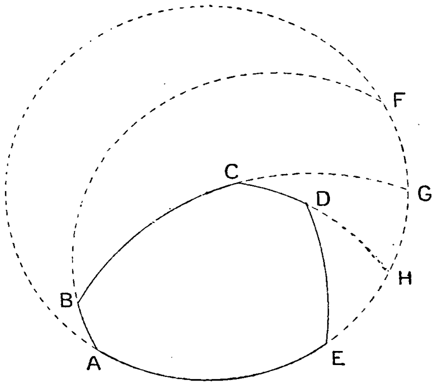

Fig. 384.

La démonstration continue à s'appliquer quand le polygone enveloppant est remplacé par une circonférence de grand cercle (voir *fig.* 384). Donc :

Le périmètre d'un polygone sphérique convexe est inférieur à la circonférence d'un grand cercle, énoncé qui équivaut à celui du n° **374**.

473. La *disposition* d'un triangle sphérique ABC est le sens de l'angle $\widehat{BAC}$ de ce triangle, vu de l'extérieur de la sphère. Il est clair que cette disposition est la même que celle du trièdre correspondant.

Deux triangles sphériques sont dits *symétriques*, lorsqu'ils ont tous leurs éléments égaux chacun à chacun, mais diffèrent par la disposition.

C'est ce qui arrive, en particulier, pour deux triangles symétriques l'un de l'autre par rapport au centre de la sphère, c'est-à-dire tels que les sommets de l'un soient diamétralement opposés aux sommets de l'autre.

474. Triangles sphériques polaires.

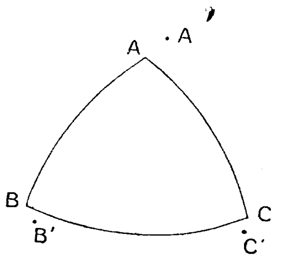

Fig. 385.

Soit ABC un triangle sphérique (*fig.* 385). Soient A′, celui des deux pôles du grand cercle BC qui est situé (par rapport à ce grand cercle) dans le même hémisphère que A ; B′, celui des deux pôles du grand cercle CA qui est (par rapport au grand cercle CA), dans le même hémisphère que B ; C′, celui des pôles du grand cercle AB qui est dans le même hémisphère que C. Le triangle sphérique A′B′C′ est dit le triangle *polaire* de ABC.

Si l'on se reporte à la définition des trièdres supplémentaires (**377**), on voit que *le trièdre qui correspond au triangle* A′B′C′ *est le supplémentaire du trièdre qui correspond au triangle* ABC.

Dès lors, les théorèmes des n^{os} **377**, **378** donnent immédiatement les conclusions suivantes :

Si un triangle sphérique est polaire d'un autre : réciproquement, celui-ci est polaire du premier.

Si deux triangles sphériques sont polaires l'un de l'autre, chaque côté de l'un est supplémentaire de l'angle correspondant de l'autre.

474 *bis.* Nous venons de déduire les propriétés des triangles polaires de celles des trièdres supplémentaires. Mais on peut également démontrer directement les mêmes propositions, en suivant, relativement aux triangles sphériques, la marche correspondante à celle qui a été suivie pour les trièdres.

On démontrera d'abord les lemmes suivants :

Lemmes. — I. *L'arc de grand cercle qui joint un point quelconque* B *de la sphère à l'un des pôles* A *d'un grand cercle donné, est plus petit ou plus grand qu'un quadrant, suivant que le pôle* A *est ou non, par rapport au grand cercle donné, dans le même hémisphère que le point* B.

Car le grand cercle AB et le grand cercle donné se coupent en un point I (*fig.* 386, 386 *bis*), tel que l'arc AI soit égal à un quadrant. Cet arc AI est d'ailleurs évidemment supérieur ou inférieur à AB,

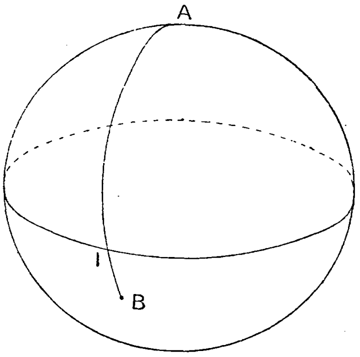

Fig. 386.

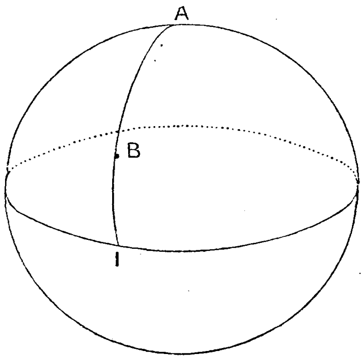

Fig. 386 *bis*.

suivant que les points A et B sont du même côté (*fig.* 386) ou de côtés différents (*fig.* 386 *bis*) du point I.

II. *Étant donnés deux demi-grands cercles* AMA′, ANA′ (*fig.* 387) *terminés à un diamètre commun, si* P *est le pôle du premier situé, par rapport à celui-ci, dans le même hémisphère que le second, et* Q, *le pôle du second situé, par rapport à lui, dans le même hémisphère que le premier, l'arc de grand cercle* PQ [1] *est supplémentaire de l'angle des deux demi-grands cercles donnés.*

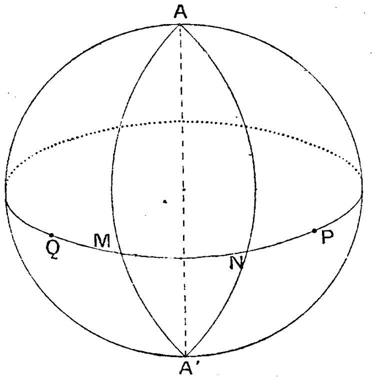

Fig. 387.

D'après le n° **468**, il suffit, pour arriver à cette conclusion, de démontrer que, si M et N sont les points où nos deux demi-grands cercles rencontrent le grand cercle de pôle A, les arcs MP et NQ sont de sens contraires. Or, cela est manifeste, puisque, d'après l'hypothèse, l'arc MP a le sens MN et l'arc NQ, le sens NM.

Cela posé, il est aisé de démontrer la première propriété des triangles polaires, à savoir que *si un triangle est polaire d'un autre, inversement celui-ci est polaire du premier.*

Soit, en effet, ABC un triangle sphérique (*fig.* 385) dont A′B′C′ est le polaire. C′ étant un pôle de AB, l'arc de grand cercle AC′ est égal à un quadrant, et il en est de même de l'arc AB′, pour une raison analogue : d'où résulte que A est un pôle de l'arc de grand cercle B′C′ (**470** *bis*).

Ce pôle est d'ailleurs bien, par rapport au grand cercle B′C′, dans le même hémisphère que le point A. Car cette conclusion et la partie de l'hypothèse d'après laquelle le point A′ est, par rapport au grand cercle BC, du même côté que A, expriment, en vertu du lemme I, un seul et même fait : à savoir, que l'arc de grand cercle AA′ est inférieur à un quadrant.

Quant à la propriété d'après laquelle *chaque côté d'un triangle sphérique est le supplément de l'angle correspondant du triangle polaire du premier*, elle résulte évidemment du lemme II : car les sommets du premier triangle sont bien déduits des côtés du second comme le veut l'hypothèse de ce lemme.

---

[1] Voir **465**, Remarque II.

Des propriétés fondamentales des triangles polaires, on déduit, comme au n° **379**, les théorèmes suivants :

Chaque angle d'un triangle sphérique, augmenté de deux droits, est plus grand que la somme des deux autres ;

La somme des angles d'un triangle sphérique est comprise entre deux droits et six droits.

475. La notion de *polygones sphériques polaires* s'étend au cas où le nombre des côtés est quelconque. C'est ce que nous allons voir en nous bornant toutefois, pour simplifier, aux polygones convexes.

Soit, par exemple, le polygone ABCDE (*fig.* 388), lequel est supposé convexe. Désignons par P le pôle du grand cercle AB, pris dans l'hémisphère qui contient le polygone par Q, le pôle de BC, pris dans l'hémisphère qui contient le polygone ; par R, le pôle de CD, par S le pôle de DE, par T celui de EA, chacun de ces pôles étant pris, par rapport au grand cercle correspondant, du même côté que le polygone donné.

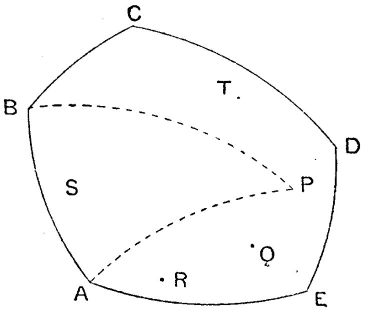

Fig. 388.

Les points P,Q,R,S,T sont les sommets d'un nouveau polygone sphérique, qui est dit le *polaire* du premier.

Nous allons voir que, réciproquement, le polaire du polygone PQRST est le polygone donné ABCDE.

Pour cela, nous remarquerons que les distances sphériques PA, PB sont égales à un quadrant, mais que les distances PC, PD, PE sont inférieures à un quadrant, puisque les points C,D,E sont, par rapport au grand cercle AB, dans l'hémisphère qui contient le point P. De même les distances QB, QC sont égales à un quadrant, les distances QD, QE, QA inférieures à un quadrant; et ainsi de suite, chaque pôle étant distant d'un quadrant des sommets situés sur le côté qui lui correspond, et situé à une distance moindre qu'un quadrant des autres sommets.

Les distances PB, QB étant égales à un quadrant, le point B est un pôle du grand cercle PQ ; de même, C est un pôle du grand cercle QR ; et ainsi de suite.

D'ailleurs, les distances BR, BS, BT sont, d'après ce qui vient d'être dit, inférieures à un quadrant. Donc (n° précédent, lemme I) les points R,S,T sont d'un même côté du grand cercle PQ, celui où est situé le point B.

Le même raisonnement pouvant se répéter pour les autres côtés du polygone PQRST, nous voyons : 1° que ce polygone est convexe comme le premier ; 2° que les points B,C,D... sont bien déduits de ses côtés, comme les points P,Q,R... l'ont été des côtés du polygone ABCDE.

Quant à cette proposition que les côtés d'un polygone sont les suppléments des angles du polygone polaire, elle se démontre comme pour les triangles.

476. De même que les propositions des numéros précédents, celles qui vont suivre correspondent, pour la plupart, à des théorèmes démontrés au livre V (nos **380-384**) et peuvent soit se déduire de ces théorèmes, soit se démontrer directement par une marche exactement calquée sur celle qui a été suivie au livre V.

Cas d'égalité des triangles sphériques.

Sur une même sphère ou sur des sphères égales, deux triangles sphériques sont égaux ou symétriques :

1° *Lorsqu'ils ont un côté égal adjacent à deux angles égaux chacun à chacun ;*

2° *Lorsqu'ils ont un angle égal compris entre deux côtés égaux chacun à chacun ;*

3° *Lorsqu'ils ont les trois côtés égaux chacun à chacun ;*

4° *Lorsqu'ils ont les trois angles égaux chacun à chacun.*

Propriétés du triangle sphérique isoscèle.

Tout triangle sphérique isoscèle est superposable à son symétrique ; inversement, tout triangle sphérique égal à son symétrique est isoscèle.

Dans un triangle sphérique isoscèle, les angles opposés aux côtés égaux sont égaux. Inversement, tout triangle sphérique qui a deux angles égaux est isoscèle.

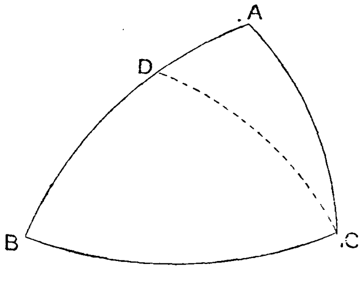

Fig. 389.

Théorème. — *Dans un triangle sphérique, à des angles inégaux correspondent des côtés inégaux, et inversement ; au plus grand angle correspond le plus grand côté* (*fig.* 389) (1).

476 *bis*. **Théorème.** — *Si deux triangles sphériques d'une même sphère ont un angle inégal compris entre côtés égaux chacun à chacun, les troisièmes côtés sont inégaux et au plus grand angle est opposé le plus grand côté.*

Soient les deux triangles sphériques ABC, A'B'C', tels que l'on ait

---

(1) Pour suivre la marche analogue à celle qui a été suivie au Ve livre (n° **384**), il faut, étant donné le triangle ABC dans lequel $\widehat{B} < \widehat{C}$, tracer, jusqu'à rencontre avec AB, l'arc de grand cercle CD tel que $\widehat{DCB} = \widehat{B}$. Cette construction est représentée sur la figure 389.

$\widehat{A} > \widehat{A'}$, $AB = A'B'$, $AC = A'C'$. Supposons que ces deux triangles aient même disposition et transportons le second sur le premier, de manière à faire coïncider les côtés égaux A'B', AB. Le côté A'C' viendra alors suivant un arc de grand cercle AC_1 égal à AC, mais intérieur à l'angle $\widehat{A}$ (*fig* 390).

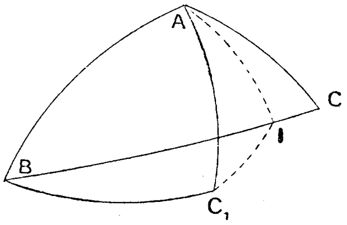

Fig. 390.

Menons l'arc de grand cercle qui divise en deux parties égales l'angle $\widehat{C_1AC}$, Cet arc de grand cercle passe, lui aussi, à l'intérieur de l'angle $\widehat{BAC}$ et coupe, par conséquent, l'arc BC en un point I situé entre B et C. Menons encore l'arc de cercle C_1I.

Les deux triangles sphériques ACI, AC_1I sont symétriques (1), comme ayant un angle égal (en A, par construction) compris entre côtés égaux chacun à chacun (AI commun; $AC = AC_1$). Donc on a $C_1I = CI$.

Or le triangle BC_1I donne

$$BC_1 < BI + IC_1.$$

Donc aussi

$$BC_1 < BI + IC,$$

ou

$$BC_1 < BC.$$

C. Q. F. D.

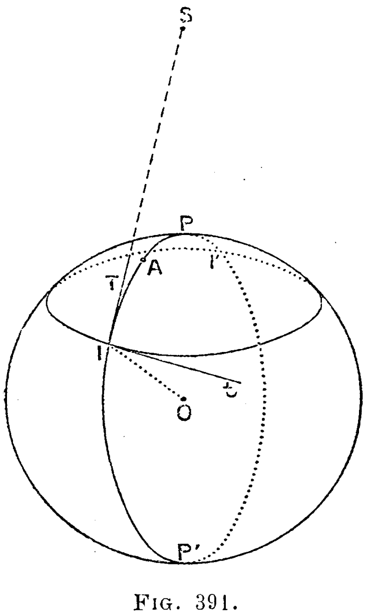

Fig. 391.

477. Théorème. — *La condition nécessaire et suffisante pour qu'un grand cercle et un cercle quelconque se coupent à angle droit est que le premier contienne les pôles du second.*

Soient I un point commun aux deux cercles; IT, I*t*, les tangentes au grand et au petit cercle en ce point ; P, P' les pôles du petit cercle; O, le centre de la sphère (*fig.* 391).

La condition indiquée dans l'énoncé est suffisante : car, si le grand cercle passe par P, P', son plan contient deux droites non parallèles entre elles et toutes deux perpendiculaires à I*t* : à savoir, le diamètre PP′ et le rayon OI. Ce plan, et par suite la tangente IT, sont donc perpendiculaires à I*t*.

---

(1) Les dispositions sont inverses, puisque les deux triangles sont de part et d'autre du côté commun AI.

La condition est d'ailleurs nécessaire : car, si les deux cercles se coupent à angle droit, le plan du grand cercle contient les deux droites IT, OI, perpendiculaires à I*t*. Il est donc lui-même perpendiculaire à cette droite, par suite au plan du petit cercle et contient, dès lors, le diamètre PP′, perpendiculaire à ce dernier plan menée par le point O.

Corollaire. — *Par un point pris sur une sphère, on peut mener un grand cercle perpendiculaire à un cercle donné de cette sphère: et on n'en peut mener qu'un seul, si le point donné n'est pas un pôle du cercle donné.*

Le grand cercle répondant à la question, sera déterminé par le point donné A et les pôles P, P′ du cercle cherché.

On remarquera qu'il existe deux *arcs* de grand cercle issus du point A et perpendiculaires au cercle donné; à savoir, ceux qui aboutissent aux deux points I, I′ où ce cercle est coupé par le grand cercle dont l'existence vient d'être établie (1).

477 *bis*. Le théorème qui précède est un cas particulier du suivant:

Théorème. — *La condition nécessaire et suffisante pour que deux cercles de la sphère se coupent à angle droit, est que le plan de l'un d'eux passe par le sommet du cône (ou du cylindre) circonscrit suivant l'autre.*

Tout d'abord, dans le cas où le premier cercle est un grand cercle, cette proposition résulte de la démonstration précédente: car, dans celle-ci, la droite IT, tangente au grand cercle IPP′, passe (**452**) par le sommet S du cône circonscrit suivant le petit cercle considéré.

Mais tout cercle qui coupe celui-ci à angle droit en I doit être tangent à IT; car IT est la seule tangente à la sphère en I qui soit perpendiculaire à I*t*. Donc le plan d'un tel cercle devra passer par le point S.

Inversement, tout cercle passant en I et dont le plan passe par S est tangent à IT et, par conséquent, la condition est aussi suffisante.

478. Théorème. — *Si, par un point d'une sphère, on mène les deux arcs de grand cercle perpendiculaires à un cercle donné et divers arcs de grands cercles obliques au même cercle, les arcs perpendiculaires sont, l'un plus court, l'autre plus long que tous les arcs obliques.*

---

(1) Nous considérons exclusivement, ici, les arcs issus du point A et terminés à leur *premier* point d'intersection avec le cercle donné. Si l'on ne tenait pas compte de cette restriction, le nombre des arcs perpendiculaires serait supérieur à deux : par exemple, l'arc AP′I′ (fig. 391) répondrait encore à la question.

Un arc oblique est d'autant plus long que son extrémité est plus éloignée de celle de l'arc perpendiculaire le plus court.

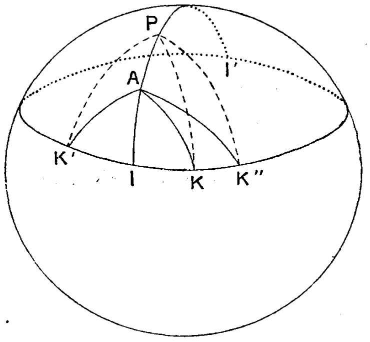

FIG. 392.

Soient A le point donné; P, celui des pôles du cercle donné qui est, par rapport à ce cercle, du même côté que le point A; AI, AI', les deux arcs de grand cercle perpendiculaires, dont le second est celui qui contient le point P à son intérieur; AK, AK', AK'' les divers arcs obliques (*fig.* 392).

1° L'arc AK est supérieur à AI, mais inférieur à AI'. Car si nous menons l'arc de grand cercle PK, le triangle sphérique APK donne

$$AK > PK - PA, \quad AK < PK + PA,$$

alors que l'on a

$$PK - PA = PI - PA = AI$$
$$PK + PA = PI' + PA = AI';$$

2° Supposons que les points K, K' du cercle donné soient tels que les arcs IK, IK' soient égaux. Il en est alors de même des cordes de ces arcs et le point I est également distant des deux points K, K'. Comme le point P jouit de la même propriété, le lieu des points de la sphère également distants de K et de K' est le grand cercle PI. Celui-ci contenant le point P, les cordes AK, AK' sont bien égales, et aussi, par conséquent, les arcs de grands cercles correspondants.

3° Soit maintenant, sur le cercle donné, un point K'' tel que $IK'' > IK$. Nous pouvons d'ailleurs supposer (¹), moyennant ce qui vient d'être établi (2°), que les deux points K, K'' sont du même côté du point I. Menons les arcs de grands cercles PK, PK''. Le point K étant intérieur à l'angle $\widehat{K''PI}$, on a $\widehat{KPI} < \widehat{K''PI}$.

Les triangles sphériques APK, APK'' ont donc un angle inégal (en A) compris entre côtés égaux chacun à chacun, et l'on a bien $AK < AK''$.

C. Q. F. D.

---

(1) Comparer Pl. **29**.

L'arc de grand cercle AI est dit la *distance sphérique* du point A au cercle KIK'I'. Cette dénomination est justifiée par le théorème qui précède.

479. Outre les constructions que nous avons précédemment appris à réaliser sur la sphère (n° **470**-**470** *bis*), on peut effectuer, sur cette surface, la plupart des constructions analogues à celles que nous avons indiquées en géométrie plane (liv. II, chap. VI). Nous donnons, à cet égard, un certain nombre d'exemples aux exercices (exercice 702).

EXERCICES

695. Si on joint un point pris dans l'intérieur d'un triangle sphérique aux trois sommets par des arcs de grands cercles, la somme de ces arcs est plus petite que le périmètre du triangle et plus grande que la moitié de ce périmètre.

696. Si deux triangles sphériques rectangles sont tels que les côtés de l'angle droit du premier soient respectivement plus petits que les côtés de l'angle droit du second, l'hypoténuse du premier est plus petite que celle du second.

697. Si la médiane d'un triangle sphérique (arc de grand cercle qui joint un sommet au milieu du côté opposé) est égale à un quadrant, elle est en même temps bissectrice de l'angle qui la comprend.

Si elle est plus petite qu'un quadrant, elle est plus grande que la bissectrice de l'angle en question, limitée au troisième côté. Elle est, au contraire, plus petite que cette bissectrice si elle est plus grande qu'un quadrant.

698. Si, dans un quadrilatère sphérique convexe, les côtés opposés sont égaux, les diagonales se coupent mutuellement en parties égales. Leur point d'intersection est le pôle du grand cercle qui passe par les points d'intersection des côtés opposés (Utiliser liv. VII). Deux sommets consécutifs et les points diamétralement opposés aux deux autres sommets sont sur un même cercle.

Dans un quadrilatère (*losange sphérique*) dont les quatre côtés sont égaux, les diagonales sont, en outre, perpendiculaires entre elles.

Si, les côtés opposés étant égaux, les diagonales sont égales, leur point d'intersection et les points d'intersection des côtés opposés sont les sommets d'un triangle trirectangle. Les quatre angles du quadrilatère sont alors égaux entre eux.

699. Si un grand cercle varie en restant constamment tangent à un petit cercle fixe C, et qu'on prenne, parmi les deux pôles du grand cercle, celui qui est situé dans le même hémisphère que C, ce pôle décrit un petit cercle C', qui est dit *polaire* du premier.

La relation entre C et C' est réciproque, c'est-à-dire que le polaire de C' n'est autre que C.

700. Les grands cercles bissecteurs des angles d'un triangle sphérique se coupent aux deux mêmes points diamétralement opposés. Il en est de même des trois médianes et des trois hauteurs (grands cercles menés par chaque sommet perpendiculairement au côté opposé).

701. Connaissant la distance des pôles de deux cercles et leurs rayons sphériques, trouver les conditions pour que ces cercles se coupent. Examiner successivement le cas où les rayons sont plus petits qu'un quadrant, de sorte que les pôles donnés sont intérieurs, et le cas où cette restriction n'est pas donnée.

702. Résoudre *effectivement* (voir page 59, note), à l'aide de constructions sphériques et, au besoin, de constructions planes, les problèmes suivants :

a) Trouver le point diamétralement opposé à un point donné ;

b) Faire passer un grand cercle par deux points donnés ;

c) Faire passer un cercle par trois points donnés de la sphère. Trouver les pôles d'un cercle donné ;

d) Mener, d'un point donné, un grand cercle perpendiculaire sur un cercle donné ;

e) Diviser en deux parties égales l'angle de deux grands cercles. Diviser en deux parties égales un arc de cercle quelconque.

f) Construire un triangle sphérique connaissant les trois côtés; discussion (ex. 701) ;

g) Par un point donné de la sphère, mener un grand cercle faisant avec un grand cercle donné un angle égal à un angle donné. Minimum de cet angle ;

Construire un triangle sphérique :

h) connaissant deux côtés et l'angle compris ;

i) connaissant deux côtés et l'angle opposé à l'un d'eux ;

j) connaissant un côté et deux angles (1) (discussion);

k) connaissant les trois angles;

l) Construire un triangle sphérique rectangle, connaissant l'hypoténuse et un angle adjacent ou un côté ;

m) Tracer un cercle tangent à un cercle donné en un point donné et passant par un autre point donné.

n) Tracer le grand cercle tangent à un cercle donné en un point donné de ce cercle ;

o) Mener, d'un point quelconque de la sphère, un grand cercle tangent à un petit cercle donné (pour cette construction et la suivante, utiliser ex. 699). Discussion;

p) Mener un grand cercle tangent à deux petits cercles donnés. Discussion ;

q) Mener, d'un point donné comme pôle, un cercle qui coupe un cercle donné à angle droit ;

r) Construire un petit cercle tangent à trois grands cercles donnés ;

s) Construire un cercle tangent à un cercle donné en un point donné et tangent à un autre cercle donné.

703. Tracer un grand cercle sur lequel deux petits cercles donnés interceptent des arcs égaux à des arcs donnés.

704. Étant donnés, sur une sphère, un grand cercle C et, sur ce grand cercle un point A, placer (à l'aide de constructions planes et sphériques) le point qui, lorsqu'on considère la sphère donnée comme sphère céleste, le grand cercle donné comme équateur et le point A comme origine des ascensions droites, a une ascension droite et une déclinaison (2) données.

705. Étant donnés trois cercles sur la sphère, il existe un cercle et un seul qui partage chacun d'eux en deux parties égales. Quel est le plan de ce cercle ?

---

(1) On remarquera que, si les angles donnés ne sont pas tous deux adjacents au côté donné, on ne peut pas procéder comme en Géométrie plane (**85**, constr. 8) : il faut recourir à la considération des triangles polaires (**474**), comme pour la construction suivante.

(2) TISSERAND et ANDOYER, *Leçons de Cosmographie*, n^{os} **9-12**.

706. Étant donnés deux grands cercles tangents à un même petit cercle C, un troisième grand cercle quelconque tangent à C forme avec les deux premiers un triangle sphérique de périmètre constant.

707. Construire (effectivement) un triangle sphérique connaissant un côté, un angle adjacent et la somme des deux autres côtés (donnée par un arc de grand cercle égal à cette somme).

708. Construire (effectivement) un triangle sphérique, connaissant un angle, une hauteur (ex. 700) et le périmètre. (Utiliser ex. 706 ; deux cas à distinguer).

709. Trouver les conditions pour qu'un quadrilatère sphérique soit circonscriptible à un cercle. (Comparer ex. 652.)

710. D'un point de la sphère, extérieur à un petit cercle donné, on lui mène les deux grands cercles tangents (ex. 702, *o*); pour quelle position du point ces deux grands cercles font-ils le plus petit angle ?

711. Le grand cercle qui passe par les milieux M, N des côtés AB, AC d'un triangle sphérique coupe le grand cercle BC aux milieux des deux arcs qui ont pour extrémités le point B et le point diamétralement opposé à C. Le pôle du grand cercle MN est également distant de B et de C et les arcs de grands cercles qui le joignent à B et à C font entre eux un angle double de l'angle au centre correspondant à l'arc de grand cercle MN.

CHAPITRE V

SURFACE ET VOLUME DE LA SPHÈRE

480. Théorème. — *La surface engendrée par un segment de droite tournant autour d'un axe situé avec lui dans un même plan et ne le traversant pas, a pour mesure la projection du segment sur l'axe, multipliée par la circonférence qui a son centre sur l'axe et touche le segment en son milieu* (1).

La surface engendrée par un segment de droite AB (*fig.* 394) tournant autour d'un axe xy situé avec lui dans un même plan et ne le traversant pas, est en général, celle d'un tronc de cône dont les circonférences de bases ont pour rayons les perpendiculaires Aa, Bb abaissées des points A, B sur l'axe.

Exceptionnellement, le tronc de cône se réduit à un cône, lorsque le segment a une extrémité sur l'axe (*fig.* 393), ou à un cylindre, lorsque le segment est parallèle à l'axe (*fig.* 393 *bis*) (2).

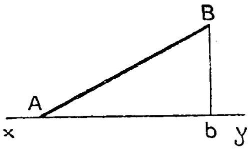

Fig. 393.

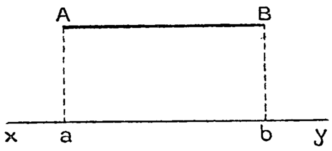

Fig. 393 *bis*.

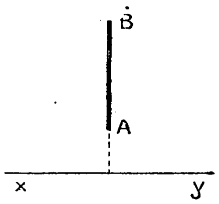

Fig. 393 *ter*.

Soient M le milieu de AB ; Mm, la perpendiculaire abaissée de ce point sur l'axe. La surface latérale du tronc de cône a pour mesure (**445**) le produit 2π AB. M*m*; et cette expression est encore valable lorsque le tronc de cône est remplacé, soit par un cône, soit par un cylindre (**445**, Rem.).

---

(1) L'expression ainsi obtenue cesse d'avoir un sens lorsque le segment est perpendiculaire à l'axe (fig. 393 *ter*). Cette circonstance ne se présentera pas dans les raisonnements qui suivront.

(2) Dans le cas, exclu par la note précédente, où le segment donné serait perpendiculaire à l'axe, on aurait une couronne circulaire ou un cercle.

Par le point M, menons la perpendiculaire à AB, jusqu'à rencontre en O avec l'axe. D'autre part, par le point A, menons la parallèle AH à l'axe, jusqu'à rencontre en H avec B*b*. Le segment AH est égal à *ab*, c'est-à-dire à la projection de AB sur l'axe. D'autre part, les triangles ABH, M*m*O sont semblables, comme ayant leurs côtés perpendiculaires, et donnent

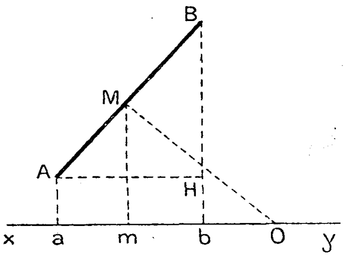

Fig. 394.

$$\frac{AB}{OM} = \frac{AH}{Mm},$$

ce qui s'écrit

$$AB \cdot Mm = OM \cdot AH.$$

Donc

$$\text{Surf. } AB = 2\pi\ AB.\ Mm = 2\pi\ OM \cdot AH = 2\pi\ OM.\ ab.$$

C. Q. F. D.

481. Aire de la zone.

Définition. — On nomme *zone*, la portion de surface sphérique comprise entre deux plans parallèles (*fig.* 395). Les circonférences situées dans ces deux plans et qui limitent, par conséquent, la zone, en sont dites les *bases*. La distance des deux plans de bases est la *hauteur* de la zone.

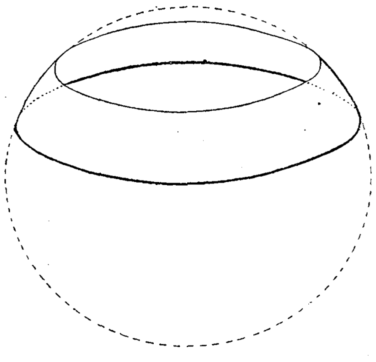

Fig. 395.

L'une quelconque des deux portions que l'on détermine dans une surface sphérique en la coupant par un plan, est dite une *calotte sphérique*. On peut évidemment considérer la calotte sphérique comme une zone dans laquelle un des plans de bases est tangent à la sphère.

La zone (ou la calotte) peut être encore définie comme la surface engendrée par la révolution d'un arc de cercle AB (*fig.* 396, 396 *bis*) autour d'un diamètre sans point commun avec lui (cas de la zone) ou passant par une de ses extrémités (cas de la calotte). La *hauteur* est alors la projection de l'arc AB sur l'axe.

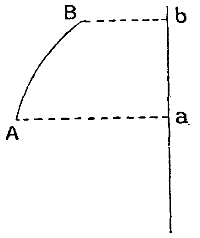

Fig. 396.

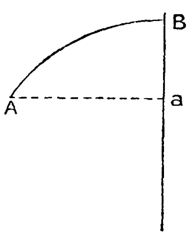

Fig. 396 *bis*.

482. Pour définir l'*aire* de la zone, nous remplacerons d'abord l'arc AB par une ligne brisée (ACDEB, *fig*. 397) inscrite dans cet arc. L'aire de la zone sera, par définition, la limite vers laquelle tend l'aire engendrée par cette ligne en tournant autour de l'axe, lorsque le nombre des côtés de la ligne augmente indéfiniment de manière que chacun d'eux tende vers zéro.

L'existence de cette limite et son expression résultent des deux théorèmes suivants :

Théorème. — *L'aire engendrée par une ligne brisée inscrite à un cercle, en tournant autour d'un diamètre qui ne la coupe pas, est égale à la projection de la ligne brisée sur le diamètre, multipliée par la longueur d'une circonférence dont le rayon est compris entre la plus petite et la plus grande des distances du centre aux côtés de la ligne brisée.*

Soit la ligne brisée ACDEB (*fig*. 397) inscrite dans un cercle de centre O et tournant autour du diamètre xy, lequel ne la traverse pas (une des extrémités de la ligne brisée, ou les deux, pouvant être sur xy). Soient a, c, d, e, b, les projections des sommets sur xy.

Les perpendiculaires aux milieux H, K, L, M des côtés de la ligne brisée concourant toutes en O, le théorème du n° **480** donne ici (¹) :

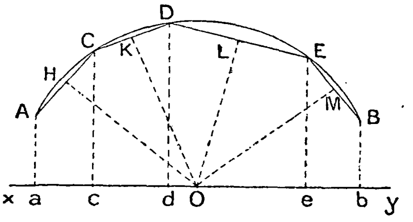

Fig. 397.

$$\text{Surf. AC} = 2\pi\,\overline{ac}\cdot\overline{OH}$$
$$\text{Surf. CD} = 2\pi\,\overline{cd}\cdot\overline{OK}$$
$$\text{Surf. DE} = 2\pi\,\overline{de}\cdot\overline{OL}$$
$$\text{Surf. EB} = 2\pi\,\overline{eb}\cdot\overline{OM}$$

---

(1) Le cas d'exception signalé à la page 169, note 2, ne peut se présenter dans le raisonnement actuel, une corde d'un cercle ne pouvant être perpendiculaire à un diamètre sans être traversée par lui.

La surface engendrée par la ligne ACDEB est donc mesurée par

$$2\pi\,(\overline{ac}\cdot\overline{\mathrm{OH}}+\overline{cd}\cdot\overline{\mathrm{OK}}+\overline{de}\cdot\overline{\mathrm{OL}}+\overline{eb}\cdot\overline{\mathrm{OM}}).$$

Or, d'après un théorème connu d'arithmétique (¹), l'expression entre parenthèses est égale au produit de la somme $ac + cd + de + eb$, c'est-à-dire de ab, par une quantité comprise entre la plus grande et la plus petite des quantités OH, OK, OL, OM : ce qui démontre le théorème.

Corollaire. — Si la ligne brisée est régulière, les distances OH, OK, OL, OM, sont toutes égales à l'apothème de cette ligne brisée.

Donc l'*aire engendrée par une ligne brisée régulière tournant autour d'un axe situé dans son plan*, *passant par son centre et ne la traversant pas*, *est égale à la projection de cette ligne sur l'axe*, *multipliée par la longueur de la circonférence inscrite.*

483. Théorème. — *L'aire engendrée par un arc de cercle tournant autour d'un diamètre qui ne le traverse pas*, *est égale à la projection de l'arc sur le diamètre*, *multipliée par la longueur de la circonférence entière.*

Autrement dit, l'*aire de la zone est égale au produit de sa hauteur par la circonférence d'un grand cercle.*

Soient, en effet, l'arc AB, de centre O, tournant autour du diamètre xy ; ab, la projection de AB sur xy. Si, dans l'arc AB, nous inscrivons une ligne brisée ACDEB, celle-ci, en tournant autour de xy, engendrera une aire égale au produit de $2\pi\cdot\overline{ab}$ par une quantité intermédiaire entre la plus grande et la plus petite des distances du centre aux côtés de la ligne brisée.

Si maintenant on augmente indéfiniment le nombre des côtés, de manière que chacun d'eux tende vers zéro, toutes les distances dont il vient d'être question tendent vers le rayon $\mathrm{OA} = \mathrm{R}$ de la circonférence.

Donc l'aire engendrée a bien une limite, indépendante de la loi suivant laquelle on fait croître le nombre des côtés de la ligne brisée (pourvu que tous ces côtés tendent vers zéro) et cette limite est

$$2\pi\,\mathrm{R}\cdot\overline{ab}.$$

C. Q. F. D.

---

(1) TANNERY, *Leçons d'Arithmétique*, nº **212**, page 180.

Remarque. — Le raisonnement précédent et sa conclusion sont applicables au cas d'une calotte sphérique.

Corollaire. — On voit, par le théorème précédent, que *deux zones d'une même sphère sont proportionnelles à leurs hauteurs.*

484. Aire de la sphère.

Théorème. — *L'aire de la sphère de rayon* R *est* $4\pi R^2$.

En effet, le raisonnement du numéro précédent est encore applicable lorsque l'arc AB devient la demi-circonférence. La projection *ab* est alors le diamètre 2R ; la zone engendrée n'est autre que la sphère entière. La surface de cette sphère est donc mesurée par le produit

$$2\pi R \times 2R = 4\pi R^2.$$

C. Q. F. D.

Corollaire. — *La surface de la sphère est égale à quatre fois la surface d'un grand cercle.*

Remarque. — On voit que *les surfaces de deux sphères sont proportionnelles aux carrés de leurs rayons.*

485. Théorème. — *Le volume engendré par un triangle tournant autour d'un axe situé dans son plan, passant par un de ses sommets et ne le traversant pas, a pour mesure le produit de la surface que décrit le côté opposé au sommet situé sur l'axe, par le tiers de la hauteur correspondante.*

Nous distinguerons trois cas :

1° *Un des côtés du triangle est situé sur l'axe.*

Soit le triangle ABC (*fig.* 398, 398 *bis*) dont le côté AB est situé sur l'axe *xy*. Par le sommet C, menons, sur cet axe, la perpendiculaire C*c*. Les deux triangles rectangles AC*c*, BC*c* engendreront,

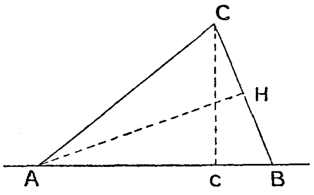

Fig. 398.

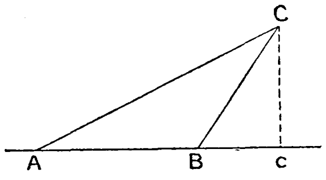

Fig. 398 *bis*.

en tournant autour de xy, deux cônes ayant pour base commune le cercle de rayon cC, pour hauteurs respectives Ac, Bc, et dont les volumes seront respectivement $\frac{1}{3}\pi\overline{Cc}^2\cdot\overline{Ac}$, $\frac{1}{3}\pi\overline{Cc}^2\cdot\overline{Bc}$. Le volume engendré par ABC sera la somme ou la différence des deux cônes ainsi obtenus, suivant que le point c sera sur le segment AB (*fig.* 398) ou sur un de ses prolongements, par exemple au delà du point B (*fig.* 398 *bis*) : on aura donc

$$\text{Vol. ABC} = \frac{1}{3}\pi\cdot\overline{Cc}^2\cdot\overline{Ac} + \frac{1}{3}\pi\overline{Cc}^2\cdot\overline{BC} = \frac{1}{3}\overline{Cc}^2(\overline{Ac}+\overline{Bc})$$

dans le premier cas, et

$$\text{Vol. ABC} = \frac{1}{3}\pi\overline{Cc}^2\cdot\overline{Ac} - \frac{1}{3}\pi\overline{Cc}^2\cdot\overline{Bc} = \frac{1}{3}\pi\overline{Cc}^2(\overline{Ac}-\overline{Bc})$$

dans le second.

Mais comme on a, dans le premier cas,

$$\text{AB} = \text{A}c + \text{B}c$$

et, dans le second,

$$\text{AB} = \text{A}c - \text{B}c,$$

il vient, en toute hypothèse,

$$\text{Vol. ABC} = \frac{1}{3}\pi\overline{Cc}^2\cdot\text{AB}.$$

D'autre part, si AH est la hauteur du triangle issue du point A, on a

$$\text{C}c\cdot\text{AB} = \text{BC}\cdot\text{AH} :$$

car ces deux produits représentent tous deux le double de l'aire du triangle ABC. On peut donc écrire

$$\text{Vol. ABC} = \frac{1}{3}\pi\overline{Cc}\cdot\text{BC}\cdot\text{AH},$$

ce qui donne

$$\text{Vol. ABC} = \frac{1}{3}\text{AH}\cdot\text{Surf. BC},$$

car la surface décrite par le côté BC est celle d'un cône et a pour mesure (**443**) $\pi\ \overline{BC} \cdot \overline{Cc}$.

2° *Le côté opposé au sommet situé sur l'axe est parallèle à l'axe.*

Soit le triangle ABC (*fig.* 399, 399 *bis*) dans lequel le sommet A est situé sur l'axe xy, tandis que le côté BC est parallèle à cet axe. Menons encore la hauteur AH et projetons les points B, C en b, c sur l'axe. Lorsqu'on fait tourner la figure autour de cet axe, le rectangle BbAH engendre un cylindre et le triangle ABb engendre un cône ; comme ces deux solides ont même base (le cercle de rayon bB) et même hauteur (Ab), le cône est le tiers du cylindre : leur différence, c'est-à-dire le volume engendré par le triangle ABH, est les $\frac{2}{3}$ du cylindre engendré par le rectangle AbBH.

De même, le volume engendré par le triangle ACH est les $\frac{2}{3}$ du cylindre engendré par AcCH.

Donc le volume engendré par le triangle ABC, lequel est la somme (*fig.* 399) ou la différence (*fig.* 399 *bis*) des volumes engendrés par les deux triangles précédents, est les $\frac{2}{3}$ du cylindre engendré par le rectangle BbCc, ce cylindre étant la somme ou la différence des deux cylindres que nous venons de considérer. Autrement dit, on a

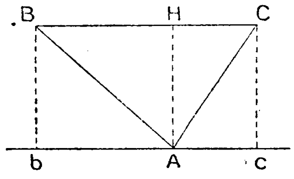

FIG. 399.

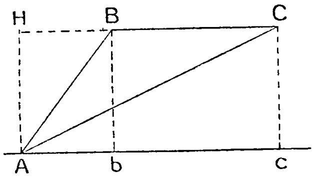

FIG. 399 *bis*.

$$\text{Vol. ABC} = \frac{2}{3}\,\text{Vol. B}b\text{C}c = \frac{2}{3}\,\pi\,\overline{Bb}^2 \cdot \overline{BC}$$

$$= \frac{1}{3}\,\text{AH} \times 2\pi\,\text{B}b \cdot \text{BC} = \frac{1}{3}\,\text{AH} \times \text{surf. BC}.$$

3° *Cas général.*

Soit le triangle ABC (*fig.* 400) dont le sommet A est sur l'axe xy, le côté BC n'étant pas parallèle à cet axe. Soit D le point de rencontre de xy avec BC prolongé. On a (1°), en appelant toujours AH la hauteur issue de A,

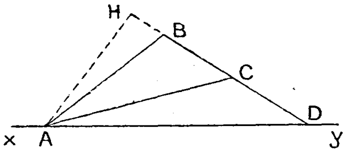

Fig. 400.

$$\text{Vol. ABD} = \text{surf. BD} \times \frac{1}{3}\,\text{AH},$$

$$\text{Vol. ACD} = \text{surf. CD} \times \frac{1}{3}\,\text{AH},$$

d'où, par différence,

$$\text{Vol. ABC} = \text{surf. BC} \times \frac{1}{3}\,\text{AH}.$$

C. Q. F. D.

486. Volume du secteur sphérique.

Définition. — On nomme *secteur sphérique*, la figure engendrée par un secteur circulaire tournant autour d'un diamètre qui ne le traverse pas. Dans ce mouvement, l'arc qui sert de base au secteur circulaire engendre une zone, qui est dite *base* du secteur sphérique.

Pour définir le volume du secteur sphérique, nous remplacerons le secteur circulaire par un secteur polygonal inscrit. Le volume du secteur sphérique sera, par définition, la limite vers laquelle tend le volume engendré par ce secteur polygonal, lorsque le nombre des côtés de la ligne brisée qui lui sert de base augmente indéfiniment, de manière que chacun d'eux tende vers zéro.

Les théorèmes suivants montrent l'existence de cette limite et en fournissent l'expression, laquelle est indépendante de la loi suivant laquelle on construit les lignes brisées inscrites.

Théorème. — *Le volume engendré par un secteur polygonal* (Pl., **253** *bis*) *en tournant autour d'un axe situé dans son plan, passant par son centre et ne le traversant pas, est égal au tiers de la surface engendrée par la ligne brisée qui sert de base au secteur, multiplié par une quantité intermédiaire entre la plus grande et la plus petite des distances du centre aux côtés de cette ligne.*

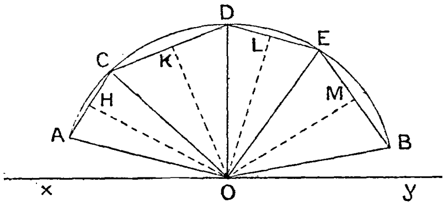

Fig. 401.

Soit le secteur polygonal OACDEB (*fig.* 401), tournant autour d'un axe xy passant par son centre O, situé dans son plan et ne le traversant pas. Les triangles OAC, OCD, ODE, OEB engendrent respectivement des volumes dont l'expression est fournie par le théorème précédent. On a ainsi, en désignant par OH, OK, OL, OM, les distances du centre aux côtés AC, DC, DE, EB :

$$\text{Vol. OAC} = \frac{1}{3}\ \text{surf. AC} \times \text{OH}$$

$$\text{Vol. OCD} = \frac{1}{3}\ \text{surf. CD} \times \text{OK}$$

$$\text{Vol. ODE} = \frac{1}{3}\ \text{surf. DE} \times \text{OL}$$

$$\text{Vol. OEB} = \frac{1}{3}\ \text{surf. EB} \times \text{OM}.$$

En faisant la somme et recourant encore au théorème d'arithmétique déjà appliqué n° **482**, on voit bien que le volume engendré par le secteur est égal au tiers de la somme surf. AC + surf. CD + surf. DE + surf. EB, — c'est-à-dire au tiers de la surface qu'engendre la ligne ACDEB, — multiplié par une quantité intermédiaire entre la plus grande et la plus petite des quantités OH, OK, OL, OM.

C. Q. F. D.

Corollaire. — Si le secteur polygonal est régulier, les lignes OH, OK, OL, OM sont toutes égales à l'apothème de la ligne brisée régulière ACDEB.

Donc *le volume engendré par un secteur polygonal régulier tournant autour d'un axe situé dans son plan, passant par son centre et ne le traversant pas, est égal à la surface engendrée par la ligne brisée qui sert de base au secteur, multipliée par le tiers de l'apothème.*

Théorème. — *Le volume du secteur sphérique est égal à la zone qui lui sert de base, multipliée par le tiers du rayon.*

En effet, si l'on augmente indéfiniment le nombre des côtés d'une ligne brisée inscrite dans l'arc AB (*fig.* 401) qui engendre la zone de base, — et cela de manière que chacun d'eux cités tende vers zéro, — la surface engendrée par cette ligne brisée inscrite tend vers la surface de zone, pendant que les distances OH, OK, etc. (*fig.* 401), des différents côtés au centre tendent toutes vers le rayon. Donc le volume engendré par le secteur polygonal correspondant tend bien vers la limite indiquée dans l'énoncé.

Corollaire. — *Si* R *est le rayon de la sphère, h la hauteur de la zone qui sert de base au secteur, le volume de celui-ci est* $\frac{1}{3}\pi R^2 h$.

Cette expression est bien, en effet, le produit de $\frac{1}{3}$ R par l'aire de la zone, trouvée au nº **483**.

487. Volume de la sphère.

Théorème. — *Le volume de la sphère de rayon* R *est* $\frac{4}{3}\pi R^3$.

En effet, les raisonnements qui précèdent sont applicables à la figure engendrée par un demi-cercle tournant autour de son diamètre, c'est-à-dire au volume de la sphère. On doit alors, dans l'expression indiquée au corollaire du numéro précédent, remplacer la hauteur h par 2R; ce qui conduit bien au résultat annoncé.

Corollaire. — *Le volume de la sphère de diamètre* D *est* $\frac{1}{6}\pi D^3$.

Il suffit, pour le voir, de remplacer R, par $\frac{D}{2}$, dans l'expression $\frac{4}{3}\pi R^3$.

Remarque. — On voit que *les volumes des deux sphères sont proportionnels aux cubes de leurs rayons* (*ou de leurs diamètres*).

488. Volume de l'anneau sphérique.

On nomme *anneau sphérique* le solide engendré par la révolution d'un segment de cercle (Pl., **263**) autour d'un diamètre qui ne le traverse pas.

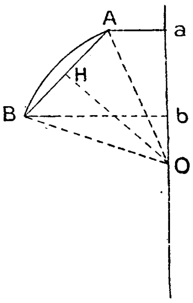

Fig. 402.

Le volume engendré par un segment de cercle tournant autour d'un diamètre qui ne le traverse pas (volume de l'*anneau sphérique*) *est le sixième du volume du cylindre qui a pour base la corde du segment et pour hauteur la projection de cette corde sur l'axe.*

Soit le segment de cercle compris entre l'arc AB d'une circonférence O (*fig.* 402) et sa corde, tournant autour de l'axe xy qui passe par O. Soit encore ab la projection AB sur xy.

Lorsque la figure tourne autour de xy, le secteur circulaire OAB engendre un volume qui est mesuré (**486**) par le produit $\frac{2}{3}\pi\overline{OA}^2\,\overline{ab}$.

D'autre part, le triangle rectiligne OAB engendre, dans les mêmes conditions, un volume égal (**485**) à surf. AB $\times \frac{1}{3}$ OH (en désignant par OH la distance du centre à la corde AB), c'est-à-dire (**480**) à

$$2\pi\,\overline{ab}.\,\overline{OH} \times \frac{1}{3}\,\overline{OH} = \frac{2}{3}\pi\,\overline{OH}^2.\,\overline{ab}.$$

La différence des deux volumes précédents est évidemment constituée par le volume de l'anneau sphérique : celui-ci a donc pour mesure

$$\frac{2}{3}\pi\,\overline{OA}^2.\overline{ab} - \frac{2}{3}\pi\,\overline{OH}^2.\overline{ab} = \frac{2}{3}\pi\,\overline{ab}\,(\overline{OA}^2 - \overline{OH}^2).$$

Mais, dans le triangle OAH, on a

$$\overline{OA}^2 - \overline{OH}^2 = \overline{AH}^2 = \frac{\overline{AB}^2}{4}.$$

Donc

$$\text{Vol. anneau AB} = \frac{2}{3}\pi\,\overline{ab}\,\frac{\overline{AB}^2}{4} = \frac{1}{6}\pi\,\overline{AB}^2.\,\overline{ab}.$$

C. Q. F. D.

489. Volume du segment sphérique.

On nomme *segment sphérique* la portion de sphère comprise entre deux plans parallèles : volume limité, en général, par une zone et deux cercles dont les plans sont parallèles entre eux (*fig.* 403), ces cercles étant dits les *bases* du segment. Le segment sphérique peut aussi être à une seule base, c'est-à-dire limité par un cercle et une calotte sphérique (*fig.* 403 *bis*); le plan de l'autre base doit être

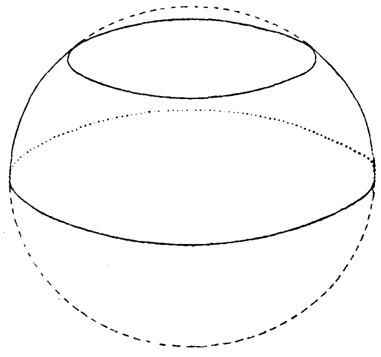

FIG. 403.

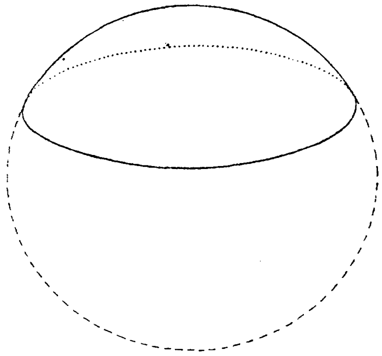

FIG. 403 *bis*.

alors, pour l'application des raisonnements, réputé tangent à la sphère.

La *hauteur* du segment est la distance des plans des deux bases.

Le segment sphérique est équivalent à la demi-somme des deux cylindres qui ont pour hauteur commune, la hauteur du segment et pour bases respectives les deux bases de ce segment, augmentée de la sphère qui a la hauteur pour diamètre.

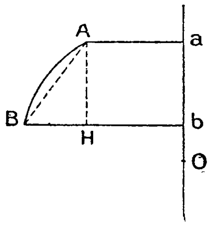

Fig. 404.

Soit le segment sphérique engendré par la révolution du trapèze mixtiligne $aABb$ (*fig.* 404) autour de l'axe ab et limité, par conséquent, d'une part par deux cercles de rayons respectifs aA, bB, d'autre part par la zone qu'engendre l'arc AB. Ce solide est manifestement la somme du tronc de cône engendré par le trapèze *rectiligne* $AaBb$ et de l'anneau sphérique AB.

Le tronc de cône a pour volume

$$\frac{1}{3}\pi\overline{ab}\left(\overline{Aa}^2+\overline{Bb}^2+\overline{Aa}\cdot\overline{Bb}\right);$$

l'anneau sphérique a pour volume

$$\frac{1}{6}\pi\overline{ab}\cdot\overline{AB}^2.$$

Nous trouvons donc comme somme

$$\frac{1}{6}\pi\overline{ab}\left(\overline{AB}^2+2\overline{Aa}^2+2\overline{Bb}^2+2\overline{Aa}\cdot\overline{Bb}\right).$$

Mais $\overline{AB}^2$ peut s'exprimer à l'aide de Aa, Bb et ab ; car, si l'on mène par le point A la parallèle AH à l'axe, jusqu'à rencontre en H avec Bb, le triangle rectangle ABH donne

$$\overline{AB}^2=\overline{AH}^2+\overline{BH}^2,$$

et comme, d'autre part, on a (¹)

$$AH=ab;\quad BH=Bb-Hb=Bb-Aa,$$

(¹) Nous supposons, pour fixer les idées, que Bb soit plus grand que Aa : autrement dit, que l'on a désigné par B celle des extrémités de l'arc donné qui est le plus éloignée de l'axe.

il vient

$$\overline{AB}^2 = \overline{ab}^2 + (Bb - Aa)^2.$$

Le volume du segment est donc

$$\frac{1}{6}\pi\overline{ab}\left[\overline{ab}^2 + (Bb - Aa)^2 + 2\overline{Aa}^2 + 2\overline{Bb}^2 + 2\overline{Aa}\cdot\overline{Bb}\right]$$

$$= \frac{1}{6}\pi\overline{ab}\left(\overline{ab}^2 + \overline{Aa}^2 - 2\overline{Aa}\cdot\overline{Bb} + \overline{Bb}^2 + 2\overline{Aa}^2 + 2\overline{Aa}\cdot\overline{Bb} + 2\overline{Bb}^2\right),$$

ou, toutes réductions faites,

$$\frac{1}{6}\pi\overline{ab}^3 + \frac{1}{2}\pi\overline{ab}\left(\overline{Aa}^2 + \overline{Bb}^2\right),$$

ce qui est bien la somme de la sphère et des deux demi-cylindres indiqués dans l'énoncé.

EXERCICES

712. Partager la surface d'une sphère en parties équivalentes par des plans passant par une droite donnée, extérieure à la sphère.

713. Une sphère varie en passant constamment par le centre d'une sphère fixe. Montrer que celle-ci intercepte sur la sphère variable une calotte d'aire constante.

714. Un cylindre est circonscrit à une sphère. Montrer que la zone de la sphère comprise entre deux plans perpendiculaires à l'axe du cylindre est équivalente à l'aire cylindrique comprise entre les deux mêmes plans.

715. Un cylindre étant circonscrit à une sphère, on mène à celle-ci un plan tangent P perpendiculaire à l'axe du cylindre et l'on prend la section droite ainsi déterminée dans ce dernier comme base d'un cône ayant pour sommet le centre de la sphère. Montrer :

1° Que si l'on coupe les trois solides par un même plan parallèle à P, le cercle, section du cylindre, a une aire équivalente à la somme des cercles suivant lesquels sont coupés respectivement le cône et la sphère.

2° Que si l'on coupe les trois solides par deux plans parallèles à P, le volume intercepté, entre ces deux plans, dans le cylindre, est la somme des volumes interceptés dans le cône et dans la sphère.

716. Montrer que les volumes du cylindre, du cône, du tronc de cône et du segment sphérique satisfont tous à la relation :

$$V = \frac{h}{6}\left(B + B' + 4B''\right),$$

h, B, B′, B″ désignant, comme à l'exercice 575, la hauteur du solide, les aires des deux bases (la base supérieure du cône étant nulle) et l'aire de la section menée, parallèlement aux bases, à égale distance de ces deux bases.

717. Deux petits cercles polaires l'un de l'autre (ex 699) sont tels que si l'on prenait pour unité de longueur la longueur d'un grand cercle et pour unité de surface l'aire de la demi-sphère, le nombre qui mesure la longueur de l'un serait égal à l'unité, moins le nombre qui mesure la calotte sphérique intérieure à l'autre.

718. Pour tous les polyèdres circonscrits à une même sphère, le rapport du volume à la surface est le même.

719. L'énoncé précédent subsiste encore pour un cylindre, un cône ou un tronc de cône circonscrits à la sphère (on dit qu'un cylindre, un cône ou un tronc de cône sont circonscrits à la sphère, si : 1° la surface cylindrique ou conique est circonscrite à cette sphère ; 2° les plans de bases sont tangents à la même sphère) ; ou plus généralement, pour tout solide limité par des portions de surfaces cylindriques ou coniques circonscrites et par des plans tangents.

720. Quel est le rapport des volumes engendrés par un parallélogramme tournant successivement autour de deux côtés adjacents !

721. Construire (effectivement) un triangle, connaissant les rayons des sphères équivalentes aux volumes qu'engendre ce triangle en tournant successivement autour de chacun de ses côtés.

722. Calculer le rayon d'un cercle tracé sur une sphère de rayon R, sachant que l'aire de ce cercle est égale à la différence des calottes qu'il détermine.

Quelle est la hauteur du cône circonscrit suivant ce cercle ?

723. Trouver, sur une sphère donnée, une calotte qui soit dans un rapport donné avec l'aire du cercle qui lui sert de base.

724. Couper une sphère par un plan de manière que l'un des segments sphériques (à une base) obtenus soit dans un rapport donné avec le secteur sphérique limité par la même calotte.

725. On prend un cercle d'une sphère comme base d'un cône qui a pour sommet l'un des pôles du cercle. Trouver le cercle de manière que le volume du cône soit dans un rapport donné avec le segment sphérique qui a pour base unique le même cercle et qui contient le cône.

Vers quelle limite tend le rapport du cône au segment sphérique, lorsque leur hauteur commune tend vers zéro?

726. Construire un segment sphérique appartenant à une sphère donnée, connaissant son volume (égal à celui d'une sphère de rayon donné) et l'aire de la zone qui le limite (égale à celle d'un cercle donné).

Quel est le maximum du volume du segment, lorsque l'aire de la zone est donnée?

727. Tracer, sur une sphère, trois cercles tangents entre eux deux à deux, ayant leurs plans parallèles à une même droite, dont les deux premiers soient égaux entre eux et divisent en quatre parties équivalentes l'une des calottes déterminées par le troisième.

728. Soient A le point de contact de deux circonférences O et O′ tangentes extérieurement ; T, T′ les points de contact d'une tangente commune extérieure à ces circonférences. Montrer que le volume compris entre le tronc de cône engendré par TT′ (dans sa révolution autour de la ligne des centres) et la sphère qui passe par les cercles de bases de ce tronc de cône est double de la portion de ce même tronc de cône

extérieure aux sphères S, S′, engendrées par les circonférences données, et que cette portion est équivalente à la somme des anneaux sphériques situés respectivement dans les sphères S, S′, à l'extérieur des cônes engendrés par les cordes AT, AT′. Exprimer ces volumes à l'aide des rayons des circonférences données.

PROBLÈMES

PROPOSÉS SUR LE LIVRE VIII

729. Lieu des centres des sphères qui coupent deux sphères données suivant des grands cercles. — Même problème lorsqu'il y a trois sphères données.

730. Lieu des centres des sphères qui sont coupées par deux (ou trois) sphères données suivant des grands cercles.

731. Si le centre radical de quatre sphères leur est intérieur, il est le centre d'une sphère qui est coupée par chacune des premières suivant un grand cercle.

732. Lieu des génératrices de contact des plans tangents menés par un point donné de l'espace aux cônes de révolution qui passent par les côtés d'un angle donné (se ramène à l'exerc. 681 par la considération des sphères inscrites aux cônes considérés).

Par deux points donnés A, B d'une sphère, on fait passer un petit cercle variable et, par un point C situé le grand cercle AB, on mène un grand cercle tangent à ce petit cercle. Quel est le lieu du point T de contact ? Montrer qu'on a $\overline{CT}^2 = \frac{CA.\ CB.\ R}{d}$, en désignant par R le rayon de la sphère et par d la distance du centre à la corde AB.

733. On considère deux droites rectangulaires entre elles, non situées dans un même plan, et on les coupe par un plan variable, mais parallèle à un plan fixe. Montrer que la sphère qui a pour points diamétralement opposés les deux points d'intersection passe par un cercle fixe.

734. Sur deux droites données D, D′ on prend, à partir de deux points fixes A, A′ deux segments AM, A′M′ dont le rapport $\frac{A'M'}{AM}$ soit égal à un nombre donné k, et on considère la sphère (ex. 665) lieu des points P tels que $\frac{PM'}{PM} = k$.

Montrer que si les points M, M′ varient sur leurs droites respectives (de manière que le rapport $\frac{A'M'}{AM}$ soit constamment égal à k), les sphères obtenues, comme il vient d'être dit, appartiennent à l'une ou à l'autre de deux séries (suivant les sens dans lesquels sont portés les segments AM, A′M′), les sphères de la première série passant toutes (¹) par un même cercle C_1 ; les sphères de la seconde série passant toutes par un même cercle C_2.

La direction du plan du cercle C_1, comme celle du plan du cercle C_2, est indépendante du choix des points A, A′ lorsque les droites D, D′ et le rapport k sont donnés. Lorsque k varie, ces plans restent parallèles à une droite fixe.

---

(1) Il est d'abord nécessaire de prouver que deux sphères de la même série se coupent. C'est ce que l'on fera aisément à l'aide de l'exercice 733.

Tout point appartenant à un cercle C_1 ou C_2 est tel que ses distances aux deux droites données soient entre elles dans le rapport k. Inversement, par tout point tel que le rapport de ses distances à D et à D′ soit égal à k, il passe un cercle C_1 et un cercle C_2.

735. Étant données deux sphères et un point P, le lieu d'une droite passant par P, joignant entre eux deux points pris respectivement sur les deux sphères et qui soit divisée par ces points et le point P dans un rapport donné, est un cône à base circulaire.

Ce cône peut se réduire à un plan. Trouver le lieu du point P pour qu'il en soit ainsi.

736. Le lieu des arêtes des dièdres droits dont les faces passent respectivement par deux droites concourantes données est un cône à base circulaire (ex. 462).

737. Le lieu des points tels que le rapport de leurs distances à deux droites concourantes données soit constant est un cône circulaire oblique (ex. 734).

738. Le lieu des bissectrices des angles dont un côté est fixe et dont l'autre côté décrit un plan fixe (en passant constamment par le point d'intersection de ce plan avec le premier côté) est un cône (généralement oblique) à base circulaire.

739. Lieu des sommets d'un angle polyèdre dont les quatre faces passent respectivement par les côtés d'un quadrilatère plan donné, sachant que cet angle polyèdre peut être coupé (ex. 500) suivant un rectangle.

Même problème, lorsqu'au lieu d'être un rectangle, on sait que la section peut être un losange.

Même problème, lorsqu'on sait que l'angle polyèdre peut être coupé suivant un carré. Lieu du centre du carré (cône oblique à base circulaire).

740. On considère un tronc de cône dans lequel la hauteur est moyenne proportionnelle entre les diamètres des deux bases : Démontrer qu'on peut inscrire une sphère (ex. 719) à ce solide (Pl., ex. 135).

Montrer que la surface latérale de ce tronc de cône est équivalente à celle d'un cercle ayant pour rayon l'arête latérale.

Construire les rayons des bases, connaissant la hauteur et l'arête latérale.

741. Construire trois sphères passant respectivement par les sommets d'un triangle donné, tangentes en ces sommets au plan du triangle et tangentes entre elles deux à deux. Calculer leur rayons, connaissant les côtés du triangle.

742. Sur la sphère céleste, on considère les points M tels que leur ascension droite soit égale à leur déclinaison (¹) :

1° Trouver le lieu des projections des points M sur le plan de l'équateur :

2. Trouver le lieu des droites AM, A étant, sur l'équateur, le point origine des ascensions droites.

743. Étant donnés trois points A, B, C, en ligne droite (B entre A et C), on décrit, sur BC comme diamètre, un demi-cercle auquel on mène la tangente AD; soit M un point de l'arc BD. On propose de déterminer le point M de sorte qu'en joignant MC, MA et en faisant tourner la figure autour de AC, le volume engendré par le triangle MAC soit partagé dans le rapport donné k par la zone qu'engendre l'arc MB. Trouver les limites de k en fonction du rapport h de OA à OB, O étant le milieu de BC.

744. On donne un carré ABCD, dont le côté est égal à $2a$, et on considère un point M dans le plan de ce carré.

---

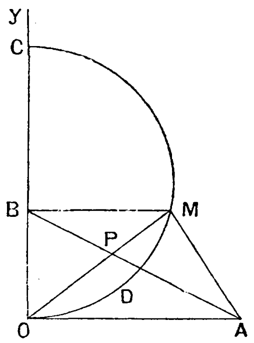
(1) Tisserand et Andoyer, *Leçons de Cosmographie*, nᵒˢ 9-12.

1° Calculer la somme S des volumes engendrés par les triangles MAB, MBC, MCD, MDA tournant respectivement, le premier autour de AB, le second autour de BC, le troisième autour de CD, le quatrième autour de DA.

2° Démontrer que la somme S ne dépend que des quantités a et d, en désignant par d la distance du point M au centre du carré, et trouver le lieu géométrique du point M lorsque ce point se déplace de manière que la somme S reste équivalente au volume du cône de hauteur a et de rayon donné r.

3° Déterminer, sur le lieu précédent, les positions de M pour lesquelles le rapport des volumes engendrés par le triangle MAB, tournant successivement autour de MA et de MB, est égal à un nombre donné m.

745. Soit un trapèze OAMB dans lequel le côté OB est perpendiculaire aux bases OA, BM. On suppose que les sommets O et A sont fixes et que le sommet B se déplace sur la droite fixe Oy perpendiculaire à OA. On fait tourner la figure autour de Oy.



1° On suppose que les volumes engendrés par les triangles OAB et ABM sont équivalents et on demande de trouver, dans le plan AOy, le lieu géométrique du point M ainsi que le lieu géométrique du point de rencontre P des diagonales OM et AB.

2° Soit ODMC la demi-circonférence tangente en O à OA et passant par M; on fait tourner la figure autour de Oy et on suppose que les volumes engendrés par le triangle OAB et par la surface ODMA (limitée par les droites OA, AM et par l'arc de cercle ODM) sont équivalents. Trouver, dans cette deuxième hypothèse, le lieu décrit par M dans le plan AOy.

3° Déterminer le point M, sachant que les volumes décrits par les triangles OAB et ABM et par la surface ODMA sont équivalents. (On désignera par a la longueur donnée OA.)

LIVRE X

NOTIONS SUR LA TOPOGRAPHIE

CHAPITRE PREMIER

GÉNÉRALITÉS. PLANIMÉTRIE

551. La *topographie* est l'art de déterminer la forme d'un terrain. Nous nous proposons uniquement, ici, d'exposer les principes géométriques sur lesquels repose la topographie, en renvoyant, pour les indications pratiques et les détails de toute espèce, aux traités spéciaux. Il est, d'ailleurs, à peine utile d'ajouter que la lecture de ceux-ci ne saurait être poursuivie utilement si on ne la complète en effectuant soi-même, sur le terrain, les opérations étudiées.

Nous nous bornons aux méthodes approximatives qui suffisent dans la pratique courante. Les opérations de grande précision nécessitent une série de précautions auxquelles nous ferons allusion, chemin faisant, mais dont nous ne saurions donner même une idée sans dépasser le cadre de cet ouvrage.

552. On appelle *verticale* en un point la direction de la pesanteur en ce point.

On détermine pratiquement cette direction comme position d'équilibre du *fil à plomb*, c'est-à-dire d'un fil auquel est suspendu un corps pesant. Lorsqu'on voudra, par exemple, s'assurer qu'une tige est verticale, il faudra constater qu'elle est parallèle à la direction du fil à plomb.

Cette direction n'est pas la même en des points différents de la surface du globe, puisque la terre a sensiblement la forme d'une sphère (¹) et que les verticales vont concourir au centre de cette sphère. Mais elle change très lentement (²) et l'on peut admettre, dans la topographie usuelle (mais non, bien entendu, dans les opérations de précision), que les verticales menées par les différents points du terrain que l'on veut étudier sont parallèles entre elles.

Un plan est dit vertical lorsqu'il est parallèle à la verticale.

553. Un plan *horizontal* est celui qui est perpendiculaire à la verticale.

Une droite est également dite horizontale quand elle est perpendiculaire à la verticale.

Lorsqu'un liquide est en équilibre, sa surface libre (considérée sur une étendue telle qu'on puisse y admettre le parallélisme des verticales) a la forme d'un plan horizontal (³).

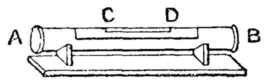


Fig. 466.
Niveau à bulle d'air.

On utilise cette propriété pour s'assurer qu'une direction est horizontale. L'instrument employé à cet effet est connu sous le nom de *niveau à bulle d'air*. C'est un tube de verre légèrement convexe, enchâssé dans une monture métallique AB (*fig.* 466) et dans lequel on a versé un liquide qui le remplit incomplètement de manière à y laisser une bulle d'air. On reconnaît que l'axe du tube est horizontal lorsque la surface libre du liquide affleure entre deux traits C, D (*fig.* 466), marqués à l'avance sur le verre.

On voit que le niveau à bulle d'air sert à reconnaître l'horizontalité d'une droite.

Pour constater l'horizontalité d'un plan, on constate l'horizontalité de deux droites de ce plan.

Il faut que ces deux droites ne soient pas parallèles, et

---

(1) Tisserand et Andoyer, *Leçons de Cosmographie*, livre II.

(2) Il résulte de la manière même dont a été obtenu le mètre que les verticales en deux points du globe font entre elles un angle de 90° lorsque ces points sont distants d'environ 10 000 kilomètres. Dès lors, pour une altération de 1° dans la direction de la verticale, il faut un déplacement de $\frac{10\,000}{90} = 111$ km. Une altération d'une minute correspond encore, comme on le voit, à un déplacement d'environ 2 kilomètres.

(3) Le fait cesse d'être exact aux bords de la surface, la direction de celle-ci étant alors altérée par l'effet d'une action due aux parois et nommée *capillarité* (voir ci-après, n° 574).

on doit même les choisir à peu près perpendiculaires l'une à l'autre (¹).

554. Pour rendre un plan matériel (par exemple une planche ou un plateau métallique) horizontal, on opère par tâtonnements, en modifiant progressivement la direction de ce plan, jusqu'à ce que, par l'emploi du niveau à bulle d'air, on constate l'horizontalité parfaite.

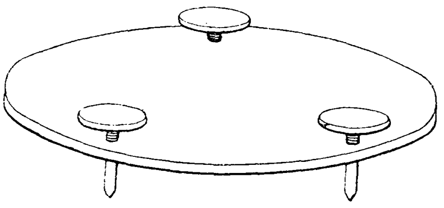

FIG. 468.

Pour pouvoir déplacer le plan de manière à modifier arbitrairement sa direction, on emploie plusieurs dispositifs.

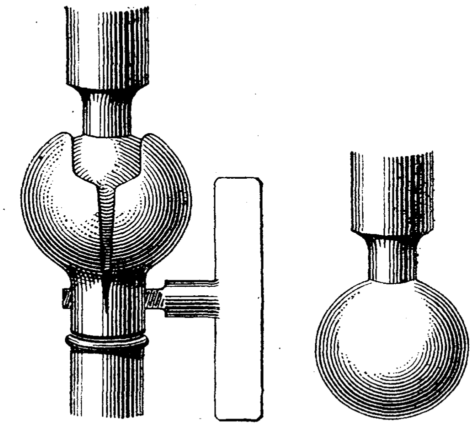

FIG. 469.

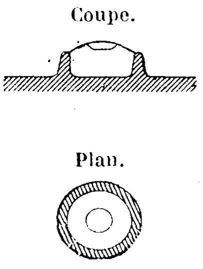
1° On peut faire supporter le plan en question par trois vis (*fig.* 468) dont l'action permet d'élever ou d'abaisser à volonté trois points du plan. Cette disposition, permettant d'opérer les déplacements par degrés insensibles, est adoptée, à l'exclusion de toute autre, toutes les fois qu'une certaine précision est nécessaire.

2° On obtient le même résultat, mais beaucoup plus grossièrement, à l'aide du *genou à coquilles* (*fig.* 469). Dans ce mode de suspension, le plan mobile porte une sphère pleine qui vient remplir exactement une sphère creuse fixée au support (²), la première sphère pouvant tourner arbitrairement à l'intérieur de la seconde.

3° Dans un autre système de genou, le plan mobile n'est pas lié à son support directement, mais par l'intermédiaire d'un cylindre intermédiaire C (*fig.* 470), de manière que le plan peut tourner autour de l'axe AA′ du cylindre, ce dernier pouvant,



Coupe.
Plan.
FIG. 467.

---

(1) Dans certains appareils, on emploie des niveaux à bulle d'air de forme arrondie (*fig.* 467) : lorsqu'il y a horizontalité, la bulle d'air vient se placer dans un cercle tracé sur la face supérieure de l'instrument ; on n'a alors besoin que d'une seule opération pour reconnaître l'horizontalité d'un plan.

(2) La sphère creuse est formée de deux parties ou *coquilles*, d'où le nom de l'instrument.

d'autre part, tourner autour d'un axe B (*fig.* 470) perpendiculaire au premier et fixé au support. Cette disposition permet bien (ex. 577, 578) de donner au plan une direction arbitraire.

Dans l'un comme dans l'autre des deux appareils précédents, il existe des vis permettant de supprimer toute mobilité, une fois l'horizontalité obtenue.

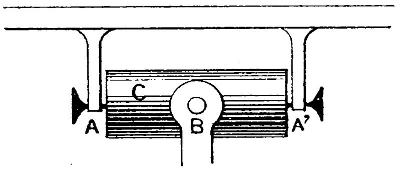


Fig. 470.

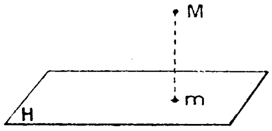

Fig. 471.

555. Soit choisi une fois pour toutes un plan horizontal déterminé H (*fig.* 471), dit *plan de comparaison*. Un point quelconque M sera déterminé si l'on se donne sa *projection horizontale m* (*fig.* 471) (projection sur le plan H) et sa *cote* (¹) *m*M. Il serait, toutefois, d'une manière générale, nécessaire d'indiquer le sens dans lequel cette cote doit être portée ; mais cette nécessité disparaît si l'on a pris, ainsi qu'on le fait généralement en topographie, le plan de comparaison au-dessous de tous les points de la figure étudiée (²).

D'après cela, on voit qu'on connaîtra entièrement la forme d'une figure, en particulier d'un terrain, si l'on a déterminé :

1° Sa projection horizontale, qui en est encore dite le *plan;*

2° Les cotes des différents points,

d'où deux sortes d'opérations en topographie : la *planimétrie* et le *nivellement*.

556. Levé du plan.

Lever le plan d'un terrain, c'est noter tous les éléments qui déterminent la forme et les dimensions de ce plan.

Lorsqu'on a levé le plan d'un terrain, on est à même de construire, sur le papier, une figure semblable à la projection horizontale de ce terrain, avec un rapport de similitude donné. C'est ce qu'on nomme *rapporter* le plan sur le papier, et le rapport de similitude en question se nomme l'*échelle* du plan ainsi tracé.

---

(1) Voir le cours de Géométrie descriptive.

(2) Il est d'ailleurs clair qu'au besoin on pourrait indiquer le sens de la longueur *m*M par le signe donné à la cote.

Les opérations fondamentales de la planimétrie sont : 1° la détermination d'une droite; 2° la mesure d'une longueur; 3° la mesure d'un angle.

557. Détermination d'un alignement.

Au point de vue de la planimétrie, un point du terrain peut être évidemment considéré comme déterminé si l'on connaît sa projetante, c'est-à-dire la verticale qui passe par ce point. On représente sur le terrain cette projetante par un *jalon*, c'est-à-dire par une tige, munie d'une marque destinée à la faire reconnaître de loin, et que l'on plante dans le sol bien verticalement (à l'aide du fil à plomb).

De même la direction d'une droite n'est intéressante à connaître en planimétrie que par le plan vertical ou *alignement* qui la contient.

L'alignement est déterminé par les deux extrémités de la droite. Si ces extrémités sont assez éloignées l'une de l'autre, les jalons qui les représentent peuvent, dans les opérations usuelles, être assimilés à des droites géométriques, sans que l'incertitude due à leur épaisseur dépasse la grandeur des erreurs admises.

Pour des raisons diverses, on peut avoir besoin de *jalonner* un alignement, c'est-à-dire de placer des jalons intermédiaires sur cet alignement, ou encore de le prolonger au delà de l'extrémité primitive.

On reconnaît que trois jalons font partie du même alignement si l'on peut placer l'œil de manière à ce que le premier jalon masque en même temps les deux autres.

Le jalonnement d'un alignement nécessite — comme d'ailleurs les opérations de topographie en général — la présence de deux opérateurs. L'un d'eux vérifie l'alignement, comme il vient d'être dit; l'autre se déplace sur les indications du premier, en transportant le jalon à poser, jusqu'à ce que l'alignement soit réalisé.

558. On a besoin, ainsi qu'on le verra plus loin, de pouvoir déterminer un alignement par deux verticales dont la distance ne dépasse pas les dimensions des instruments que nous décrirons aux n^{os} **560-561**.

On arrive à ce résultat par l'emploi de l'*alidade à pinnules*.

Une *pinnule* est une plaque allongée (*fig.* 472) percée, sur une moitié de sa longueur, d'une fente rectiligne étroite *ab*, et sur l'autre d'une fenêtre rectangulaire que traverse un fil fin *cd*. Le fil étant dans le prolongement de la fente, une droite est ainsi déterminée.

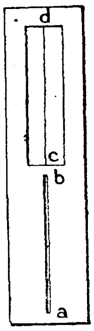

Fig. 472.

Une *alidade* est une règle munie à ses deux extrémités, de pinnules perpendiculaires à son plan (voir *fig.* 476). Ces pinnules sont disposées de manière que le fil de l'une soit en face de la fente de l'autre et inversement. En plaçant l'œil de manière que le premier fil masque la seconde fente et que la première fente laisse apercevoir le second fil, on vise un plan déterminé avec l'exactitude voulue.

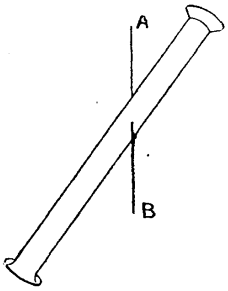

Fig. 473.

Une précision plus grande est obtenue par l'emploi des lunettes. Si une lunette est mobile autour d'une droite AB (*fig.* 473) perpendiculaire à son axe, ce dernier se meut dans un plan, lequel est vertical si la droite AB est horizontale.

559. Mesure directe d'une longueur.

On mesure les longueurs sur le terrain à l'aide de la *chaîne d'arpenteur*, qui est un décamètre divisé en *chaînons* de 20 centimètres chacun.

Si la droite à mesurer est parfaitement horizontale, on portera la chaîne sur cette droite autant de fois qu'on pourra le faire ; il restera, en général, un dernier segment moindre qu'un décamètre, et qu'on évaluera en comptant les chaînons et mesurant la fraction de chaînon qu'il comprend. On devra prendre soin :

1° Que, dans chacune de ses positions successives, la chaîne soit bien tendue ;

2° Qu'elle soit bien dans l'alignement donné (n° précéd.) ;

3° Que dans chaque position, l'extrémité postérieure de la chaîne soit à la place exacte où était l'extrémité antérieure dans la position précédente.

On marque, à cet effet, à l'aide d'une petite tige de fer, appelée *fiche*, que l'on plante dans le sol, l'endroit où arrive l'extrémité antérieure de la chaîne avant de relever celle-ci.

Mais dans la pratique, la droite à lever n'est jamais horizontale. C'est alors (d'après ce qui précède) sa projection horizontale qu'il s'agit de mesurer.

On y arrive en tendant la chaîne horizontalement, dans chacune de ses positions successives, et plaçant chaque fiche (à l'aide du fil à plomb) dans la verticale qui passe par l'extrémité antérieure de la chaîne (¹). Par exemple, la figure 474 représente un alignement AB sur lequel la chaîne a été reportée trois fois en AB_1, A_2B_2, A_3B_3, un dernier segment A_4B_4 étant plus petit que la longueur de la chaîne. Si tous ces segments sont dans un même plan et horizontaux, que les points A_2, A_3, A_4, B_4 soient bien sur les verticales menées respectivement par B_1, B_2, B_3, B, la somme des quatre segments A_1B_1, A_2B_2, A_3B_3, A_4B_4 (soit trois fois la longueur de la chaîne, plus le segment A_4B_4) représentera bien la projection horizontale de AB.

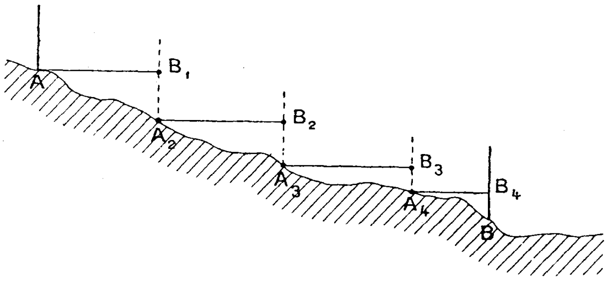

Fig. 474.

L'horizontalité de la chaîne, sa parfaite tension, etc., ne peuvent être obtenues qu'assez approximativement dans la pratique : néanmoins, avec des opérateurs exercés, on arrive à ne pas dépasser une erreur de $\frac{1}{1000}$. Dans les opérations très précises, on est obligé, pour éviter les causes d'erreur dont nous venons de parler et d'autres sur lesquelles nous n'insisterons pas, à une série de précautions délicates et compliquées. Aussi, dans ces derniers levés et même dans les levés usuels, réduit-on les mesures *directes* de longueur au moindre nombre possible, toutes les autres longueurs étant évaluées indirectement, comme il est expliqué ci-après (nº **563**) (²).

---

(1) Nous nous plaçons dans l'hypothèse où la droite à lever est descendante, ce qui revient à dire que l'on part de l'extrémité la plus élevée de cette droite. C'est d'ailleurs ainsi que l'on procède généralement.

(2) Il ressort avec évidence de ce qui est dit au nº **563**, que l'on ne peut se dispenser de mesurer directement au moins une longueur.

Dans les opérations de précision, on mesure *deux* droites ou *bases*, situées aussi loin que possible l'une de l'autre. Si les opérations ont été bien conduites, la valeur de la seconde base, calculée à l'aide de la première, doit coïncider avec la valeur mesurée directement.

560. Mesure directe d'un angle.

La projection horizontale de l'angle de deux droites AB, AC n'est évidemment autre que l'angle plan du dièdre formé par les alignements qui les contiennent : c'est ce que montre la simple inspection de la *fig.* 475.

L'instrument le plus généralement usité pour la mesure des angles sur le terrain est le *graphomètre* (*fig.* 476).

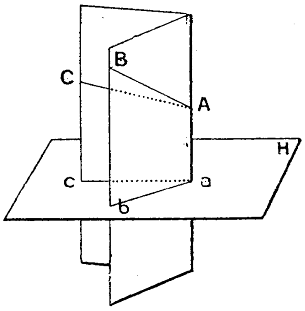

FIG. 475.

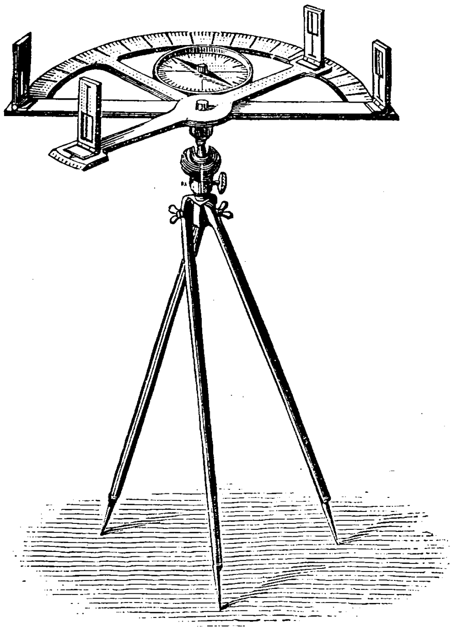

FIG. 476. — Graphomètre.

Il se compose d'un demi-cercle métallique ou *limbe*, monté sur genou (**554**) et, de plus, mobile dans son plan. Ce limbe, sur lequel est tracée une division en degrés et minutes (1), porte en outre deux alidades : l'une est fixe et a l'un de ses bords le long de la ligne 0° — 180° de la graduation ; l'autre alidade est mobile autour du centre du limbe.

Pour mesurer l'angle de deux alignements, on installe le graphomètre de manière que son centre soit dans la verticale du sommet de l'angle. On rend le limbe horizontal en faisant mouvoir le genou, puis on fait tourner ce limbe dans son plan de manière à amener l'alidade fixe dans le premier des deux alignements donnés. Plaçant ensuite la seconde alidade dans le second de ces deux alignements, il ne reste plus qu'à lire l'angle cherché.

Dans des instruments plus exacts, on substitue aux alidades une lunette mobile. C'est ce qui est réalisé dans le *théodolite* (2), instrument qui remplace le graphomètre dans les mesures de précision.

---

(1) En réalité, le limbe n'est gradué qu'en degrés et demi-degrés. Un dispositif spécial appelé *vernier*, et sur lequel nous n'insisterons pas, permet de lire les minutes.

(2) TISSERAND et ANDOYER, *Leçons de Cosmographie*, n° 5, page 6.

On sait (¹) qu'on appelle *azimuth* d'une direction, l'angle que fait l'alignement vertical qui contient cette direction avec un plan vertical fixe pris comme origine. L'angle de deux alignements peut évidemment être considéré comme la différence de leurs azimuths.

On prend souvent, comme direction origine, la direction sud-nord (plan méridien du lieu). Pour permettre d'évaluer les azimuths ainsi définis, le graphomètre est, en général, muni d'une boussole.

561. La *planchette* est un instrument qui permet, en même temps, de lever un plan et de le rapporter sur le papier.

Elle se compose, comme son nom l'indique, d'une planche bien plane, montée sur genou, pouvant également pivoter et glisser sur elle-même dans son plan et sur laquelle on tend une feuille de papier à dessin (*fig.* 477).

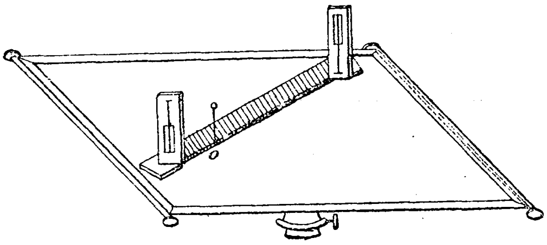

Fig. 477. — Planchette.

Une alidade mobile peut être posée à volonté sur la planchette. Le bord de cette alidade porte une petite échancrure qui permet de la faire pivoter autour d'une aiguille *o* (*fig.* 477) piquée à volonté dans le papier.

Soit à lever un angle à la planchette.

En général, le sommet *o* de l'angle et un côté *oa* sont marqués d'avance sur le papier. Il faut alors :

1° A l'aide du genou, rendre l'instrument horizontal ;

2° Par les mouvements de l'appareil dans son plan, s'arranger pour que le sommet *o* marqué sur le papier soit dans la verticale du sommet donné sur le terrain (²) et pour que, plaçant l'alidade suivant *oa*, cette alidade soit dans le premier alignement donné.

Toute cette première partie du travail se nomme la *mise en station* de l'instrument.

On fait alors pivoter l'alidade autour de l'aiguille piquée en *o*

---

(1) Tisserand et Andoyer, *Leçons de Cosmographie*, n° 4, page 5.

(2) Le point *o* peut être à 3 ou 4 centimètres de la verticale du sommet donné sans qu'il en résulte d'erreur dépassant les limites admises.

jusqu'à ce qu'elle vise le second alignement donné, et on trace un trait de crayon ob le long du bord, dans cette nouvelle position. L'angle $\widehat{boa}$ représente évidemment l'angle cherché.

Cette manière de procéder peut sembler, au premier abord, plus exacte que celle dans laquelle on fait usage du graphomètre, puisque, *théoriquement*, l'angle $\widehat{boa}$ obtenu est rigoureusement égal à l'angle qu'il s'agit d'évaluer, tandis que la lecture au graphomètre ne donne cet angle qu'à une ou deux minutes près.

En réalité, c'est le contraire qui a lieu : en raison des petites dimensions du dessin tracé sur la planchette, les erreurs dues à l'épaisseur du trait de crayon, aux petites déviations de l'alidade, etc., sont notablement supérieures à celles qu'introduit l'emploi du graphomètre. Mais la planchette, instrument inférieur au point de vue de l'exactitude, a souvent pour elle l'avantage de la rapidité.

562. Levé d'un triangle.

Un levé de plan quelconque peut se ramener (voir ci-après) à une série de levés de triangles. Or, cette dernière opération peut toujours être effectuée à l'aide de celles que nous avons décrites aux trois numéros précédents. Pour lever un triangle, il suffit d'avoir mesuré :

1° Un côté et deux angles ;

2° Ou deux côtés et l'angle compris ;

3° Ou les trois côtés.

En particulier, on peut alors rapporter le triangle sur le papier, à une échelle donnée quelconque. Si, par exemple, on a mesuré un côté AB et les deux angles adjacents $\widehat{A}$, $\widehat{B}$, on tracera sur la feuille un segment de droite ab qui soit avec la longueur mesurée dans un rapport égal à l'échelle donnée (1). Puis, si l'on a opéré avec le graphomètre, il restera à construire, à l'aide du rapporteur (2), deux droites ac, bc faisant avec ab des angles respectivement égaux à ceux qui ont été levés sur place.

---

(1) Comme précédemment pour les lectures angulaires, des artifices spéciaux permettent de déterminer le segment ab au 1/10 de millimètre près, quoique les règles servant aux mesures ne soient divisées qu'en millimètres.

(2) Le rapporteur, en raison de ses petites dimensions, ne permet d'obtenir que des approximations assez grossières dans la mesure des angles. Aussi, lorsqu'on veut une certaine exactitude, doit-on construire le triangle à l'aide de ses trois côtés, calculés s'ils ne sont pas connus directement (voir numéro suivant).

Si, au contraire, on a employé la planchette, le tracé des droites *ac*, *bc* aura été effectué (**561**) au moment même du levé sur le terrain.

563. Mesure indirecte des longueurs et des angles. De ce que nous venons de dire résulte qu'on peut connaître une longueur ou un angle sans les avoir mesurés directement. Il suffit de lever un triangle ayant pour un de ses éléments la longueur ou l'angle en question ; cet élément peut alors être considéré comme déterminé.

Si l'on veut obtenir effectivement la mesure — en mètres, s'il s'agit d'une longueur; en degrés et minutes, s'il s'agit d'un angle — on pourra rapporter le triangle sur le papier, à une échelle prise arbitrairement. La grandeur cherchée sera :

Si c'est un angle, égale à l'angle homologue de la figure ainsi tracée ;

Si c'est une longueur, égale à la longueur homologue, multipliée par un rapport inverse de l'échelle choisie.

Si celle-ci n'est pas trop petite, l'erreur commise dans la mesure sur le papier, multipliée par le rapport inverse dont nous venons de parler, pourra ne pas donner un produit supérieur à l'erreur admise, et en particulier à l'erreur provenant des opérations sur le terrain qui ont donné les éléments directement connus.

S'il en est autrement, il faudra, soit construire sur le terrain un triangle égal ou semblable à celui qu'on a levé — moyen évidemment très incommode et que nous ne mentionnons que pour mémoire — soit recourir à la trigonométrie, laquelle fait connaître le résultat cherché sans introduire aucune erreur nouvelle (¹).

564. La remarque qui précède est d'une application constante en topographie. Citons-en immédiatement deux conséquences :

1° *On peut lever un angle sans employer d'autre instrument que la chaîne.*

Il suffira de lever les trois côtés d'un triangle ayant l'angle donné parmi ses éléments.

Par conséquent, *on peut lever un plan quelconque avec la chaîne*

(¹) Bourlet, *Leçons de Trigonométrie*, livre III. — Les quantités fournies par les calculs trigonométriques ne le sont qu'avec une certaine approximation ; mais l'erreur provenant de ce fait est d'ordre de beaucoup inférieur à celui des erreurs qui résultent des mesures sur le terrain.

seule, puisque nous ramènerons tout levé de plan à des mesures de longueurs et d'angles.

2° *On peut mesurer la distance* (*horizontale*) *de deux points* A, B (*fig.* 478) *dont le second est inaccessible, quoique visible.* Il suffit, évidemment, de mesurer une distance AC et de viser les deux angles $\widehat{BAC}$, $\widehat{BCA}$.

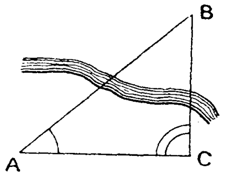

Fig. 478.

On voit seulement qu'il est nécessaire, pour déterminer exactement la position du point B, d'observer ce point, non seulement du point A, mais d'un autre point C. La visée faite du point A ne peut servir qu'à faire connaître la direction de la droite AB et ne peut donner à elle seule la longueur de cette droite.

Remarquons encore que le procédé est en défaut lorsqu'on prend le point C sur la droite AB. Il est même inapplicable si l'angle en B est trop aigu, car alors l'intersection des droites AB, CB détermine mal le point B.

565. Triangulation.

Il est aisé de comprendre comment un levé quelconque peut être ramené à des levés de triangles.

Supposons qu'on ait déjà levé un plan comprenant un certain nombre de points A, B, C, ..., K, L (*fig.* 479) et qu'on veuille *rattacher* à ce levé un nouveau point M, c'est-à-dire lever la figure formée par les points A, B, C, ..., K, L, M.

Il suffira, pour cela, de lever le triangle formé par le point M et deux des points appartenant à la figure primitive, les points K et L, par exemple (triangle dans lequel le côté KL doit déjà être regardé comme connu, puisqu'il appartient à la figure déjà levée). Si l'on a noté en outre le sens de ce triangle, autrement dit si l'on a observé de quel côté se trouve M par rapport à la droite KL, le problème est bien résolu : car si, connaissant par avance les points A, B, C, ..., K, L, on se donnait les éléments et le sens du triangle KLM, cela suffirait pour que la position du point M fût déterminée.

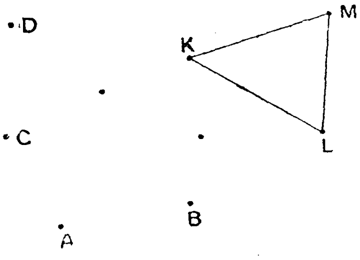

Fig. 479.

Donc, pour lever le plan de la figure composée des points A, B, C, ..., on mesurera d'abord la distance de deux d'entre eux, A, B, puis on rattachera un troisième point C aux deux premiers; un quatrième point D au levé ABC, et ainsi de suite.

La méthode comporte évidemment un certain degré d'arbitraire. En particulier, on peut évaluer une quelconque des distances CD, CE, ... de plusieurs manières différentes. On a ainsi un moyen de vérification des opérations.

La série de levés de triangles par laquelle on obtient le plan d'un terrain quelconque se nomme une *triangulation*.

566. Dans les levés simples que l'on rencontre usuellement, il est commode de réduire au moindre nombre possible les mises en station du graphomètre ou de la planchette : d'où les deux méthodes dites par *intersections* et par *rayonnement*.

Dans la méthode par *intersections*, on chaîne un alignement AB, auquel on rattache tous les autres points de la figure. A cet effet, M étant un point quelconque, on visera les angles en A et B du triangle ABM. Cette méthode n'exige, comme on le voit, que deux mises en station, en A et en B. Elle suppose qu'on ait choisi la *base* AB de manière à ce qu'aucun des angles tels que $\widehat{AMB}$ ne soit trop aigu (**564**).

Dans la méthode par *rayonnement*, on donne à tous les triangles un même sommet A et l'on mesure : 1° les angles en A ; 2° les côtés issus de A. On n'a ainsi qu'une seule mise en station, en A.

567. Levé d'un polygone par cheminement.

On peut lever un polygone par une méthode toute semblable à celle qui sert pour un triangle, à savoir, en en mesurant les côtés et les angles.

Il n'est pas nécessaire, théoriquement, de mesurer tous les côtés et tous les angles du polygone; il suffit de connaître tous ces éléments, moins trois. Par exemple, on aura levé le pentagone ABCDE (*fig.* 480) si on a déterminé les angles $\widehat{B}$, $\widehat{C}$, $\widehat{D}$ et les côtés AB, BC, CD, DE : car on aura ainsi rattaché les différents sommets les uns aux autres par l'intermédiaire des triangles ABC, BCD, CDE (dans chacun desquels on connaît deux côtés et l'angle compris), et il ne restera plus qu'à joindre EA.

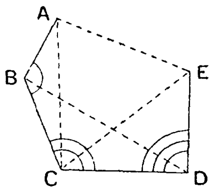

Fig. 480.

On voit, en même temps, que le cheminement n'est qu'un mode particulier de triangulation.

Dans la pratique, on relève tous les côtés et tous les angles, afin d'obtenir des vérifications.

La première de ces vérifications peut être faite dès la levée des angles : elle consiste à s'assurer que la somme de ceux-ci est bien égale à autant de fois deux droits qu'il y a de côtés moins deux.

La seconde ne se fait (du moins si l'on n'emploie pas la trigonométrie) qu'au moment où l'on rapporte le plan sur papier. Le polygone doit se fermer exactement si le levé a été bien fait (1).

568. Emploi de l'équerre d'arpenteur.

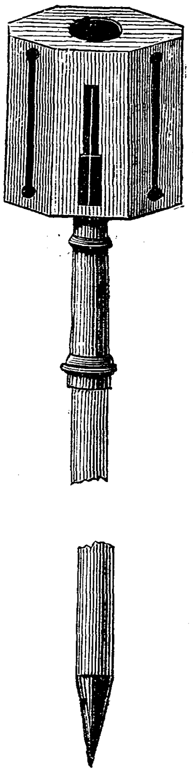

Fig. 481.
Équerre d'arpenteur.

L'équerre d'arpenteur est un instrument qui sert à mener des perpendiculaires sur le terrain. Elle consiste en un prisme octogone (*fig.* 481) dont quatre faces (2) sont munies de pinnules. Ce prisme est porté sur une tige, parallèle aux arêtes du prisme, et que l'on enfonce *verticalement* dans le sol. Si p, p' (*fig.* 482) sont les pinnules portées par deux faces opposées ; q, q', celles qui appartiennent à deux autres faces également opposées, on a ainsi déterminé deux alignements pp', qq'. L'équerre est *juste* lorsque ces deux alignements sont perpendiculaires entre eux.

Les deux problèmes fondamentaux que l'on peut résoudre avec l'équerre supposée juste sont les suivants :

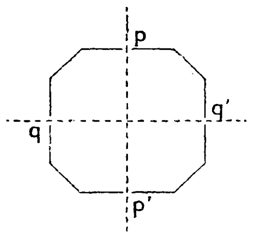

Fig. 482.

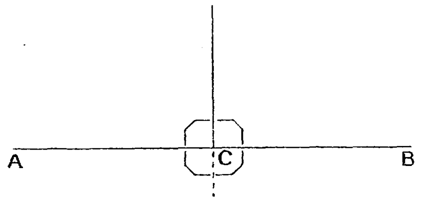

Fig. 483.

1° *Élever une perpendiculaire à un alignement* AB (*fig.* 483) *par un point* C *pris sur cet alignement.*

---

(1) Dans la pratique on n'arrive pas, en général, à une fermeture rigoureusement exacte. Mais l'erreur de fermeture ne doit pas dépasser une limite assez faible.

(2) En réalité, les huit faces portent des pinnules. Mais nous ne décrivons ici, pour simplifier, que ce qui est essentiel pour le fonctionnement de l'appareil.

On place l'équerre au point C de manière qu'un de ses plans de visée soit dans l'alignement donné ; le plan de visée perpendiculaire donnera l'alignement cherché.

2° *Abaisser d'un point* C, *extérieur à un alignement* AB, *une perpendiculaire sur cet alignement.*

Cette opération est la plus délicate de la topographie usuelle. Il faut, en effet, procéder par tâtonnement et déplacer l'équerre jusqu'à ce qu'on l'ait amenée à une position O située dans l'alignement AB et telle que la perpendiculaire élevée en O à AB (problème précédent) passe par C.

569. Soient un alignement jalonné sur le terrain, projeté horizontalement suivant Ox (*fig.* 484), et un autre alignement, perpendiculaire au premier, projeté horizontalement suivant Oy, et qui ne joue un rôle que dans le raisonnement. On peut déterminer, à l'aide de la chaîne et de l'équerre, les coordonnées de la projection horizontale d'un point quelconque M par rapport aux axes Ox, Oy. Il suffira d'abaisser, du point M, la perpendiculaire MM' sur Ox (n° précédent) et de chaîner OM', M'M.

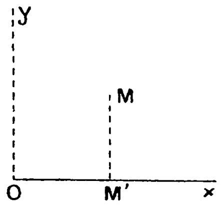

Fig. 484.

La connaissance de ces coordonnées détermine entièrement, comme nous le savons, la position de M par rapport aux axes Ox, Oy. Il suffira donc de répéter l'opération précédente avec un nombre quelconque de points donnés pour *lever*, *avec la chaîne et l'équerre*, *le plan de la figure formée par ces points.*

Rien n'empêche, d'ailleurs, de lever séparément différentes parties de la figure avec des axes différents pour chacune de ces parties.

570. En général, lorsqu'on veut lever le plan d'un terrain quelconque, on divise l'opération en deux parties.

On fait d'abord choix d'un certain nombre de points importants suffisamment éloignés les uns des autres et formant un polygone (*polygone topographique* ou *canevas*). On lève ce polygone avec le plus grand soin possible : on peut employer à cet effet l'une quelconque des méthodes que nous venons d'indiquer et opérer :

1° *Par cheminement*, à la chaîne et au graphomètre — ou même à la chaîne seule (en employant la remarque du n° **564**). Toutefois, cette dernière méthode, très longue et même peu exacte, n'est employée que dans les levés très peu étendus ;

2° *Par intersections*, si l'on a pu trouver une base qui ne soit vue d'aucun des sommets du polygone sous un angle trop aigu ;

3° *Par rayonnement ;*

4° Plus généralement, par une *triangulation* quelconque ;

5° *A l'équerre* (numéro précédent).

Toutefois, il faut observer que les deuxième et troisième méthodes (et souvent la dernière) deviennent inapplicables lorsque le terrain offre trop d'obstacles à la vue.

On n'emploie pas, en général, la planchette dans le levé du canevas, à cause de sa moindre exactitude.

571. Le canevas une fois levé, on y rattache les autres points intéressants en appliquant toujours les mêmes principes, mais visant un peu plus à la rapidité. La planchette est employée avec avantage dans cette partie du travail.

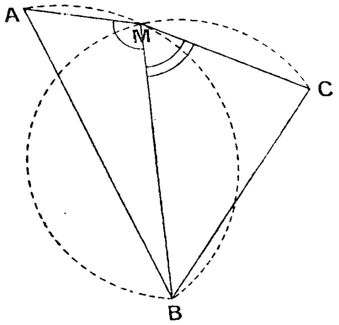

FIG. 485.

En dehors des méthodes précédemment décrites, un moyen simple de rattacher un point M au canevas consiste à viser de ce point trois points déjà relevés, A, B, C, et à noter les angles $\widehat{AMB}$, $\widehat{BMC}$. La connaissance de ces deux angles donne deux lieux du point M, à avoir deux segments de cercles (*fig.* 485) décrits l'un sur la corde AB, l'autre sur la corde BC. On n'a plus qu'à prendre, sur le papier, le point, autre que B, où se coupent les deux cercles. La trigonométrie permet d'ailleurs (¹) de déterminer tous les éléments des triangles ABM, BCM.

---

(1) *Leçons de trigonométrie rectiligne* de M. BOURLET, n° 179.

572. La remarque du n° **563** se généralise évidemment en ce sens que, pour connaître une longueur ou un angle, on peut rattacher les deux extrémités de la longueur, ou le sommet de l'angle et deux points pris sur ses côtés, à un levé que l'on effectue.

C'est ainsi que l'on procède, par exemple : pour *trouver la distance de deux points* A, B, *tous deux inaccessibles*, *mais visibles* (*fig.* 486). On mesure une base CD à laquelle on rattache les deux points donnés, par intersections (¹).

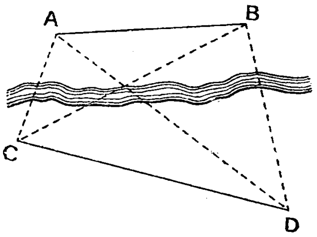

Fig. 486.

573. Lorsque le plan à lever contient une ligne (par exemple, une route ou le bord d'une rivière (*fig.* 487)), on lèvera des points M, M′, M″, ..., pris sur cette ligne et assez rapprochés les uns des autres pour faire connaître suffisamment sa forme.

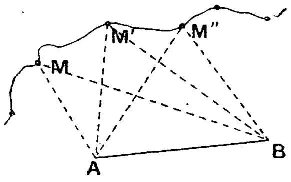

Fig. 487.

---

(1) *Leçons de trigonométrie rectiligne* de M. Bourlet, n° 177.

CHAPITRE II

NIVELLEMENT

574. Nivellement direct.

On mesure la différence des cotes de deux points à l'aide du *niveau d'eau*.

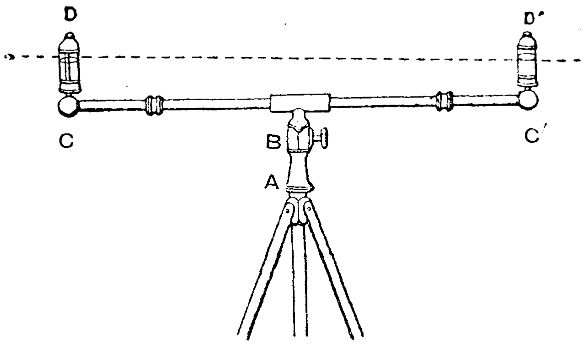

Fig. 488. — Niveau d'eau.

Cet appareil se compose (*fig.* 488) de deux fioles en verre F, F', communiquant entre elles par un tube TT' perpendiculaire à leur direction, qui aboutit au fond de chacune d'elles, et que l'on remplit incomplètement d'eau colorée. Le tout est porté sur un axe A que l'on installe verticalement. En vertu du principe des *vases communiquants*, établi en hydrostatique, les surfaces libres du liquide dans les deux fioles font partie d'un seul et même plan horizontal.

Le principe des vases communiquants n'est toutefois pas applicable sans modification, à cause de l'action de la *capillarité*, action dont l'effet est : 1° de relever toute la surface libre de l'eau dans chaque fiole, d'une petite quantité dépendant du diamètre de cette fiole; 2° de relever les bords de cette surface, de manière que celle-ci cesse d'être horizontale dans le voisinage de la paroi et prend la forme indiquée (*fig.* 489).

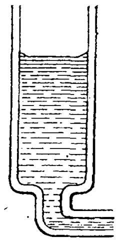

Fig. 489.

Mais, si les fioles sont exactement de même calibre, les actions capillaires sont identiques de part et d'autre. On a soin, en construisant l'appareil, que cette condition soit remplie. Lorsqu'il en est ainsi, les bords *ab*, *a'b'* des deux surfaces libres font partie d'un seul et même plan horizontal.

En plaçant l'œil suivant une tangente commune intérieure aux deux circonférences *ab*, *a'b'* et s'assurant qu'on voit bien ces deux lignes sous l'aspect de deux petites droites en prolongement l'une de l'autre (*fig.* 490), on vise une droite horizontale bien déterminée.

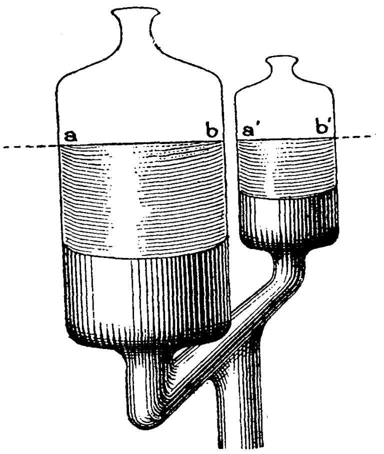

Fig. 490.

575. Pour pouvoir viser successivement toutes les directions d'un même plan horizontal, il suffit évidemment de faire tourner l'appareil autour de l'axe A, si celui-ci est bien vertical. La hauteur de l'eau dans les fioles reste alors invariable et la droite considérée tout à l'heure engendre un plan horizontal, dit *plan de visée* de l'appareil.

Lorsque l'axe A autour duquel tourne le niveau n'est pas exactement vertical, la conclusion précédente n'est pas applicable en général. Toutefois, on peut encore admettre, même dans ces conditions, que le niveau du liquide reste invariable dans la rotation, si l'on a constaté : 1° que les deux fioles sont de même diamètre intérieur (c'est ce que nous avons déjà supposé) ; 2° que l'axe aboutit au milieu du tube.

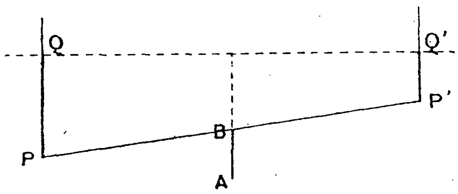

Fig. 491.

En effet, en toute hypothèse, le volume du liquide compris dans l'appareil demeure constant. Or, ce volume comprend : 1° le volume du tube horizontal, lequel est toujours le même ; 2° les volumes compris dans les fioles. Ceux-ci, puisque les fioles sont cylindriques et de même calibre, sont proportionnels aux hauteurs (¹) PQ, P'Q' (*fig.* 491) occupées par le liquide dans chacune d'elles, de sorte que leur somme est proportionnelle à la somme PQ + P'Q'.

Le volume total étant constant, nous voyons que, lors d'une

---

(1) Nous raisonnons comme si les fioles restaient verticales, ce qui n'est évidemment pas exact; mais, lorsque les inclinaisons sont petites, l'erreur provenant de ce fait est tout à fait négligeable.

rotation autour d'un axe non vertical, la hauteur occupée par le liquide dans l'une des fioles augmentera pendant qu'elle diminuera dans l'autre, mais que *la somme de ces hauteurs ne changera pas.*

Or, le trapèze (¹) PQ P′Q′ montre que cette somme est double de la distance verticale qui existe entre le milieu du tube et le niveau supérieur du liquide. Ce dernier devra donc rester invariable si le milieu du tube est sur l'axe. Il est même aisé de voir (exercice 855) que si la distance du milieu du tube à l'axe est petite, en même temps que l'angle de cet axe avec la verticale, la variation du plan de visée sera négligeable. On peut donc toujours, dans la pratique, considérer ce plan de visée comme fixe.

576. L'opération fondamentale exécutable avec le niveau d'eau est la suivante :

Étant donné un point M (*fig.* 492) *situé plus bas que le plan de visée de l'appareil*, *déterminer la cote de ce point au-dessous de ce plan.*

Il suffira à cet effet, de trouver, sur la verticale du point M, le point M′ qui est situé dans le plan de visée de l'appareil, et de noter la distance MM′.

C'est ce qu'on réalise à l'aide de la *mire*, c'est-à-dire d'une règle graduée portant une plaque carrée mobile, appelée *voyant*, laquelle est partagée en quatre parties peintes alternativement en blanc et en couleur (*fig.* 493) de manière que le centre en soit très nettement visible de loin.

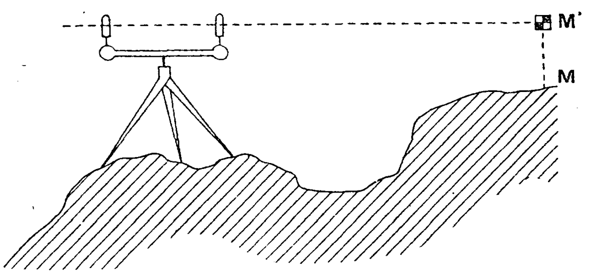

FIG. 492.

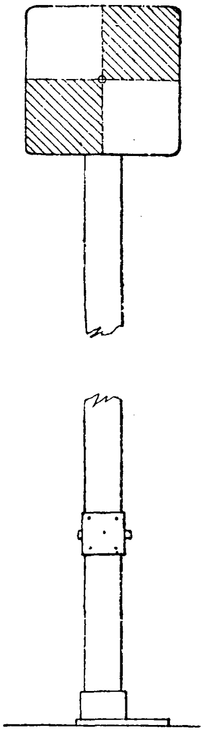

FIG. 493.

Un aide place cette règle bien verticalement au point M, puis, sur les indications de l'opérateur, fait monter ou descendre le

---

(¹) Nous réduisons, pour simplifier, le tube et les fioles à des droites.

voyant le long de la règle jusqu'à ce que son centre soit en M', dans le plan de visée du niveau. Il ne reste plus qu'à lire sur la graduation de la règle, la longueur MM'.

Il faut supposer toutefois : 1° que le point M, ou tout au moins le point M' peut être aperçu de l'endroit où est placé le niveau ; 2° que la distance horizontale des deux appareils ne soit pas trop grande, car la petite erreur commise par l'opérateur sur la direction de la visée a évidemment une influence croissante avec la distance en question ; 3° que la différence de cote cherchée ne soit pas supérieure à 2 mètres si la mire est *simple*, et à 4 mètres si la mire est à *coulisse*, c'est-à-dire se compose de deux règles pouvant glisser l'une sur l'autre, de manière à pouvoir s'allonger jusqu'au double de la longueur primitive. Cette dernière ne peut d'ailleurs dépasser 2 mètres, afin que l'extrémité de la première règle puisse être atteinte sans difficulté.

577. Nivellement simple.

Soit à *déterminer la différence de cote de deux points* M, N.

On installe le niveau d'eau de manière que son plan de visée soit supérieur aux deux points donnés et l'on mesure (n° précéd.) la cote de chacun de ces points au-dessous de ce plan de visée. Il ne reste plus qu'à soustraire l'une de l'autre les cotes ainsi mesurées.

On pourra faire les deux lectures sans aucun dérangement du niveau, si celui-ci est dans l'alignement MN. Sinon, on fera tourner l'appareil autour de son axe. On pourra, en employant ce dernier procédé, déterminer avec une seule mise en station du niveau, les différences existant entre les cotes d'une série de points visibles d'un même poste d'observation.

Pour que la méthode précédente soit applicable, il faut (n° précéd.) : 1° que l'on ait pu placer le niveau de manière à apercevoir en même temps les points donnés ; 2° que la distance horizontale de ces points au niveau d'eau ne soit pas trop grande ; 3° que les différences de cote cherchées soient assez petites.

578. Nivellement composé.

Si l'une ou l'autre des conditions que nous venons d'énumérer n'est pas remplie, il faut recourir au *nivellement composé*, c'est-à-dire faire choix d'un certain nombre de points auxiliaires P, Q,... S, tels que l'on puisse mesurer, par nivellement simple, les différences de cote qui existent entre M et P, entre P et Q, ..., entre S et N. La somme algébrique des quantités trouvées donne évidemment le résultat cherché.

579. Nivellement indirect.

De même que la mesure des angles et des longueurs horizontales, le nivellement peut s'effectuer indirectement.

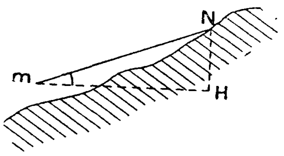

FIG. 494.

Soit, en effet, à mesurer la différence de cote entre un point m où l'on peut placer l'œil et un point N quelconque.

Soit H (*fig.* 494) la projection du point m sur la verticale du point N. Le triangle rectangle mNH sera complètement déterminé et, par conséquent, la différence de cote cherchée NH connue, si l'on a pu mesurer : 1° Le côté mH; 2° l'angle en m, lequel n'est autre que l'angle de la direction mN avec le plan horizontal, ou la *hauteur* (¹) de cette direction.

La première mesure est du ressort de la planimétrie : elle s'effectue, — directement ou indirectement suivant les cas, — à l'aide des méthodes exposées au chapitre précédent.

Pour mesurer la hauteur de la direction mN, on peut se servir du graphomètre, dont on installe le limbe verticalement de manière que le plan de visée de l'alidade fixe soit horizontal, en faisant ensuite passer le plan de visée de l'alidade mobile par la droite mN.

Mais, ainsi que nous venons de le voir, le nivellement indirect comporte une opération de planimétrie : de sorte que, la plupart du temps, lorsqu'on emploie cette méthode, on effectue concurremment le levé et le nivellement. Il y a, dans ces conditions, tout avantage à employer le théodolite, qui permet de mesurer, *à la fois et pour une même position de l'instrument*, l'azimuth et la hauteur d'une direction.

580. Pour obtenir effectivement la mesure de NH, on pourra, ainsi que nous l'avons dit plus haut :

1° Soit employer la trigonométrie (²) : c'est ce que l'on fait toujours lorsqu'on vise à une grande exactitude ;

---

(1) TISSERAND et ANDOYER, *Leçons de Cosmographie*, n° 4, page 5.

(2) *Leçons de trigonométrie rectiligne* de M. BOURLET, liv. III, ch. I et aussi n° 173-174.

2° Soit construire sur le papier un triangle semblable à mNH ;

3° Soit construire un tel triangle sur le terrain. Ceci conduit à un procédé de mesure très simple, en ce qu'il n'exige l'emploi d'aucun instrument angulaire. On plante, bien verticalement, dans l'alignement mN, une tige H'N' (*fig.* 495), sur laquelle on marque le point H' qui est situé dans le même plan horizontal que m et le point N qui est situé sur le rayon visuel mN. On a ainsi réalisé le triangle mH'N' semblable à mHN et la mesure de la distance horizontale mH, ainsi que des longueurs mH', H'N' fait connaître la cote cherchée par une simple proportion.

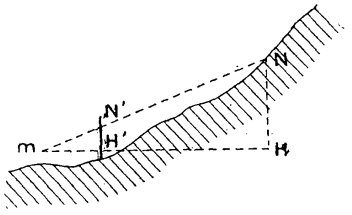

Fig. 495.

581. Si maintenant on veut la différence de cote existant entre deux points M, N du terrain, on pourra, suivant les cas :

Soit placer l'œil en m, au-dessus du point M, et ajouter (ou retrancher) à la différence de cote NH la distance verticale des points m,M, évaluée directement. C'est, par exemple, ainsi qu'on procède lorsqu'on emploie la méthode indiquée en 3° au numéro précédent ;

Soit opérer par différence, absolument comme avec le niveau d'eau.

Le nivellement indirect peut ainsi être considéré comme une opération tout à fait analogue au nivellement direct, le plan horizontal mené par le point m considéré aux deux numéros précédents remplaçant le plan de visée du niveau d'eau.

Seulement, au lieu que ce dernier devait toujours être *au-dessus* des points visés, la différence de cote ne dépassant d'ailleurs pas 4 mètres, on peut mesurer, par nivellement indirect, des dénivellations de sens et de grandeurs quelconques. Le nivellement indirect pourra donc être *simple* dans des circonstances où le nivellement direct serait forcément *composé.*

Mais il est, de plus, une série de circonstances (mesure de la hauteur d'un clocher, d'une montagne inaccessible, etc., etc.) où le nivellement direct est impraticable, au lieu que le nivellement indirect s'applique à tout point visible.

582. Ayant ainsi déterminé les différences mutuelles des cotes, il suffit, pour connaître ces cotes elles-mêmes, de se donner l'une d'entre elles. Cette dernière inconnue dépend d'ailleurs évidemment du choix du plan horizontal de comparaison, de sorte qu'on peut la considérer comme arbitraire. Par exemple, on pourra faire passer le plan de comparaison par le point le plus bas du terrain donné et, par conséquent, prendre pour ce point la cote zéro.

Pour changer de plan de comparaison, il suffit d'ailleurs d'augmenter ou de diminuer toutes les cotes d'une même quantité, égale à la distance de l'ancien plan au nouveau. C'est ce qu'on devra faire, par exemple, lorsqu'on aura nivelé, indépendamment l'un de l'autre et avec des plans de comparaison différents, deux terrains voisins et qu'on voudra réunir en un seul les deux nivellements.

Si enfin on veut comparer entre eux des nivellements portant sur des régions très différentes, il importe d'avoir un niveau (1) de comparaison commun pour toutes ces opérations. On compte alors les cotes au-dessus du *niveau de la mer :* les cotes ainsi estimées prennent le nom d'*altitudes* des points correspondants.

On a effectué, par des opérations de précision, un *nivellement général* du territoire français, de manière à faire connaître les altitudes d'un très grand nombre de points. Pour rapporter un nivellement quelconque au niveau de la mer, il suffira donc d'y rattacher un point qui ait fait partie du nivellement général.

583. **Représentation des cotes. Courbes de niveau.**

Un plan étant rapporté sur le papier, il faut encore arriver à donner une idée nette du relief du terrain ainsi figuré. On arrive à ce résultat à l'aide des *courbes de niveau.*

On appelle *courbe de niveau* (*fig.* 496, 501) le lieu des points qui ont une même cote donnée, autrement dit la section de la surface du terrain par un plan horizontal.

On détermine une telle courbe en plantant (à l'aide du niveau d'eau) des piquets en des points suffisamment rapprochés les uns des autres et ayant la cote donnée, puis relevant, par intersections ou par toute autre méthode de planimétrie, les positions de ces piquets.

On représente le relief d'un terrain en figurant les courbes de niveau dont les cotes diffèrent les unes des autres d'une même quantité ou *équidistance* (dépendant, bien entendu, de la nature du terrain et de l'échelle du plan).

---

(1) Nous disons *niveau* de comparaison et non *plan* de comparaison, puisque, pour des points très éloignés les uns des autres, il n'est plus possible d'admettre le parallélisme des plans horizontaux.

Si l'équidistance a été convenablement choisie, la forme et la disposition des courbes de niveau permettront de se rendre compte de toutes les particularités du relief. En particulier, le terrain sera d'autant plus incliné que les courbes de niveau, pour une même équidistance, seront plus rapprochées les unes des autres.

Sur beaucoup de cartes topographiques, le relief est figuré par des hachures tracées entre les courbes de niveau successives, normalement à ces courbes, par conséquent d'autant plus courtes que ces dernières sont plus voisines les unes des autres ou que la pente est plus forte, les hachures étant d'ailleurs d'autant plus rapprochées et plus grosses qu'elles sont plus courtes. Ce mode de figuration a toutefois l'inconvénient de surcharger la carte sans donner aucun renseignement que ne fournisse le tracé des courbes de niveau.

Indépendamment du figuré général du terrain, la carte porte indication des cotes d'un certain nombre de points importants.

584. Lorsqu'on veut représenter les ondulations du terrain le long d'une ligne donnée dont la projection est figurée en L (*fig.* 496) sur le plan, on a recours aux *profils*.

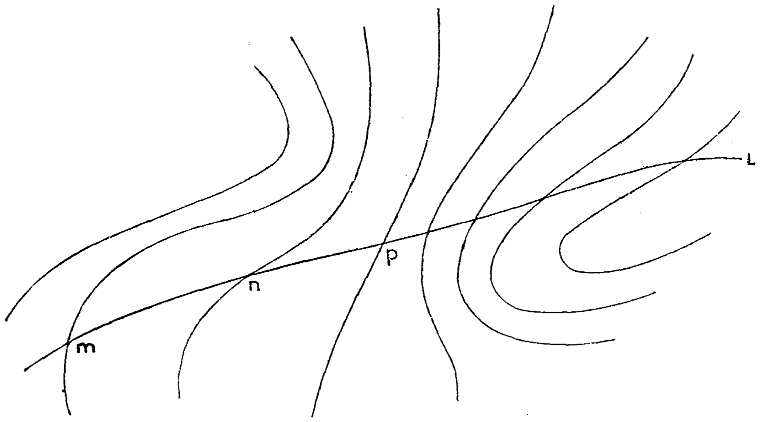

Fig. 496.

On nomme *profil* la figure obtenue en développant (**538**) le cylindre qui projette horizontalement la ligne considérée. Il est clair que si L est une ligne droite, le profil n'est autre que la section même du terrain par le plan vertical qui projette cette droite.

Puisque le tracé des courbes de niveau donne, à lui seul, la forme du terrain, il doit permettre de construire le profil suivant une ligne quelconque L.

On remarquera, à cet effet, qu'on connaît les ordonnées ou cotes d'un certain nombre de points m, n, p, ... (*fig.* 496) de la ligne L, à savoir, des points où cette ligne coupe les courbes de niveau. On relèvera, sur le plan, les abscisses curvilignes des mêmes points, que l'on reportera en O_1m_1, O_1n_1, O_1p_1, ... (*fig.* 496 *bis*), et l'on aura ainsi, aux extrémités des ordonnées m_1M_1, n_1N_1, ... une série de points du profil cherché.

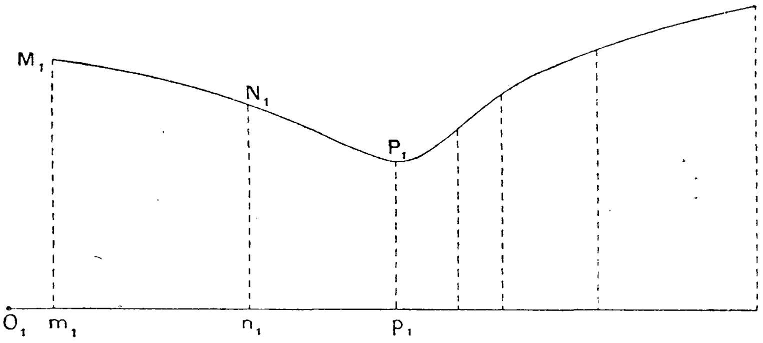

Fig. 496 *bis*.

585. Pour terminer ce qui concerne la planimétrie et le nivellement, nous dirons un mot de quelques simplifications qui peuvent être apportées dans ces deux opérations.

Les *méthodes photographiques*, qui présentent l'avantage important de réduire à la plus courte durée possible les opérations à effectuer sur place, sont fréquemment appliquées à la topographie. La place occupée par l'image d'un objet sur l'épreuve photographique dépend, en effet, de la direction du rayon lumineux joignant ce point au centre optique de la lentille objective. On peut dès lors en déduire, moyennant certaines précautions dans le détail desquelles nous n'entrerons pas, l'azimuth et la hauteur de cette direction. Il suffira donc d'avoir deux photographies, prises de deux points séparés l'un de l'autre par une distance connue, pour en déduire, par *intersections*, le levé et le nivellement du terrain ainsi doublement reproduit.

586. Nous avons, d'autre part, remarqué, à propos de la méthode par intersections, que nous ne pouvions pas obtenir la position relative de deux points A, B en visant simplement le point B du point A et qu'il était nécessaire de compléter cette visée, soit en chaînant l'alignement AB, soit en rattachant le point B à un *troisième* point C, non en ligne droite avec les deux premiers.

Il existe cependant un moyen d'échapper à cette nécessité. C'est de se servir d'un principe emprunté au *Cours de Cosmographie* (¹) :

Les diamètres apparents d'un même objet, vu à différentes distances, sont inversement proportionnels à ces distances.

D'après cela, si un aide se transporte au point B avec un *voyant* de dimensions connues, l'observation du diamètre apparent sous lequel ce voyant apparaît du point A fera connaître la distance AB.

Il faut observer que c'est la distance AB elle-même qui est ainsi mesurée et non pas (comme lorsqu'on opère à la chaîne) sa projection horizontale AH (*fig.* 497). Mais on pourra évaluer cette dernière si on lit la hauteur du rayon visuel AB, puisque, dans le triangle rectangle ABH, on connaîtra l'hypoténuse et un angle aigu.

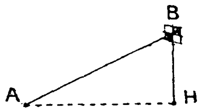

Fig. 497.

On peut, en se fondant sur ce principe, lire et noter sur le papier, en même temps, l'azimuth, la hauteur et la longueur de la droite qui joint un point quelconque M à un point O choisi une fois pour toutes, et, par conséquent, obtenir par *rayonnement* le levé et le nivellement d'un terrain, avec une seule visée pour chaque point.

---

CHAPITRE III

ARPENTAGE

587. L'*arpentage* a pour objet de trouver l'aire d'un terrain, ou, plus exactement, l'aire de sa projection horizontale. C'est, en général, cette dernière qui est utile à connaître. Les terrains que l'on arpente sont, en effet, le plus ordinairement destinés à la culture ou à la bâtisse : or, comme c'est verticalement que les végétaux croissent et que les constructions sont élevées, les dimensions des édifices, ou le nombre de plantes d'une espèce déterminée, qui peuvent trouver place sur un terrain donné, ne dépendent que de la projection horizontale de ce terrain.

588. Toute méthode par laquelle on a pu lever le plan d'un terrain permet, par cela même, de l'arpenter. Pour mesurer, en effet, l'aire d'un terrain polygonal, on le considérera comme une somme de triangles et, du moment que l'on aura les éléments nécessaires pour déterminer chaque triangle (lesquels seront fournis par le levé), les formules de la trigonométrie permettront d'en calculer la surface.

Si l'on a mesuré les trois côtés de chaque triangle, on en aura l'aire par la formule (Pl., **251**)

$$S = \sqrt{p(p-a)(p-b)(p-c)}.$$

589. L'arpentage est le plus ordinairement effectué par des opérateurs qui ne sont pas en état de se livrer à des calculs trigonométriques : l'instrument employé est alors l'équerre d'arpenteur.

Pour arpenter un polygone, on pourrait le décomposer en triangles dont on mesurerait la base et (avec l'équerre) la hauteur.

Mais on préfère opérer différemment et faire choix tout d'abord d'une droite *xy* (*fig.* 498) ou *base*, par exemple la plus grande diagonale AE du polygone, sur laquelle on abaisse des perpendiculaires B*b*, C*c*, D*d*, F*f*, G*g* (*fig.* 498) de tous les sommets. On a ainsi décomposé le polygone en triangles (AB*b*, AG*g*, D*d*E, F*f*E, *fig.* 498) et en trapèzes rectangles (B*b*C*c*, C*c*D*d*, G*g*F*f*, *fig.* 498), dont on sait évaluer les aires par les formules connues.

Sur la figure 498, tous les triangles et trapèzes sont *additifs :* il peut en être autrement : sur la figure 498 *bis*, par exemple, l'aire du polygone s'obtient en retranchant, de la somme AB*b* + B*b*C*c* + C*c*D*d* + D*d*E*e* + FG*g* + G*g*H*h* + K*k*A, la somme FE*e* + H*h*K*k*.

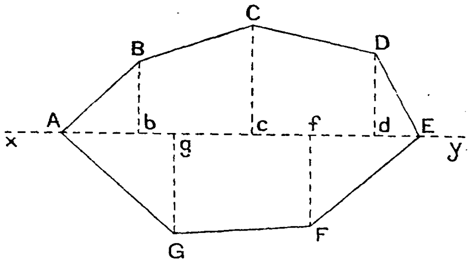

FIG. 498.

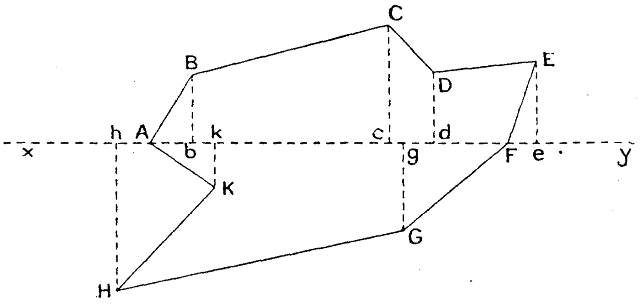

FIG. 498 *bis*.

Il est clair que, dans cette manière d'arpenter, on opère comme s'il s'agissait d'un levé à l'équerre, la base jouant le rôle d'axe des abscisses.

590. Quant au cas où le terrain est limité par un contour curviligne, il se ramène au précédent en remplaçant la courbe par un polygone d'un nombre suffisamment grand de côtés.

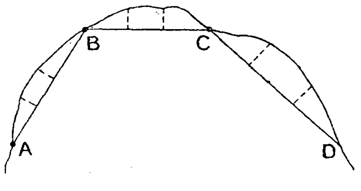

FIG. 499.

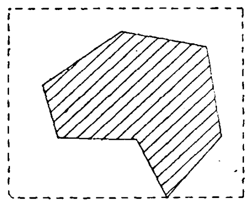

FIG. 500.

On commence par inscrire un premier polygone ABCD... (*fig.* 499) d'un nombre de côtés peu élevé, que l'on arpente comme nous l'avons dit au numéro précédent, puis on évalue la partie comprise entre la courbe et chaque côté en prenant ce côté pour base (1).

---

(1) Il existe des formules d'approximation permettant d'arriver, pour ces aires mixtilignes, à des résultats un peu plus exacts que ceux que l'on obtiendrait par la sommation pure et simple des trapèzes.

591. Il peut être nécessaire d'arpenter un terrain dans lequel on ne peut pénétrer (*fig.* 500). On entoure alors ce terrain d'un polygone facile à mesurer, par exemple d'un rectangle (*fig.* 500) et l'on arpente la partie de ce dernier comprise à l'extérieur du terrain proposé : il ne reste plus qu'à faire la différence des deux résultats.

592. Cubage.

On peut se proposer d'évaluer le volume d'un terrain compris à l'intérieur du cylindre qui projette sur un plan horizontal déterminé une aire S (*fig.* 501) prise sur ce terrain.

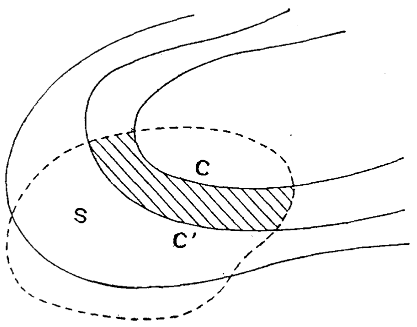

Fig. 501.

Supposons d'abord que la surface S soit comprise entre deux courbes de niveau consécutives C, C'. Alors on pourra, avec une approximation suffisante, considérer tous ses points comme ayant au-dessus du plan horizontal donné, une même cote, par exemple une moyenne entre la cote de C et la cote de C'. Le volume à évaluer sera alors celui d'un cylindre ayant pour hauteur cette cote et pour base, la projection horizontale de S.

Si maintenant l'aire S est quelconque, on pourra toujours (*fig.* 501) la décomposer en parties comprises entre courbes de niveau consécutives et que l'on traitera comme il vient d'être dit.

592 *bis*. Le plus ordinairement, toutefois, l'aire S a la forme d'une bande étroite tracée dans le voisinage d'une certaine ligne L (*fig.* 502). C'est ce qui arrive lorsque le cubage proposé est destiné à l'établissement d'une route.

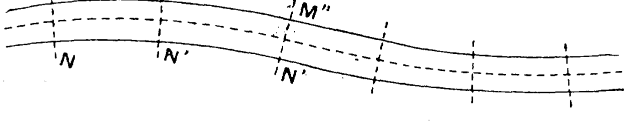

Fig. 502.

Dans ce cas, la méthode que nous venons d'indiquer n'est pas la plus commode : il convient plutôt de déterminer une série de *profils* *en travers*, c'est-à-dire de profils (**584**) suivant des alignements MN, M'N'... normaux à L et de considérer le volume compris entre chacun de ces profils et le suivant comme un cylindre ayant pour hauteur la distance des deux profils et pour base l'un d'eux.

EXERCICES

852. Vérifier si une équerre d'arpenteur est juste.

853. Mener, à un alignement donné, une perpendiculaire par un point extérieur sans employer d'autre instrument que la chaîne et sans tâtonnement (appliquer Pl., **126**).

854. Diviser un alignement en deux parties égales, à l'aide du graphomètre seul.

854 *bis*. Porter sur un alignement donné, à partir d'un point donné, une longueur égale à celle d'un autre alignement donné à l'aide du graphomètre seul.

855. Un niveau d'eau a un tube horizontal de 1 mètre de long, porté par un axe qui aboutit à 1 centimètre du milieu du tube. On a installé l'appareil de manière que l'axe passe avec la verticale un angle dont la tangente est $\frac{1}{10}$. Calculer approximativement la variation maximum du plan de visée, lorsque l'appareil tourne autour de son axe. Le résultat obtenu dépend-il de la longueur du tube?

856. Prolonger un alignement au delà d'un obstacle qui arrête la vue.

857. Montrer qu'on peut remplacer le niveau d'eau par un miroir plan dont on peut faire varier la direction en la maintenant verticale.

858. Montrer que le point M (fig. 485, n° **571**) d'un plan, tel que les droites qui le joignent à trois points donnés A, B, C fassent entre elles des angles donnés, peut s'obtenir de la manière suivante : on construit sur BC, CA, AB comme bases, des triangles BC*a*, CA*b*, AB*c* tous semblables au triangle T dont les angles sont égaux aux angles donnés ou à leurs suppléments (les sommets homologues étant pris convenablement chaque fois). Les droites A*a*, B*b*, C*c* concourent en un même point, qui répond à la question. Les points *a*, *b*, *c* ne sont autres que ceux où les droites MA, MB, MC rencontrent respectivement les segments de cercles MBC, MCA, MAB.

COMPLÉMENTS DE GÉOMÉTRIE DANS L'ESPACE

CHAPITRE PREMIER

CENTRE DES DISTANCES PROPORTIONNELLES

593. Problème. — *Étant données, en grandeur et signe, les abscisses* IA *et* IB *de deux points* A, B *d'une droite, rapportées à un point* I *de la même droite, trouver l'abscisse du point* M *qui divise le segment* AB *dans un rapport donné (en grandeur et en signe)* $\frac{\mathrm{MA}}{\mathrm{MB}} = -\frac{q}{p}$.

On a

$$\mathrm{MA} = \mathrm{IA} - \mathrm{IM}$$
$$\mathrm{MB} = \mathrm{IB} - \mathrm{IM}$$

et, par conséquent,

$$\frac{\mathrm{IA} - \mathrm{IM}}{\mathrm{IB} - \mathrm{IM}} = -\frac{q}{p}.$$

Cette équation, où tout est connu, sauf OM, est du premier degré par rapport à cette quantité. Elle fait connaître l'abscisse cherchée

$$\mathrm{IM} = \frac{p.\overline{\mathrm{IA}} + q.\overline{\mathrm{IB}}}{p + q}.$$

Comme nous devions nous y attendre (Pl., **110**), cette expression est infinie pour $q = -p$, et dans ce cas seulement.

Corollaire. — Par le point I, faisons passer une droite ou un plan quelconque (*fig.* 503) et soient $\mathrm{AA}_1 = a$, $\mathrm{BB}_1 = b$, $\mathrm{MM}_1 = m$ les distances des points A, B, M à cette droite ou à ce plan. Nous supposons d'ailleurs ces distances comptées en grandeur et signe, un sens positif ayant été choisi sur leur direction commune. On aura alors

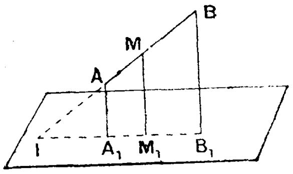

Fig. 503.

$$m = \frac{pa + qb}{p + q}.$$

En effet, les grandeurs a, b, m sont, en grandeur et signe (Pl., **190**), proportionnelles à IA, IB, IM. L'équation précédente étant homogène par rapport à ces dernières quantités, on peut donc les y remplacer par a, b, m : ce qui donne le résultat annoncé.

Remarque I. — Ce résultat ne serait d'ailleurs aucunement mis en défaut si les distances a, b, m, au lieu d'être comptées sur des perpendiculaires au plan considéré, étaient comptées suivant des parallèles à une même direction quelconque (non parallèle à ce plan).

Remarque II. — Nous savons (Pl., **113**) que le rapport $\frac{M_1A_1}{M_1B_1}$ a également la même valeur $\frac{-q}{p}$.

594. Soient donnés un certain nombre de points A, B, C, D, ... (fig. 504) et les nombres p, q, r, s, ..., positifs ou négatifs, mais non tous nuls, correspondant respectivement à ces points. Soient M le point qui divise AB dans le rapport $-\frac{q}{p}\left(\frac{MA}{MB} = -\frac{q}{p}\right)$; M′, le point qui divise MC dans le rapport $-\frac{r}{p+q}\left(\frac{M'M}{M'C} = -\frac{r}{p+q}\right)$; M″, le point qui divise M′D dans le rapport $\frac{-s}{p+q+r}\left(\frac{M''M'}{M''D} = -\frac{s}{p+q+r}\right)$; etc.

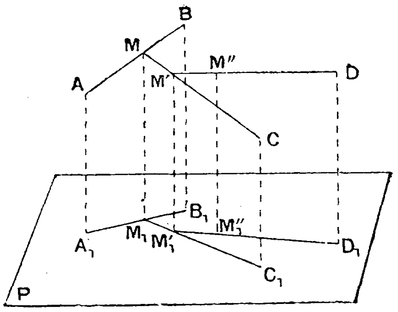

Fig. 504.

Si a, b, c, d, ... sont les distances des points A, B, C, D, ... à un plan quelconque P, la distance m du point M au même plan sera (n° précédent)

$$m = \frac{pa + qb}{p + q}.$$

La distance m' du point M' à ce plan sera

$$m' = \frac{(p+q)m + rc}{(p+q)+r} = \frac{pa + qb + rc}{p+q+r};$$

de même la distance du point M'' sera

$$m'' = \frac{(p+q+r)m' + sd}{(p+q+r)+s} = \frac{pa + qb + rc + sd}{p+q+r+s}.$$

Continuons ainsi jusqu'à ce que nous ayons utilisé tous les points donnés et chacun d'eux une seule fois; nous obtiendrons un point O qu'on appelle le *centre des distances proportionnelles* des points A, B, C, D, ... affectés des coefficients p, q, r, s, ...

La distance de ce point au plan P est

$$o = \frac{pa + qb + rc + sd + \ldots}{p+q+r+s+\ldots}.$$

Nous avons dit que l'on devait utiliser chacun des points donnés une seule fois; mais nous n'avons pas spécifié l'*ordre* dans lequel on les faisait intervenir. Il semblerait, au premier abord, que la position du point final O dût dépendre de l'ordre en question. Le résultat qui précède montre qu'il n'en est rien. La valeur trouvée pour la distance du point O au plan P est, en effet, indépendante de cet ordre (pourvu, bien entendu, qu'à chacun des points donnés corresponde toujours le même coefficient) et, par conséquent, si, en changeant l'ordre en question, on trouvait un point O' différent du premier, la droite OO' devrait être parallèle au plan P, et cela quel que soit le plan P, ce qui est absurde.

Remarque. — Soient A_1, B_1, C_1, M_1, M'_1,.., O_1 les projections sur le plan P, des points A, B, C... M, M'... O (*fig.* 504). Le point M_1 divisera A_1B_1 dans le rapport $-\frac{q}{p}$; le point M'_1 divisera C_1M_1 dans le rapport $-\frac{r}{p+q}$; etc. En un mot, le *point* O_1 *sera le centre des distances proportionnelles des points* A_1, B_1, C_1,... *affectés des mêmes coefficients que les points donnés* A, B, C... et la même chose a lieu si les droites AA_1, BB_1,... au lieu d'être perpendiculaires au plan P, sont parallèles à une même direction quelconque.

595. Le *centre des distances proportionnelles* n'est évidemment autre chose que ce que l'on nomme en statique le *centre des forces parallèles*, les points donnés étant les points d'application des forces, et les intensités de celles-ci étant représentées par les coefficients p, q, r,... lesquels sont positifs ou négatifs suivant le sens des forces correspondantes.

596. Il y a une circonstance où la suite d'opérations que nous venons d'indiquer tomberait en défaut, c'est celle où l'on aurait à diviser une droite dans un rapport égal à $+1$, par exemple, où les deux premiers coefficients seraient égaux et de signes contraires. Il est aisé de voir qu'on peut toujours tourner la difficulté en intervertissant l'ordre des points donnés, sauf dans un cas, celui où la somme de *tous* les coefficients donnés est nulle. Dans le langage de la statique, ce cas correspond à celui où les forces données équivalent à un couple[1].

597. Lorsque tous les coefficients sont égaux à $+1$, le centre des distances proportionnelles prend le nom de *centre des moyennes distances*. Le centre des moyennes distances d'un système de points peut donc être considéré comme défini par cette propriété que sa distance à un plan quelconque est la moyenne arithmétique des distances des points donnés.

598. Nous allons considérer en particulier les cas où les points donnés sont au nombre de deux, trois ou quatre.

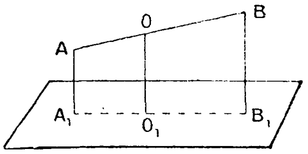

Fig. 505.

Supposons d'abord qu'il n'y ait que deux points A, B (*fig.* 505) affectés des coefficients p, q. Le centre des distances proportionnelles est alors un point de la droite AB. D'autre part, A et B étant donnés, *ce centre peut coïncider avec un point quelconque* O *de la droite* AB, *pour un choix convenable de p et de q :* il suffit évidemment de prendre

$$\frac{q}{p} = -\frac{\mathrm{OA}}{\mathrm{OB}}.$$

---

[1] Dans le cas où les forces données se font équilibre, le centre des distances proportionnelles n'est plus rejeté à l'infini, mais indéterminé. Dans la suite d'opérations indiquées dans le texte, on arriverait encore finalement à deux points affectés de coefficients égaux et de signes contraires, mais ces deux points coïncideraient entre eux.

Introduisons le nombre t donné par la relation

$$p + q + t = 0;$$

la relation précédemment obtenue

$$o = \frac{pa + qb}{p + q}$$

entre les distances des points A, B, O, devient

$$pa + qb + to = 0.$$

Ainsi, *étant donnés trois points quelconques en ligne droite, on peut trouver trois nombres non tous nuls, mais dont la somme est nulle et qui donnent lieu à la relation précédente entre les distances des trois points donnés à un plan quelconque.*

La condition précédente détermine d'ailleurs complètement, sinon les nombres p, q, t eux-mêmes, du moins leurs rapports mutuels : on a (puisque $\frac{p}{q} = -\frac{\text{IA}}{\text{IB}}$ et que $p + q + t = 0$)

$$\frac{p}{\text{BO}} = \frac{q}{\text{OA}} = \frac{p + q}{\text{BO} + \text{OA}} = -\frac{t}{\text{BA}} = \frac{t}{\text{AB}}.$$

599. Soient à présent trois points A, B, C (*fig.* 506), que nous supposerons former un triangle ; soient encore p, q, r les coefficients correspondants.

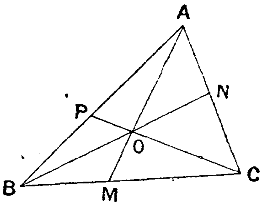

Fig. 506.

Si nous divisons BC dans un rapport $\frac{\text{MB}}{\text{MC}} = -\frac{r}{q}$, le centre des distances proportionnelles cherché O est situé sur la droite AM. On voit que *ce point est nécessairement dans le plan* ABC.

En divisant de même CA dans un rapport $\frac{\text{NC}}{\text{NA}} = -\frac{p}{r}$ et AB dans un rapport $\frac{\text{PA}}{\text{PB}} = -\frac{q}{p}$, les droites BN, CP donnent deux nouveaux lieux du point O.

Il résulte de là une nouvelle démonstration du théorème du n° **197** (Pl., Compl. du livre III).

Si, en effet, les côtés d'un triangle ABC sont divisés par les points M, N, P (*fig.* 506), de manière que $\frac{MB}{MC} \cdot \frac{NC}{NA} \cdot \frac{PA}{PB} = -1$, on peut évidemment poser

$$\frac{MB}{MC} = -\frac{r}{q}$$

$$\frac{NC}{NA} = -\frac{p}{r}$$

et, en vertu de la relation $\frac{MB}{MC} \cdot \frac{NC}{NA} \cdot \frac{PA}{PB} = -1$, l'on aura nécessairement

$$\frac{PA}{PB} = -\frac{q}{p}.$$

Les remarques précédentes montrent dès lors que les trois droites AM, BN, CP concourent en un même point, à savoir le centre des distances proportionnelles des points A, B, C.

599 *bis.* S'il s'agit du *centre des moyennes distances* des trois points A, B, C, les droites AM, BN, CP sont les médianes du triangle formé par ces points. Le centre des moyennes distances n'est donc autre chose que le point nommé précédemment *centre de gravité* du triangle ABC.

600. Coordonnées barycentriques planes.

Inversement, soient donnés le triangle ABC et le point O de son plan. Joignons OA, et soit M le point où cette droite coupe BC. Si nous prenons deux nombres q, r, satisfaisant à la relation

$$\frac{MB}{MC} = -\frac{r}{q},$$

puis un nombre p déterminé par la proportion

$$\frac{OM}{OA} = -\frac{p}{q+r},$$

le point O sera le centre des distances proportionnelles des points A, B, C, affectés des coefficients p, q, r.

Ainsi, *étant donnés quatre points dont les trois premiers ne sont pas* *en ligne droite, on peut affecter ceux-ci de coefficients tels que leur centre des distances proportionnelles soit le quatrième point donné.*

Le raisonnement semble en défaut lorsque la droite OA est parallèle à BC; mais on pourra alors le recommencer, soit en considérant la droite OB et le côté CA, soit en considérant la droite OC et le côté AB (1).

Les rapports mutuels des quantités p, q, r sont d'ailleurs déterminés quand on donne le point O (puisque ce sont les rapports dans lesquels les droites OA, OB, OC divisent respectivement les côtés BC, CA, AB).

On donne le nom de *coordonnées barycentriques* du point O, par rapport au *triangle de référence* ABC, aux coefficients p, q, r ainsi choisis. Les coordonnées barycentriques d'un point déterminé, par rapport à un triangle déterminé, sont déterminées à un facteur commun près.

Inversement, à tout système de coordonnées p, q, r, tel que la somme $p+q+r$ soit différente de zéro, correspond un point déterminé situé dans le plan du triangle.

Remarque. — Si l'on mène, par les points A, B, C, O, des parallèles à une même direction quelconque, jusqu'à rencontre en A_1, B_1, C_1, O_1 avec un plan P, le point O_1 aura, en vertu de la définition précédente et du n° **594** (Remarque), les mêmes coordonnées barycentriques, par rapport au triangle $A_1 B_1 C_1$, que le point O par rapport au triangle ABC.

601. La considération des aires permet de donner une interprétation simple des coordonnées barycentriques planes.

Considérons, en effet, les deux triangles ABM, ACM. Ces deux triangles, qui ont évidemment même hauteur, sont entre eux comme leurs bases MB, MC. Pour la même raison, ce même rapport $\frac{\mathrm{MB}}{\mathrm{MC}}$ est égal au rapport des triangles OMB, OMC. Il vient donc, en vertu d'un théorème connu sur les proportions

$$\frac{\mathrm{MB}}{\mathrm{MC}}=\frac{\mathrm{AMB}}{\mathrm{AMC}}=\frac{\mathrm{OMB}}{\mathrm{OMC}}=\frac{\mathrm{AOB}}{\mathrm{AOC}}$$

---

(1) Il est évidemment impossible que les droites qui joignent le point O aux sommets du triangle ABC soient toutes trois parallèles aux côtés du même triangle, puisque les parallèles menées aux côtés d'un triangle par les sommets opposés ne passent pas par un même point.

puisque le triangle AOB équivaut à la somme ou à la différence des triangles AMB et OMB, le triangle AOC étant en même temps équivalent à la somme ou à la différence des triangles AMC et OMC.

Le rapport $\frac{\text{AOB}}{\text{AOC}}$ est donc égal, en valeur absolue, au rapport $\frac{r}{q}$. Mais, de plus, nous pouvons remarquer que si la droite AO coupe le côté BC lui-même (c'est-à-dire si $\frac{r}{q}$ est positif) les deux triangles AOB, AOC sont tous deux additifs (voir Pl.; Note D, **315**, *fig*. 228-229) ou tous deux soustractifs (*ibid.*, *fig*. 230), au lieu que si la droite AO coupe l'un des prolongements de BC, ces deux triangles sont l'un additif, l'autre soustractif, en même temps que le rapport $\frac{r}{q}$ deviendra négatif. Si donc on fait précéder chacun des angles BOC, COA, AOB du signe $+$ ou du signe $-$ suivant qu'il est additif ou soustractif, *le rapport* $\frac{r}{q}$ *sera, en grandeur et signe, égal au rapport des triangles* AOB, AOC.

En faisant des raisonnements analogues relativement aux autres côtés du triangle ABC, on arrive évidemment à la conclusion suivante :

Les coordonnées barycentriques d'un point sont, en grandeur et signe (moyennant la convention qui vient d'être établie), *proportionnelles aux aires des triangles qui ont pour sommet commun ce point et, pour bases respectives, les côtés du triangle de référence.*

602. Introduisons le nombre t défini par la relation

$$p + q + r + t = 0$$

Alors la relation, précédemment trouvée, entre les distances a, b, c, o des points A, B, C, O à une droite quelconque du plan ABC ou à un plan quelconque

$$o = \frac{pa + qb + rc}{p + q + r}$$

peut s'écrire

$$pa + qb + rc + to = 0.$$

Ainsi, *quatre points quelconques étant donnés dans un plan, on peut trouver quatre nombres p, q, r, t dont la somme est nulle et tels* *que les distances des quatre points donnés à un plan quelconque, multipliées respectivement par ces quatre nombres, donnent une somme nulle.*

Le raisonnement précédent cesse d'être valable lorsque les trois points A, B, C sont en ligne droite. Mais alors nous savons (**598**) qu'on peut trouver les nombres p, q, r tels que l'on ait

$$pa + qb + rc = 0,$$

ce qui est la relation précédente, t étant pris égal à zéro.

603. Coordonnées barycentriques dans l'espace. — Considérons maintenant le cas où l'on part de quatre points A, B, C, D (*fig.* 507) non situés dans un même plan. p, q, r, s étant les coefficients affectés à ces points, on pourra commencer par prendre le centre des distances proportionnelles des points A, B, C affectés des coefficients p, q, r, — autrement dit, le point M du plan ABC qui a pour coordonnées barycentriques, par rapport à ce triangle, les nombres p, q, r, — puis prendre sur DM le point O tel que

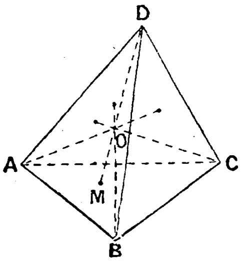

Fig. 507.

$$\frac{\text{OM}}{\text{OD}} = -\frac{s}{p+q+r}.$$

Par exemple, si les coefficients p, q, r, s sont tous égaux à $+1$, le point O appartiendra à la droite qui joint le point D au centre de gravité du triangle ABC, de sorte que cette droite et les trois autres droites joignant le point A au centre de gravité du triangle BCD, le point B au centre de gravité de CDA, le point C au centre de gravité de DAB, concourent en un même point.

Inversement, O (*fig.* 507) étant un point quelconque de l'espace, on pourra toujours déterminer les coefficients p, q, r, s de manière que le centre des distances proportionnelles obtenu soit le point O. Il suffira de prendre pour p, q, r les coordonnées barycentriques, par rapport au triangle ABC, du point M où la droite DO coupe le plan ABC, et pour s le nombre défini par la relation écrite tout à l'heure.

Les coefficients p, q, r, s, qui sont ainsi déterminés à un facteur commun près, sont dits les *coordonnées barycentriques* du point O, par rapport au *tétraèdre de référence* ABCD.

Nous laissons au lecteur le soin de démontrer que ces coordonnées barycentriques sont proportionnelles aux quatre tétraèdres ayant pour sommet commun le point considéré et pour bases respectives les faces du tétraèdre de référence, et que cette proportionnalité a lieu en grandeur et signe, si l'on a soin d'affecter les tétraèdres en question du signe + ou du signe — suivant qu'ils sont additifs ou soustractifs (¹).

604. Introduisons le nombre t défini par la relation

$$p+q+r+s+t=0.$$

La relation

$$o=\frac{pa+qb+rc+sd}{p+q+r+s},$$

qui a lieu entre les distances des cinq points A, B, C, D, O à un plan quelconque, pourra s'écrire

$$pa+qb+rc+sd+to=0.$$

Donc, étant donnés cinq points de l'espace, on peut trouver les cinq coefficients p, q, r, s, t donnant lieu à la relation précédente. On prouvera d'ailleurs, comme tout à l'heure (**602**), que la conclusion n'est pas en défaut si les points A, B, C, D cessent de former un tétraèdre.

605. On définit en mécanique le *centre de gravité* d'une figure quelconque. Cette définition, dans le cas d'un polygone ou d'un polyèdre *homogène* (cette condition, absolument essentielle, est implicitement supposée dans ce qui va suivre) conduit aux conclusions suivantes :

Le centre de gravité d'un triangle est le point de concours de ses médianes, conformément à la dénomination que nous avons adoptée depuis le n° **55** *bis*.

Le centre de gravité d'un polygone plan quelconque s'obtient en le décomposant en triangles, dont on prend les centres de gravité, et prenant le centre des distances proportionnelles des points ainsi obtenus,

---

(1) Voir note F à la fin du volume.

affectés de coefficients respectivement égaux aux aires des triangles correspondants (¹).

Le centre de gravité d'un tétraèdre est le point où se coupent (**603**) *les droites qui joignent chaque sommet au centre de gravité de la face opposée.*

Le centre de gravité d'un polyèdre quelconque s'obtient en le décomposant en tétraèdres et opérant comme il vient d'être expliqué pour les polygones dans le plan (le mot *aire* étant remplacé par le mot *volume*).

606. Théorème. — *Si on coupe un prisme par différents plans, les centres de gravité des sections ainsi obtenues sont sur une même parallèle aux arêtes.*

Pour démontrer ce théorème, nous nous appuierons sur le lemme suivant :

Lemme. — *La surface d'un polygone situé dans un plan fixe* P *est, avec sa projection sur un autre plan fixe* P′, *dans un rapport constant, quel que soit le polygone.*

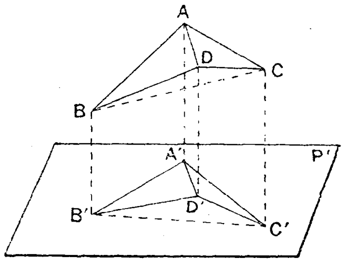

FIG. 508.

Dans la démonstration, nous distinguerons plusieurs cas :

1° Soient d'abord, dans le plan P, deux triangles ABD, ACD (*fig.* 508) qui ont un côté commun AD et dont les projections sur le plan P′ sont A′B′D′, A′C′D′. Si p, q, r sont les coordonnées barycentriques du point D, rapportées au triangle ABC, autrement dit si le point D est le centre des distances proportionnelles des points A, B, C affectés des coefficients p, q, r, le rapport $\frac{q}{r}$ sera celui des triangles ACD, ABD. Ce rapport sera donc égal à celui des triangles A′C′D′, A′B′D′, puisque le point D′ a, relativement au triangle A′B′C′, les mêmes coordonnées barycentriques que le point D, relativement au triangle ABC.

2° Ce qui précède montre que le rapport d'un triangle du plan P à sa projection sur P′ ne change pas si l'on remplace le triangle consi-

---

(1) Il résulte de la définition mécanique du centre de gravité, que ce point est indépendant du mode adopté pour la décomposition du polygone en triangles : c'est d'ailleurs ce qui peut se voir directement (exercice 869).

déré par un autre (situé également dans le plan P) ayant avec le premier un côté commun. Ce rapport est, par conséquent, le même pour deux triangles ABC, ADE (*fig.* 509) du plan P ayant un sommet commun, car on peut trouver un triangle (le triangle ABD) ayant avec ABC un côté commun et avec ADE un côté commun. Il est donc aussi le même pour deux triangles quelconques du plan P, puisqu'on peut toujours trouver un triangle ayant un sommet commun avec le premier et un sommet commun avec le second.

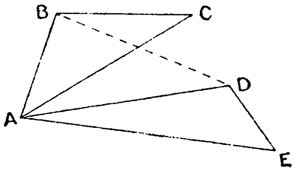

FIG. 509.

3° Si enfin il s'agit d'un polygone quelconque, on peut décomposer ce polygone en triangles. Le rapport en question est le même pour tous ces triangles et a, par conséquent, encore la même valeur pour le polygone entier, d'après un théorème connu sur les proportions (comparer Pl., **257**).

Corollaires. — I. *Le rapport de l'aire d'un polygone plan à celle de sa projection est égal au cosinus de l'angle des deux plans.*

Nous savons, en effet, que ce rapport est indépendant du polygone choisi. Nous prendrons, pour ce polygone, un triangle ABC ayant sa base BC sur l'intersection des deux plans P et P′ (*fig.* 510). Si BCA′ est la projection de ABC sur le plan P′ et que AH soit la hauteur du triangle ABC, A′H est (théorème des trois perpendiculaires), la hauteur du triangle BCA′. De plus, l'angle en H du triangle rectangle AA′H est égal à l'angle des deux plans P, P′ et, par conséquent, le rapport $\frac{\text{A}'\text{H}}{\text{AH}}$ est égal au cosinus de cet angle. Or ce rapport est égal au rapport des deux triangles A′BC, ABC, puisque ceux-ci ont même base.

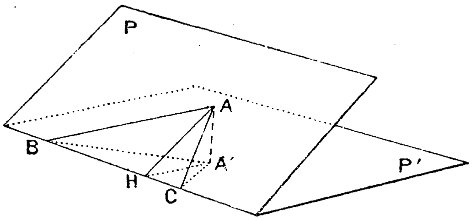

FIG. 510.

II. Le lemme précédent s'applique *à une aire curviligne quelconque* S *située dans le plan* P *et à sa projection.*

En effet, par définition (Pl., **260**, note), l'aire S (*fig.* 511) est la limite d'une aire polygonale inscrite *s*. Si S′, *s′* sont les projections de S, *s* sur le plan P′, lorsque le nombre des côtés du polygone *s* augmentera indéfiniment de manière que chacun d'eux tende vers zéro, les mêmes circonstances se présenteront pour le polygone s'.

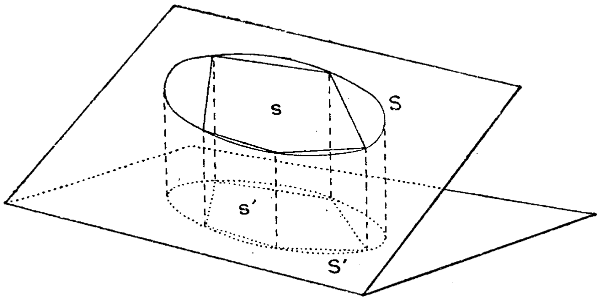

Fig. 511.

Or nous venons de voir qu'on a

$$s' = s \cos \alpha,$$

α étant l'angle des deux plans.

Donc, lorsque s tendra vers S, s' tendra vers une limite S' égale à S cos α.

C. Q. F. D.

607. A l'aide du lemme qui vient d'être démontré, il va nous être facile de démontrer le théorème précédemment énoncé.

Nous allons démontrer que *si l'on mène, dans une surface prismatique, une section droite et une section oblique, le centre de gravité de la section oblique se projette, sur le plan de la section droite, au centre de gravité de cette dernière.*

Si d'abord le prisme est triangulaire, le fait résulte (*fig.* 512) de la remarque du n° **594**, en vertu du n° **599** *bis*.

Si maintenant le prisme est polygonal, on peut le décomposer en prismes triangulaires (*fig.* 513) qui donneront, dans le plan de la section oblique, les triangles T_1, T_2, T_3,... et, dans le plan de la sec-

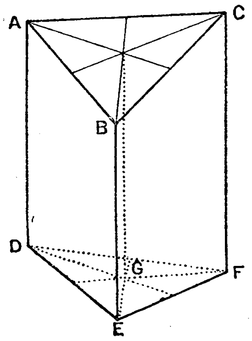

Fig. 512.

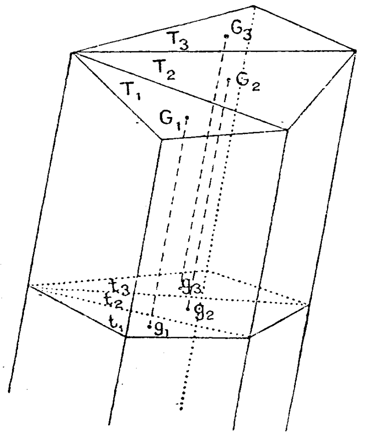

Fig. 513.

tion droite, les triangles t_1, t_2, t_3,... Soient G_1, G_2, G_3, les centres de gravité de T_1, T_2, T_3,...; g_1, g_2, g_3, les centres de gravité de t_1, t_2, t_3,... lesquels sont (comme nous venons de le voir) les projections de G_1, G_2, G_3, sur le plan de la section droite. Le centre de gravité G de la section oblique est le centre des distances proportionnelles des points G_1, G_2, G_3, affectés de coefficients proportionnels aux aires T_1, T_2, T_3,...; et, d'autre part, le centre de gravité g de la section droite est le centre des distances proportionnelles des points g_1, g_2, g_3,..., affectés des coefficients t_1, t_2, t_3,..., lesquels sont (lemme précédent) proportionnels aux premiers. Donc le point g est (**594**, Rem.) la projection de G.

Donc aussi, lorsque le plan de la section oblique varie, le point G décrit la parallèle aux arêtes menée par g.

C. Q. F. D.

608. Volume du tronc de prisme.

Théorème. — *Le volume d'un tronc de prisme quelconque est égal au produit de l'une des bases par la distance du centre de gravité de l'autre base au plan de la première.*

Nous distinguerons deux cas :

1° *Le tronc de prisme est triangulaire.* Soient ABC, DEF (*fig.* 512) les deux bases, G le centre de gravité du triangle DEF ; d, e, f, g, les distances des points D, E, F, G au plan ABC.

Le volume du tronc de prisme est (**409**)

$$\mathrm{ABC} \times \frac{d+e+f}{3}.$$

Mais (**599** *bis*) $\frac{d+e+f}{3}$ est égale à g. Le volume est donc bien mesuré par le produit ABC $\times\, g$.

2° *Le tronc de prisme est polygonal.* On le décomposera en troncs de prismes triangulaires dont les bases sont T_1, T_2, T_3,..., dans le plan P de la base inférieure ; T'_1, T'_2, T'_3,... dans le plan P′ de la base supérieure. Si g_1, g_2, g_3,... sont les distances des points G'_1, G'_2, G'_3,... au plan P, on a (1°), pour le volume du tronc :

$$V = g_1 T_1 + g_2 T_2 + g_3 T_3 + \cdots$$

Mais, si g est la distance, au plan P, du centre de gravité de la base supérieure, on a

$$g = \frac{g_1 T_1' + g_2 T_2' + g_3 T_3' + \ldots}{T_1' + T_2' + T_3' + \ldots} = \frac{g_1 T_1 + g_2 T_2 + g_3 T_3 + \ldots}{T_1 + T_2 + T_3 + \ldots}$$

puisque les triangles T_1', T_2', T_3'... sont proportionnels à T_1, T_2, T_3... (comme ayant les mêmes projections sur un plan de section droite). Tirant $g_1 T_1 + g_2 T_2 + g_3 T_3 + \ldots$ de cette égalité, il vient bien, conformément à l'énoncé,

$$V = g\,(T_1 + T_2 + T_3 + \ldots.).$$

Corollaires. — I. *Un tronc de prisme est équivalent au prisme que l'on obtiendrait en substituant à la base supérieure une section menée par le centre de gravité de cette base et parallèle à la base inférieure.*

Par conséquent, aussi :

II. *Le volume du tronc de prisme a pour mesure le produit de la section droite par la distance des centres de gravité des deux bases.*

III. Le théorème précédent montre bien que *la position trouvée, pour le centre de gravité d'un polygone*, par le procédé du n° **605**, *est indépendante du mode de décomposition du polygone en triangles.* En premier lieu, en effet, les raisonnements des n^os^ **607-608** ne supposent nullement que cette indépendance soit établie (ils sont valables en supposant que le prisme ait été décomposé *d'une manière déterminée* en prismes triangulaires). Dès lors, un polygone plan quelconque étant donné, considérons-le comme l'une des bases d'un tronc de prisme, l'autre base étant dans un plan quelconque P. Si S est l'aire de cette seconde base, g la distance du centre de gravité du polygone donné au plan P, V le volume du tronc de prisme, on aura (théor. préc.)

$$g = \frac{V}{S}.$$

Cette formule montre que la distance g du centre de gravité G au plan P est indépendante de la manière dont on a décomposé le polygone en triangles pour trouver le point G. Comme le plan P est de direction quelconque, il en résulte (comparer **594**) que la position du point G est indépendante de ce mode de décomposition.

609. Problème. — *Trouver le lieu des points tels que les carrés de leurs distances à des points donnés, multipliés respectivement par des coefficients donnés (positifs ou négatifs), aient une somme algébrique égale à une quantité donnée.*

Soient les points donnés A, B, C, D, ... et les coefficients correspondants (positifs ou négatifs) p, q, r, s, ... Nous avons à chercher le lieu des points tels que l'on ait

$$p\cdot\overline{MA}^2 + q\cdot\overline{MB}^2 + r\cdot\overline{MC}^2 + \ldots \qquad = k,$$

k étant un nombre donné.

Supposant la somme $p+q+r+\ldots$ différente de zéro, soit O le centre des distances proportionnelles des points donnés, affectés des coefficients p, q, r, s, ... Joignons OM et soit Oa (*fig.* 514) la projection de OA sur cette droite, le segment Oa étant compté en grandeur et signe avec OM comme sens positif.

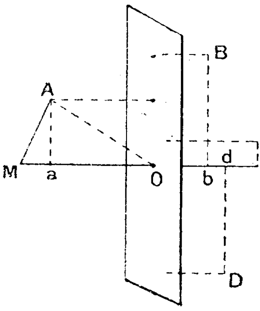

FIG. 514.

On aura, quelle que soit la position du point a,

$$\overline{MA}^2 = \overline{OM}^2 + \overline{OA}^2 - 2\overline{OM}\cdot\overline{Oa}.$$

Car si le point a est du même côté de O que le point M, le segment Oa est positif, l'angle $\widehat{AOM}$ aigu et l'on retrouve l'énoncé du n° **126**, 1° (Pl., livre III); si, au contraire, le point a est sur OM prolongé au delà de O, le segment Oa est négatif, l'angle $\widehat{AOM}$ obtus, et l'égalité précédente résulte de la seconde partie du même théorème.

Si, de même, Ob, Oc, Od ... sont les projections de OB, OC, OD, ... sur OM, comptées en grandeur et signe dans les mêmes conditions, on aura

$$\overline{MB}^2 = \overline{OM}^2 + \overline{OB}^2 - 2\overline{OM}\cdot\overline{Ob}$$
$$\overline{MC}^2 = \overline{OM}^2 + \overline{OC}^2 - 2\overline{OM}\cdot\overline{Oc}$$

. . . .

Multipliant l'égalité obtenue tout à l'heure par p, celles que nous venons d'écrire par q, r, s, ... respectivement, et ajoutant, il vient

$$\begin{aligned} &p\cdot\overline{\mathrm{MA}}^2+q\cdot\overline{\mathrm{MB}}^2+r\cdot\overline{\mathrm{MC}}^2+\dots \\ &=(p+q+r+\dots)\,\overline{\mathrm{OM}}^2+p\cdot\overline{\mathrm{OA}}^2+q\cdot\overline{\mathrm{OB}}^2+r\cdot\overline{\mathrm{OC}}^2+\dots \\ &\qquad -2\overline{\mathrm{OM}}\,(p\cdot\overline{\mathrm{O}a}+q\cdot\overline{\mathrm{O}b}+r\cdot\overline{\mathrm{O}c}+\dots). \end{aligned}$$

Mais, au second membre, la parenthèse du dernier terme

$$p\cdot\overline{\mathrm{O}a}+q\cdot\overline{\mathrm{O}b}+r\cdot\overline{\mathrm{O}c}+\dots$$

est nulle, en vertu du choix du point O; car les quantités Oa, Ob, Oc ... peuvent être considérées comme les distances (comptées en grandeur et signe) des points A, B, C, ... à un même plan mené par O, celui qui est perpendiculaire à OM (*fig.* 514).

L'égalité précédente se réduit donc à

$$p\overline{\mathrm{MA}}^2+q\cdot\overline{\mathrm{MB}}^2+r\cdot\overline{\mathrm{MC}}^2+\dots=(p+q+r+\dots)\,\overline{\mathrm{OM}}^2+l$$

en désignant par l la quantité $p\cdot\overline{\mathrm{OA}}^2+q\cdot\overline{\mathrm{OB}}^2+r\cdot\overline{\mathrm{OC}}^2+\dots$, *laquelle est indépendante de la position du point* M.

Ainsi écrite, cette égalité montre que la condition nécessaire et suffisante pour que la somme algébrique $p\cdot\overline{\mathrm{MA}}^2+q\cdot\overline{\mathrm{MB}}^2+r\cdot\overline{\mathrm{MC}}^2+\dots$ soit constante est que OM soit constant.

Donc le lieu demandé est une sphère de centre O.

610. Le raisonnement précédent serait en défaut si la somme $p+q+r+\dots$ était nulle. Dans ce cas, en effet, le lieu ne serait pas une sphère, mais un plan.

Pour le voir, divisons les points donnés en deux groupes, de manière que, dans chacun de ces deux groupes, la somme des coefficients soit différente de zéro (ce qui est évidemment possible dès que les coefficients ne sont pas tous nuls (¹)), le centre des distances proportionnelles du premier groupe étant O, celui du second O′. Supposons, par exemple, pour fixer les idées, qu'il y ait quatre points dont deux, A, B, appartiennent au premier groupe, les deux autres, C, D, au second. Les coefficients p, q, r, s sont alors tels que les deux sommes $p+q$, $r+s$, différentes de zéro, sont égales et de signes contraires.

---

(1) Il est clair que le problème cesserait de se poser si tous les coefficients étaient nuls.

Nous aurons, comme précédemment,

$$d \cdot \overline{MA}^2 + q \cdot \overline{MB}^2 = (p + q)\, \overline{OM}^2 + l$$
$$r \cdot \overline{MC}^2 + s \cdot \overline{MD}^2 = (r + s)\, \overline{O'M}^2 + l' = -(p + q)\, \overline{O'M}^2 + l'$$

en désignant par l, l' respectivement, les sommes $p \cdot \overline{OA}^2 + q \cdot \overline{OB}^2$, $r \cdot \overline{O'C}^2 + s \cdot \overline{O'D}^2$. En ajoutant ces deux égalités, il vient :

$$p \cdot \overline{MA}^2 + q \cdot \overline{MB}^2 + r \cdot \overline{MC}^2 + s \cdot \overline{MD}^2 = (p + q)(\overline{OM}^2 - \overline{O'M}^2) + l + l'.$$

Donc la condition $p \cdot \overline{MA}^2 + q \cdot \overline{MB}^2 + r \cdot \overline{MC}^2 + s \cdot \overline{MD}^2 =$ const. équivaut à $\overline{OM}^2 - \overline{O'M}^2 =$ const., c'est-à-dire donne pour lieu du point M un plan (¹).

611. Dans l'équation finale

$$p \cdot \overline{MA}^2 + q \cdot \overline{MB}^2 + r \cdot \overline{MC}^2 \ldots = (p + q + r + \ldots)\, \overline{OM}^2 + l$$

du n° **609**, introduisons (comme au n° **604**) la quantité t définie par la relation

$$p + q + r + \ldots + t = 0 :$$

il vient

$$p \cdot \overline{MA}^2 + q \cdot \overline{MB}^2 + r \cdot \overline{MC}^2 + \ldots + t \cdot \overline{MO}^2 = l.$$

Supposons qu'il y ait trois points A, B, C et soit O un point situé dans leur plan. Nous savons qu'on peut déterminer les coefficients p, q, r de manière que O soit le centre des distances proportionnelles des points A, B, C.

Ainsi, *étant donnés quatre points* A, B, C, O *d'un plan* (²) *il existe toujours quatre nombres* p, q, r, t non tous nuls, mais dont la somme est nulle, *tels que la somme* $p \cdot \overline{MA}^2 + q \cdot \overline{MB}^2 + r \cdot \overline{MC}^2 + t\, \overline{MO}^2$ *soit indépendante de la position du point* M.

Par un raisonnement tout semblable, on voit que, *étant donnés cinq points quelconques* A, B, C, D, O *de l'espace*, *il existe cinq nombres* p, q, r, s, t, *non tous nuls*, *mais dont la somme est nulle tels que la quantité* $p \cdot \overline{MA}^2 + q \cdot \overline{MB}^2 + r \cdot \overline{MC}^2 + s \cdot \overline{MD}^2 + t \cdot \overline{MO}^2$ *soit indépendante de la position du point* M.

---

(1) Dans le cas (n° **596**, note) où le point O′ coïnciderait avec le point O, il est clair que la *quantité* $p.\ MA^2 + q.\ MB^2 + \ldots$ *serait constante, quel que soit le point* M.

(2) Le raisonnement serait en défaut si les points A, B, C étaient en ligne droite ; on verrait alors, comme au n° **602**, que le résultat subsiste, t étant nul. La formule ainsi obtenue ne serait autre que celle de Stewart (Pl., **127**).

612. Relations entre les distances mutuelles de quatre points d'un plan.

Soient A, B, C, O quatre points d'un plan. Désignons par x, y, z, a, b, c, respectivement, les distances OA, OB, OC, BC, CA, AB.

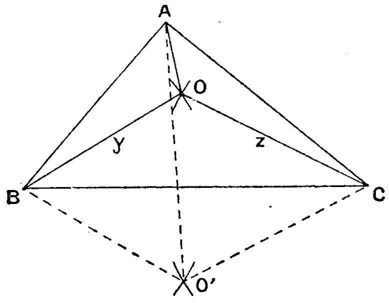

Fig. 515.

Il existe une relation entre les six quantités x, y, z, a, b, c. En effet, connaissant a, b, c, on peut construire le triangle ABC (*fig.* 515), après quoi, les circonférences de centres respectifs B, C et de rayons y, z donnent deux lieux du point O. Ces deux circonférences se coupent en deux points O, O′ (*fig.* 515) et, par conséquent, lorsqu'on donne a, b, c, y, z, la quantité x ne peut avoir que deux valeurs.

Pour trouver la relation dont nous venons de constater l'existence, nous emploierons le résultat obtenu au numéro précédent. Soient donc p, q, r, t, quatre nombres de somme nulle et tels que l'on ait

$$p.\,\overline{\mathrm{MA}}^2 + q.\,\overline{\mathrm{MB}}^2 + r.\,\overline{\mathrm{MC}}^2 + t.\,\overline{\mathrm{MO}}^2 = l$$

l étant indépendant de la position du point M.

Nous ferons coïncider successivement le point M avec les points A, B, C, O ; il viendra, en tenant compte des désignations précédemment adoptées pour les distances mutuelles des quatre points en question,

$$(1)\qquad \begin{array}{rrrrl} & qc^2 & + rb^2 & + tx^2 & = l \\ pc^2 & & + ra^2 & + ty^2 & = l \\ pb^2 & + qa^2 & & + tz^2 & = l \\ px^2 & + qy^2 & + rz^2 & & = l \end{array}$$

Si nous tenons compte de la condition

$$(2)\qquad p + q + r + t = 0,$$

nous aurons cinq équations homogènes du premier degré entre lesquelles nous pourrons éliminer les cinq inconnues, non toutes nulles, p, q, r, t, l.

Pour faire cette élimination (¹), écrivons, par exemple, les trois premières équations sous la forme

$$\frac{q}{b^2}+\frac{r}{c^2}=\frac{a^2\,(l-tx^2)}{a^2\,b^2\,c^2}$$

$$\frac{r}{c^2}+\frac{p}{a^2}=\frac{b^2\,(l-ty^2)}{a^2\,b^2\,c^2}$$

$$\frac{p}{a^2}+\frac{q}{b^2}=\frac{c^2\,(l-tz^2)}{a^2\,b^2\,c^2};$$

d'où résulte

$$\begin{aligned} p &= a^2\left[\frac{b^2\,(l-ty^2)+c^2(l-tz^2)-a^2\,(l-tx^2)}{2\,a^2\,b^2\,c^2}\right] \\ &= a^2\,\frac{l\,(b^2+c^2-a^2)-t\,(b^2\,y^2+c^2\,z^2-a^2\,x^2)}{2\,a^2\,b^2\,c^2} \\ q &= b^2\,\frac{l\,(c^2+a^2-b^2)-t\,(c^2\,z^2+a^2\,x^2-b^2\,y^2)}{2\,a^2\,b^2\,c^2} \\ r &= c^2\,\frac{l\,(a^2+b^2-c^2)-t\,(a^2\,x^2+b^2\,y^2-c^2\,z^2)}{2\,a^2\,b^2\,c^2}. \end{aligned}$$

Si nous substituons ces valeurs dans la dernière équation (1) et dans l'équation (2), celles-ci deviennent, l'une

$$(3)\qquad l\Sigma a^2(b^2+c^2-a^2)x^2-t\Sigma a^2x^2(b^2y^2+c^2z^2-a^2x^2)=2ta^2b^2c^2$$

(en désignant par $\Sigma a^2(b^2+c^2-a^2)x^2$ la somme $a^2(b^2+c^2-a^2)x^2+b^2(c^2+a^2-b^2)y^2+c^2(a^2+b^2-c^2)z^2$ et, de même, par $\Sigma a^2x^2\,(by^2+c^2z^2-a^2x^2)$ la somme de la quantité $a^2x^2(b^2y^2+c^2z^2-a^2x^2)$ et des deux autres analogues); l'autre

$$(4)\quad l\Sigma a^2(b^2+c^2-a^2)-t\Sigma a^2(b^2y^2+c^2z^2-a^2x^2)+2ta^2b^2c^2=0.$$

La quantité

$$\begin{aligned}\Sigma a^2(b^2+c^2-a^2) &= a^2(b^2+c^2-a^2)+b^2(c^2+a^2-b^2)+ \\ &\quad c^2(a^2+b^2-c^2)=2b^2c^2+2c^2a^2+2a^2b^2-a^4-b^4-c^4\end{aligned}$$

---

(1) Le lecteur familiarisé avec la théorie des déterminants écrira immédiatement le résultat de cette élimination sous la forme

$$\begin{vmatrix} 0 & c^2 & b^2 & x^2 & 1 \\ c^2 & 0 & a^2 & y^2 & 1 \\ b^2 & a^2 & 0 & z^2 & 1 \\ x^2 & y^2 & z^2 & 0 & 1 \\ 1 & 1 & 1 & 1 & 0 \end{vmatrix} = 0.$$

représente (Pl., **251**) 16 fois le carré de la surface S du triangle ABC. De même, la quantité $\Sigma a^2x^2(b^2y^2 + c^2z^2 - a^2x^2)$ représente 16 fois le carré de la surface du triangle dont les côtés sont mesurés par ax, by, cz.

Enfin, il faut remarquer que la somme

$$\begin{aligned}\Sigma a^2(b^2y^2 + c^2z^2 - a^2x^2) = a^2(by^2 + c^2z^2 + a^2x^2) + b^2(c^2z^2 + a^2x^2 - b^2y^2)\\ + c^2(a^2x^2 + b^2y^2 - c^2z^2)\end{aligned}$$

est identiquement égale à $\Sigma a^2(b^2 + c^2 - a^2)x^2$. Les deux équations (3) et (4) s'écrivent donc

$$(3') \quad l[\Sigma a^2(b^2 + c^2 - a^2)x^2 - 2a^2b^2c^2] = t\Sigma a^2x^2(b^2y^2 + c^2z^2 - a^2x^2)$$

et

$$(4') \qquad 16S^2l = t[\Sigma a^2(b^2 + c^2 - a^2)x^2 - 2a^2b^2c^2].$$

L'élimination de l et de t est immédiate et donne

$$(5) \quad [\Sigma a^2(b^2 + c^2 - a^2)x^2 - 2a^2b^2c^2]^2 = 16S^2.\Sigma a^2x^2(b^2y^2 + c^2z^2 - a^2x^2).$$

On peut ordonner cette équation par rapport à x, y, z. On obtient ainsi aisément (en divisant par $4a^2b^2c^2$) :

$$(5') \quad \Sigma a^2(x^2 - y^2)(x^2 - z^2) - \Sigma a^2(b^2 + c^2 - a^2)x^2 + a^2b^2c^2 = 0.$$

613. Nous avons à nous demander si, réciproquement, la relation précédente entre six quantités x, y, z est suffisante pour que ces quantités mesurent les distances mutuelles de quatre points d'un plan. C'est ce que nous allons démontrer *en supposant que l'on puisse construire un triangle ayant pour côtés* a, b, c.

A cet effet, nous remarquerons que, si les quantités a, b, c, x, y, z satisfont à l'équation (5), on peut (ainsi qu'on s'en assure aisément en refaisant en sens inverse les calculs précédents) trouver les quantités p, q, r, t, l satisfaisant aux équations (1) et (2).

Construisons alors le triangle ABC qui a pour côtés a, b, c, et soit O le point qui a pour coordonnées barycentriques par rapport à ce triangle, les quantités p, q, r. Si x', y', z' désignent les distances

OA, OB, OC, il existe, ainsi que nous l'avons vu, un nombre l' tel que l'on ait

$$(1')\quad \left\{\begin{array}{lllll} qc^2 & +\, rb^2 & +\, tx'^2 & = l' \\ pc^2 & +\, ra^2 & +\, ty'^2 & = l' \\ pb^2 \,+\, qa^2 & & +\, tz'^2 & = l' \\ px'^2 \,+\, qy'^2 & +\, rz'^2 & & = l' \end{array}\right.$$

La comparaison de ces équations avec les équations (1), (2) donne aisément $x' = x$, $y' = y$, $z' = z$, $l' = l$: d'où la conclusion demandée.

Notre raisonnement suppose, nous l'avons dit, que l'on puisse construire un triangle ayant pour côtés a, b, c. Toutefois, il serait encore valable (1) si l'on pouvait construire l'un des triangles qui ont respectivement pour côtés a, y, z; b, z, x; c, x, y : il suffirait, en effet, de le recommencer avec un changement de notation, le point O étant permuté avec l'un des points A, B, C.

Mais il est absolument nécessaire d'introduire l'une ou l'autre des suppositions précédentes. On peut trouver six quantités a, b, c, x, y, z satisfaisant à la relation (5) et qui, cependant, ne représentent pas les distances mutuelles de quatre points du plan, parce qu'aucun des triangles ayant pour côtés a, b, c; a, y, z; b, z, x; c, x, y, ne peut être construit (voir exercices 876, 877).

614. Volume du tétraèdre en fonction des arêtes. Soient $a = BC$, $b = CA$, $c = AB$, $\alpha = DA$, $\beta = DB$, $\gamma = DC$ les six arêtes d'un tétraèdre ABCD (*fig.* 516). La connaissance de ces six longueurs détermine le polyèdre (ex. 617) et, par conséquent, son volume. Nous allons montrer comment on peut, dans ces conditions, calculer celui-ci.

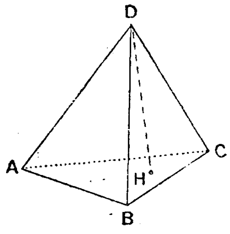

FIG. 516.

Du point D, soit abaissée la hauteur DH $= h$, et désignons par x, y, z, les distances HA, HB, HC : on aura, dans les triangles rectangles DHA, DHB, DHC,

$$\begin{aligned} \overline{HA}^2 = x^2 &= \alpha^2 - h^2 \\ y^2 &= \beta^2 - h^2 \\ z^2 &= \gamma^2 - h^2 \end{aligned}$$

---

(1) Il résulte de là que, lorsque les quantités a, b, c, x, y, z satisfont à la relation (5), si l'un des triangles qui ont respectivement pour côtés a, b, c; a, y, z; b, z, x; c, x, y peut être construit, il en est de même des trois autres.

Substituons ces valeurs dans la relation (5′), laquelle a lieu entre les longueurs a, b, c, x, y, z, puisque les points H, A, B, C sont dans un même plan. Il vient

$$\Sigma\, a^2 (\alpha^2 - \beta^2)(\alpha^2 - \gamma^2) - \Sigma\, a^2 (b^2 + c^2 - a^2)(\alpha^2 - h^2) + a^2b^2c^2 = 0$$

ou, en faisant passer tous les termes en h^2 dans le second membre,

$$\begin{aligned} &\Sigma\, a^2 (\alpha^2 - \beta^2)(\alpha^2 - \gamma^2) - \Sigma\, a^2 (b^2 + c^2 - a^2)\, \alpha^2 + a^2\, b^2\, c^2 \\ &= - h^2\, \Sigma a^2 (b^2 + c^2 - a^2) = - 16\, S^2 h^2, \end{aligned}$$

S désignant toujours la surface du triangle ABC. Mais Sh représente trois fois le volume V cherché. Donc l'expression

$$\Sigma a^2 (\alpha^2 - \beta^2)(\alpha^2 - \gamma^2) - \Sigma\, a^2 (b^2 + c^2 - a^2)\, \alpha^2 + a^2\, b^2\, c^2,$$

qui est nulle lorsque a, b, c, α, β, γ, sont les distances mutuelles de quatre points d'un plan, est, d'une façon générale, égale à $- 16 \times 3^2 . V^2$, en désignant par V le volume du tétraèdre qui a pour arêtes a, b, c, α, β, γ.

615. Relation entre les distances mutuelles de cinq points de l'espace.

Soient A, B, C, D, O cinq points de l'espace ; $a =$ BC, $b =$ CA, $c =$ AB, $\alpha =$ DA, $\beta =$ DB, $\gamma =$ DC, $x =$ OA, $y =$ OB, $z =$ OC, $u =$ OD leurs distances mutuelles. Il existe entre ces dix quantités une relation, comme on le verra en constatant (par une marche analogue à celle qui a été suivie tout à l'heure) que la connaissance des longueurs a, b, c, α, β, γ détermine le tétraèdre ABCD; la connaissance des longueurs a, b, c, x, y, z, le tétraèdre ABCO : après quoi la quantité u ne peut plus avoir que deux valeurs.

Pour trouver la relation en question, on s'appuiera sur l'existence des nombres p, q, r, s, t, de somme nulle et tels que la quantité $p.\overline{\mathrm{MA}}^2 + q.\overline{\mathrm{MB}}^2 + r.\overline{\mathrm{MC}}^2 + s.\overline{\mathrm{MD}}^2 + t.\overline{\mathrm{MO}}^2$ soit une quantité l indépendante du choix du point M ; et, faisant coïncider successivement le point M avec A, B, C, D, O, on écrira les équations

$$\begin{array}{lllllll} & qc^2 & + rb^2 & + s\alpha^2 & + tx^2 & = l \\ pc^2 & & + ra^2 & + s\beta^2 & + ty^2 & = l \\ pb^2 & + qa^2 & & + s\gamma^2 & + tz^2 & = l \\ p\alpha^2 & + q\beta^2 & + r\gamma^2 & & + tu^2 & = l \\ px^2 & + qy^2 & + rz^2 & + su^2 & & = l \\ p & + q & + r & + s & + t & = 0 \end{array}$$

entre lesquelles il faudrait éliminer p, q, r, s, t, l pour avoir la relation cherchée (¹).

EXERCICES

859. Le centre des distances proportionnelles de plusieurs points affectés de coefficients dont la somme est nulle, s'il n'est pas rejeté à l'infini, est en général indéterminé. Si on le recherche par la méthode du n° **594**, le point obtenu n'est pas indépendant de l'ordre dans lequel on prend les points donnés.

860. Si l'on fait tendre les coordonnées barycentriques d'un point M vers des nombres fixes non tous nuls, mais dont la somme est nulle, le point M s'éloigne à l'infini dans une direction déterminée.

861. Lorsqu'un point du plan d'un triangle décrit une droite, ses coordonnées barycentriques p, q, r sont liées par une relation de la forme $ap + bq + cr = 0$, les nombres a, b, c étant constants.

(Il suffit de prendre pour a, b, c les distances des sommets du triangle à la droite considérée.)

Réciproquement, le lieu des points dont les coordonnées barycentriques satisfont à une relation de la forme précédente est une droite, sauf dans les cas où a, b, et c sont égaux entre eux, et où tous les points du lieu sont rejetés à l'infini (²).

Quelles sont les propriétés analogues dans l'espace ?

862. $ap + bq + cr = 0$, $a'p + b'q + c'r = 0$ étant respectivement les *équations* de deux droites, c'est-à-dire les relations entre les coordonnées barycentriques qui les caractérisent, quelles conditions doivent vérifier a, b, c, a' b' c' pour que ces droites soient parallèles ?

Quel est le problème analogue dans l'espace ?

863. Appliquer l'exercice 861 à la recherche du lieu des points dont la somme des distances à trois droites données (dans le plan) ou à quatre plans donnés (dans l'espace) est constante.

864. Sur chaque face d'un tétraèdre, on prend un point ayant, par rapport à cette face, des coordonnées barycentriques données. Dans quel rapport le volume du tétraèdre qui a pour sommets les quatre points ainsi déterminés, est-il avec le volume du tétraèdre primitif ?

865. A tout polygone plan, on peut faire correspondre un segment tel que sa projection sur une droite quelconque de l'espace soit mesurée par le même nombre que l'aire de la projection du polygone sur un plan perpendiculaire à cette droite.

(¹) A l'aide des déterminants, le résultat s'écrit : $\begin{vmatrix} 0 & c^2 & b^2 & \alpha^2 & x^2 & 1 \\ c^2 & 0 & a^2 & \beta^2 & y^2 & 1 \\ b^2 & a^2 & 0 & \gamma^2 & z^2 & 1 \\ \alpha^2 & \beta^2 & \gamma^2 & 0 & u^2 & 1 \\ x^2 & y^2 & z^2 & u^2 & 0 & 1 \\ 1 & 1 & 1 & 1 & 1 & 0 \end{vmatrix} = o$

(²) Ce cas peut d'ailleurs être considéré comme rentrant dans le cas général (voir ci-après, n° **621**).

(Ce segment est perpendiculaire au plan du polygone et sa longueur est mesurée par le même nombre que l'aire du polygone).

866. A tout polygone gauche, on peut faire correspondre un segment tel que sa projection sur une droite quelconque, soit mesurée par le même nombre que l'aire limitée par la projection du polygone sur le plan perpendiculaire à cette droite (cette projection étant supposée ne se couper elle-même en aucun point) (¹).

Le théorème étant vrai pour un triangle (ex. précéd.), on remarquera que si on a formé les segments demandés pour deux polygones qui ont une partie commune, on peut former un segment analogue, — le résultant (²) des deux premiers — pour le contour formé en réunissant ces deux polygones et supprimant la partie commune.

(Le théorème s'étend, par voie de passage à la limite, à un contour curviligne).

867. Faire passer, par un point donné, un plan qui divise un prisme donné en deux troncs de prisme dont le rapport soit égal à un nombre donné.

868. Trouver toutes les sphères tangentes à quatre plans donnés, en remarquant qu'on connaît, au signe près, les coordonnées barycentriques du centre d'une telle sphère.

Montrer que le nombre de ces sphères est, en général, de huit. Quelles relations doit-il y avoir entre les aires des faces pour qu'une ou plusieurs d'entre elles cessent d'exister?

869. Démontrer directement que le centre de gravité d'un polygone (**605**) est indépendant de son mode de décomposition en triangles.

On montrera (comparer Pl., note D) que, quel que soit le mode de décomposition, ce centre de gravité est le même que celui qu'on obtiendrait en affectant les différents triangles qui ont pour bases respectives les côtés et pour sommet commun un point quelconque O du plan, de coefficients proportionnels aux aires de ces triangles précédées du signe + ou du signe — suivant qu'ils sont additifs ou soustractifs, et prenant, dans ces conditions, le centre des distances proportionnelles des centres de gravité de ces triangles.

Démontrer la même proposition pour le centre de gravité d'un polyèdre (comparer note F).

870. Le centre des distances proportionnelles d'un système de points d'un plan affectés de coefficients positifs, ou le centre de gravité d'un polygone plan, est à l'intérieur de tout polygone convexe comprenant ces points ou ce polygone.

Le centre des distances proportionnelles d'un système de points de l'espace affectés de coefficients positifs (ou le centre de gravité d'un polyèdre) est à l'intérieur de tout polyèdre convexe comprenant ces points ou ce polyèdre.

871. On sait qu'on appelle *centre de gravité d'une ligne brisée (supposée homogène)* le centre des distances proportionnelles des milieux des côtés de cette ligne, affectés de coefficients proportionnels aux longueurs de ces côtés.

Montrer que la surface latérale d'un tronc de prisme est égale au périmètre de la section droite, multipliée par la longueur interceptée par les bases, sur la parallèle aux arêtes menées par le centre de gravité de ce périmètre.

---

(1) Le théorème s'étend au cas où la projection du contour se croise elle-même; mais alors cette projection délimite plusieurs aires et non une seule; et il faut, pour que le théorème reste exact, l'appliquer à une somme algébrique de ces aires, multipliées par des coefficients positifs ou négatifs convenables.

(2) Voir le *Cours de Mécanique*, ou encore la *Composition des translations* (**417**).

872. Quelles conditions doivent remplir six longueurs pour qu'elles puissent être les arêtes d'un même tétraèdre ?

873. Prouver directement que si six longueurs a, b, c, x, y, z satisfont à la relation (5) du n° **612**, les deux triangles dont l'un a pour côtés a, b, c et l'autre a, y, z peuvent être construits tous deux ou ne peuvent être construits ni l'un ni l'autre.

On considérera la relation (5) comme équation en x^2. La quantité qui doit être positive pour que cette équation ait ses racines réelles est le produit de

$$(a+b+c)\ (b+c-a)\ (a+c-b)\ (a+b-c) \qquad (\text{Pl.}, \mathbf{130}),$$

par

$$(a+y+z)\ (y+z-a)\ (z+a-y)\ (a+y-z).$$

874. Quelle relation doit-il y avoir entre les arêtes a, $b, c, \alpha, \beta, \gamma$ (n° **614**) d'un tétraèdre ABCD, pour que le centre de la sphère circonscrite soit dans le plan de la face ABC ?

Réponse :

$$a^2\alpha^2(b^2+c^2-a^2)+b^2\beta^2(c^2+a^2-b^2)+c^2\gamma^2(a^2+b^2-c^2)=2a^2b^2c^2.$$

875. Si A, B, C, D sont quatre points d'un plan et M un point quelconque de l'espace, on a

$$\overline{\text{MA}}^2.(\text{DBC})+\overline{\text{MB}}^2.(\text{DCA})+\overline{\text{MC}}^2.(\text{DAB})+\overline{\text{MD}}^2.(\text{CBA})=\pm\Sigma.$$

où (DBC), (DCA), etc., désignent les aires des triangles DBC, DCA, précédées du signe + ou du signe —, suivant les sens de rotation de ces triangles, les sommets étant pris, bien entendu, dans l'ordre où ils sont écrits, et Σ est l'aire du triangle dont les côtés sont mesurés par les produits AB.CD, AC.BD, AD.BC.

Si les points A, B, C, D sont sur une même circonférence, on a

$$\overline{\text{MA}}^2.(\text{DBC})+\overline{\text{MB}}^2.(\text{DCA})+\overline{\text{MC}}^2.(\text{DAB})+\overline{\text{MD}}^2.(\text{CBA})=0.$$

(Appliquer le premier théorème du n° **611** en remarquant que les coordonnées barycentriques d'un des points A, B, C, D par rapport au triangle formé par les trois autres sont liées aux aires des triangles DBC..., comme il a été expliqué au n° **601**. On transformera ensuite les valeurs de la constante trouvée en considérant les inverses des points A, B, C par rapport à D pris comme pôle d'inversion).

876. Un angle étant donné dans un plan, appelons *distance hyperbolique* de deux points quelconques A et B du plan, le côté du carré équivalent au parallélogramme qui a ses côtés parallèles à ceux de l'angle et deux sommets opposés en A et B, cette distance étant dite de *première* ou de *seconde espèce*, suivant que la parallèle à AB menée par le sommet de l'angle donné est située dans cet angle ou dans son supplément.

Appelons également *perpendiculaire hyperbolique* à une droite, tout autre droite qui forme avec la première et les parallèles aux côtés de l'angle donné menées par leur point commun, un faisceau harmonique ; *distance hyperbolique* d'un point à une droite, la longueur hyperbolique de la perpendiculaire hyperbolique menée de ce point à cette droite.

Montrer :

1° Que si trois points A, B, C sont en ligne droite, l'une des longueurs hyperboliques BC, CA, AB est égale à la somme des deux autres ;

2° Que l'aire d'un triangle a pour mesure le demi-produit de la longueur hyperbolique d'un côté par la distance hyperbolique de ce côté au sommet opposé ;

3° Que si un triangle ABC a deux côtés AB, BC hyperboliquement perpendiculaires, et que la longueur hyperbolique AC soit de l'espèce de AB, la longueur hyperbolique perpendiculaire AB est *plus grande* que la longueur hyperbolique AC, et que le carré de cette dernière est égal à la *différence* des carrés des longueurs hyperboliques AB et BC;

4° Que si trois points A, B, C sont tels que les longueurs hyperboliques BC, CA, AB soient de même espèce, le carré de la première est égal à la somme des carrés des deux autres, moins le double produit des longueurs hyperboliques AB et AH, en désignant par H le point de rencontre de la droite AB avec sa perpendiculaire hyperbolique menée par C, et comptant le double produit dont il vient d'être question en grandeur et signe (suivant que les segments AC et AH sont de même sens ou de sens contraires).

(Imiter Pl., **126**).

5° Que, dans les mêmes conditions, l'une des distances hyperboliques BC, CA, AB est *plus grande* que la somme des deux autres (sauf dans le cas où les trois points A, B, C sont en ligne droite).

6° Que si les quatre points A, B, C, D du plan sont tels que leurs distances hyperboliques mutuelles soient de même espèce, ces distances satisfont à la relation (5′) du n° **612**.

Comment les énoncés 4° et 6° doivent-ils être modifiés si les distances hyperboliques des points considérés deux à deux ne sont pas toutes de même espèce?

Évaluer l'aire d'un triangle en fonction des longueurs hyperboliques de ses côtés (comparer Pl., **130**, **251**).

877. (Réciproque de l'exercice précédent, 6°). Si six longueurs a, b, c, x, y, z satisfont à la relation (5′) du n° **612** :

ou bien il existe quatre points d'un plan dont les distances mutuelles sont a, b, c, x, y, z ;

ou bien il existe quatre points d'un plan dont les distances hyperboliques mutuelles, toutes de même espèce, sont a, b, c, x, y, z.

Les deux hypothèses s'excluent l'une l'autre, sauf si les quatre points sont en ligne droite.

CHAPITRE VII

ELLIPSE CONSIDÉRÉE COMME PROJECTION D'UN CERCLE. HYPERBOLE RAPPORTÉE A SES ASYMPTOTES

731. Théorème. — *Un cercle étant rapporté à deux diamètres perpendiculaires entre eux, le lieu du point qu'on déduit d'un point quelconque de la circonférence en augmentant l'ordonnée dans un rapport constant, sans changer l'abscisse, est une ellipse.*

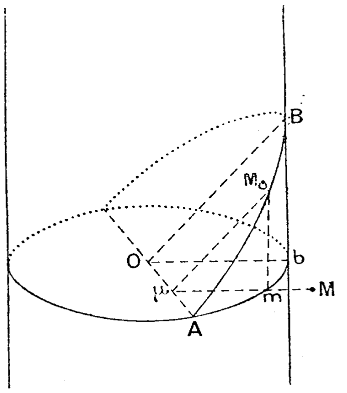

Fig. 603.

Soient O le cercle donné (*fig.* 603); OA, Ob, les deux diamètres rectangulaires; m, un point de la circonférence, ayant pour abscisse Oμ et pour ordonnée μm; M, un point pris sur μm prolongé de manière que $\frac{\mu M}{\mu m}$ soit égal à un nombre constant k plus grand que 1. Je dis que le lieu de M est une ellipse.

C'est ce qui résulte de ce fait que la section du cylindre droit qui a pour base le cercle donné par un plan passant par OA est une ellipse. Nous savons, en effet, (**360**, **364**), que si M_0 est un point de cette section; m, le point du cercle donné, projection de M_0 sur le plan de ce cercle, les points M_0, m ont même projection μ sur OA et que le rapport $\frac{\mu M_0}{\mu m}$ est constant (il est inverse du cosinus de l'angle $\widehat{M_0 \mu m}$, c'est-à-dire du cosinus de l'angle α que fait le plan de section avec le plan de base). μM_0 sera donc constamment égal à μM et, par conséquent, l'ellipse de section sera égale au lieu cherché (que l'on obtiendra en *rabattant* cette ellipse sur le plan de base, c'est-à-dire en la faisant tourner autour de OA, d'un angle égal à α), si ce rapport constant est égal à k. On arrivera évidemment à ce résultat en faisant passer le plan de section par un point B pris sur la génératrice issue du point b, de manière que OB soit égal à $k.\overline{Ob}$ (autrement dit, en déterminant l'angle des deux plans de manière que son cosinus soit égal à $\frac{1}{k}$) ce qui est possible, puisque k est supérieur à 1.

L'ellipse obtenue a d'ailleurs pour petit axe le diamètre OA commun aux deux plans.

732. Théorème. — *Un cercle étant rapporté à deux diamètres rectangulaires, le lieu du point qu'on déduit d'un point quelconque de la circonférence en diminuant l'ordonnée dans un rapport constant, sans changer l'abscisse, est une ellipse ayant le cercle donné pour cercle principal.*

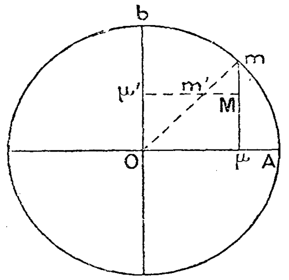

Fig. 604.

Soient encore OA, Ob les deux diamètres rectangulaires auxquels est rapporté le cercle donné ; m un point de ce cercle projeté en μ sur OA ; M un point pris sur μm de manière que $\frac{\mu \mathrm{M}}{\mu m}$ soit égal à une constante k plus petite que 1 (*fig.* 604).

Projetons le point M en μ' sur Ob et soit m' le point où Mμ' rencontre le rayon Om. Les parallèles Mm', μO et les parallèles mM, Oμ' montrent : 1° que $\frac{\mathrm{O}m'}{\mathrm{O}m} = \frac{\mu\mathrm{M}}{\mu m} = k$, de sorte que O$m'$ est constant ; 2° que $\frac{\mu'\mathrm{M}}{\mu' m'} = \frac{\mathrm{O}m}{\mathrm{O}m'} = \frac{1}{k}$. Nous voyons donc que le point m' décrit une circonférence de centre O et que, si Ob est pris pour axe des abscisses, le point M se déduit du point m' en augmentant l'ordonnée dans le rapport constant $\frac{1}{k}$ (lequel est plus grand que 1) sans changer l'abscisse. Donc le point M décrit une ellipse.

733. Projection orthogonale du cercle.

Théorème. — *La projection orthogonale d'un cercle sur un plan est une ellipse.*

On peut toujours (**413**) supposer que le plan de projection passe par le centre du cercle (*fig.* 605). Alors, si l'on prend le diamètre OA situé dans ce plan pour axe des abscisses tant du cercle que de sa projection, le rapport $\frac{\mu M}{\mu m_0}$ des ordonnées correspondant à une même abscisse $O\mu$ est une constante plus petite que 1. Donc, (théorème précédent) la projection est bien une ellipse ayant pour cercle principal un cercle égal au cercle donné. Le point m du cercle principal situé sur l'ordonnée μM prolongée est celui que l'on obtient en rabattant le point m_0 du cercle donné qui a pour projection M, c'est-à-dire en le faisant tourner, autour de OA, d'un angle égal à l'angle α des deux plans.

On peut d'ailleurs faire le rabattement de deux manières différentes, à savoir : de façon que les segments μM, μm soient toujours

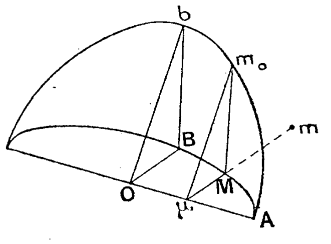

Fig. 605.

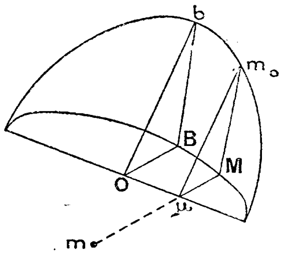

Fig. 605 *bis*.

de même sens (*fig.* 605), ou de façon que ces segments soient toujours de sens contraires (*fig.* 605 *bis*).

Remarque. — L'angle α a pour cosinus le nombre k, lequel est, d'ailleurs *égal au rapport* $\frac{b}{a}$ en désignant par $2a$ et $2b$ les axes de l'ellipse) : car lorsque le point μ est en O, on a manifestement $\mu m = Ob$ (*fig.* 605) $= a$; $\mu M = OB$ (*fig.* 605) $= b$.

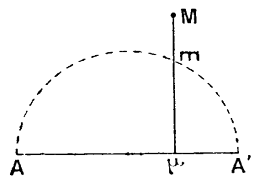

Fig. 606.

Corollaire I. — *Le lieu des points* M *d'un plan, projetés en* μ *à l'intérieur d'un segment* AA' (*fig.* 606) *et tels que* μM *soit dans un rapport constant avec la moyenne proportionnelle de* μA et de $\mu A'$, *est une ellipse*.

Car la moyenne proportionnelle de μA et de $\mu A'$ n'est autre (Pl., **125**, Coroll.) que l'ordonnée μm du cercle qui a AA' pour diamètre. L'énoncé précédent résulte donc des deux premiers théorèmes du numéro précédent.

II. *Équation de l'ellipse.* — Soient a, b les deux demi-axes; x, y, l'abscisse $O\mu$ et l'ordonnée μM du point M. L'ordonnée μm du cercle principal est évidemment donnée par

$$\overline{\mu m}^2 + x^2 = a^2.$$

Par conséquent, y qui est égal à $k.\,\overline{\mu m}$ ou (Rem. précéd. à $\frac{b}{a}.\,\overline{\mu m}$ sera donné par la relation

$$y^2 = \frac{b^2}{a^2}\,\overline{\mu m}^2 = \frac{b^2}{a^2}(a^2 - x^2).$$

ou

$$\frac{x^2}{a^2} + \frac{y^2}{b^2} = 1,$$

laquelle représente l'*équation de l'ellipse*, rapportée aux deux axes de symétrie de la courbe.

734. L'ellipse et le cercle principal sont (**630-633**) deux *figures homographiques*, dans lesquelles les points à l'infini se correspondent. Les points du grand axe sont également communs aux deux figures.

Un point P étant donné dans la figure F dont fait partie l'ellipse, on construira son homologue p dans la figure f dont fait partie le cercle en augmentant l'ordonnée de P dans le rapport $\frac{a}{b}$ sans changer l'abscisse. On trouvera d'ailleurs l'homologue d'une droite de la figure F en construisant les homologues de deux de ses points ou, plus simplement, en construisant l'homologue d'un de ses points que l'on joindra au point de rencontre de la droite avec l'axe (ce dernier point se correspondant à lui-même).

L'ellipse et le cercle du n° **731** sont également deux figures homographiques et on peut leur appliquer des considérations toutes semblables aux précédentes : ce sont, cette fois, les points du petit axe qui sont communs aux deux figures.

On peut tirer de ce que nous venons de dire des solutions nouvelles pour les problèmes déjà traités au livre IX, chap. I, tels que :

Intersection d'une droite et d'une ellipse. — On déterminera l'homologue de la droite donnée dans la figure f. Les points cherchés sont les homologues (dans la figure F) des points de rencontre de la droite ainsi déterminée avec le cercle principal (*fig.* 607).

Tangentes à une ellipse par un point de son plan. — On déterminera l'homologue p de ce point dans la figure f (*fig.* 608) : les tangentes cherchées correspondront aux tangentes menées par p au cercle principal.

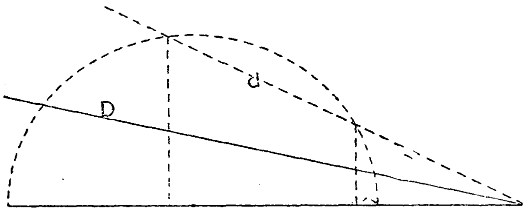

Fig. 607.

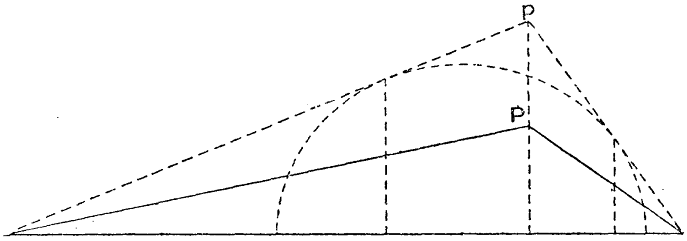

Fig. 608.

On mènera d'une manière analogue les *tangentes à l'ellipse parallèles à une direction donnée.*

735. Diamètres de l'ellipse.

Théorème. — *Le lieu des milieux des cordes parallèles à une direction donnée est une droite passant par le centre* (ou, du moins, la portion de cette droite intérieure à la courbe).

En effet, dans le cercle qui a pour projection l'ellipse (*fig.* 609), les cordes qui sont correspondantes à celles dont il est question dans l'énoncé, sont elles-mêmes parallèles à une direction fixe. Le lieu de leurs milieux est donc un diamètre (perpendiculaire à leur direction) dont la projection sera le lieu cherché.

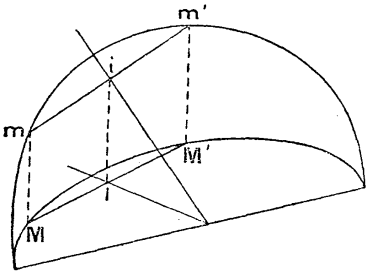

Fig. 609.

Ce lieu est nommé le *diamètre* de l'ellipse, *conjugué* de la direction considérée.

736. *Le diamètre conjugué d'une direction passe par les points de contact des tangentes parallèles à cette direction. Il passe également par le point de rencontre des tangentes aux extrémités d'une corde quelconque ayant la direction considérée.*

Car ces propriétés, qui appartiennent au cercle, se conservent dans la projection parallèle (1).

737. Diamètres conjugués.

Théorème. — *Si deux diamètres d'une ellipse sont tels que l'un est*

---

(1) Ces deux théorèmes peuvent d'ailleurs se démontrer directement, comme nous le ferons dans le cas de l'hyperbole (n^{os} **746-747**).

parallèle aux cordes conjuguées de l'autre, réciproquement celui-ci est parallèle aux cordes conjuguées du premier.

Car, la condition nécessaire et suffisante pour qu'un diamètre D d'une ellipse soit parallèle aux cordes conjuguées d'un autre diamètre D′ est (**735**) que D, D′ correspondent à deux diamètres rectangulaires du cercle qui a pour projection l'ellipse considérée : et il est clair que cette condition est réciproque, c'est-à-dire ne change pas lorsqu'on permute l'un avec l'autre les deux diamètres considérés.

Remarques. — I. *Les diamètres conjugués* (c'est-à-dire tels que chacun d'eux divise en deux parties égales les cordes parallèles à l'autre) *sont les rayons correspondants d'une involution*, projection de celle qui est formée par les rayons rectangulaires du cercle.

II. *Les seuls diamètres conjugués qui soient rectangulaires sont les axes* (**363**).

738. Théorème. — *Les cordes qui joignent un point d'une ellipse à deux points diamétralement opposés de cette courbe sont parallèles à deux diamètres conjugués.*

On donne souvent le nom de *cordes supplémentaires* à deux cordes ayant une extrémité commune et leurs secondes extrémités diamétralement opposées, de sorte que le théorème peut encore s'énoncer : *Deux cordes supplémentaires sont parallèles à deux diamètres conjugués.*

Car deux cordes supplémentaires d'un cercle sont rectangulaires, comme formant un angle inscrit dans une demi-circonférence [1].

739. Théorème *d'Apollonius.* — *Dans une ellipse :* 1° *La somme des carrés de deux demi-diamètres conjugués quelconques est constante, et égale à la somme des carrés des deux demi-axes;*

2° *L'aire du parallélogramme construit sur deux demi-diamètres conjugués est constante et égale à l'aire du rectangle construit sur les deux demi-axes.*

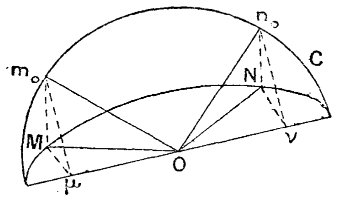

Fig. 610.

1° Soient une ellipse, projection d'un cercle C (*fig.* 610); deux diamètres conjugués OM, ON, projections de deux diamètres rectangulaires Om_0, On_0 du cercle C. Soient μ la projection commune de m_0

---

[1] Le théorème peut aussi se démontrer directement : voir le cas de l'hyperbole (n° **748**).

et de M sur OA; ν, la projection de n_0, N sur la même droite. Les deux triangles rectangles m_0MO, n_0NO montrent que la somme des carrés de OM et de ON est égale à la somme des carrés des deux hypoténuses (soit $2a^2$) diminuée de $\overline{m_0M}^2 + \overline{n_0N}^2$. Mais cette dernière somme est dans un rapport constant avec $\overline{m_0\mu}^2 + \overline{n_0\nu}^2$, car on a :

$$(21) \qquad \frac{a^2-b^2}{a^2} = \frac{\overline{m_0\mu}^2 - \overline{M\mu}^2}{\overline{m_0\mu}^2} = \frac{\overline{m_0M}^2}{\overline{m_0\mu}^2} = \frac{\overline{n_0N}^2}{\overline{n_0\nu}^2} = \frac{\overline{m_0M}^2 + \overline{n_0N}^2}{\overline{m_0\mu}^2 + \overline{n_0\nu}^2}$$

Enfin, on a $\overline{m_0\mu}^2 + \overline{n_0\nu}^2 = a^2$, car les triangles rectangles $Om_0\mu$, $On_0\nu$, ayant même hypoténuse et étant équiangles (puisqu'ils ont leurs côtés perpendiculaires), sont égaux, de sorte qu'on a $n_0\nu = O\mu$, d'où $\overline{m_0\mu}^2 + \overline{n_0\nu}^2 = \overline{m_0\mu}^2 + \overline{O\mu}^2 = \overline{Om_0}^2$.

Dès lors, $\overline{m_0M}^2 + \overline{n_0N}^2$, est égal, d'après l'équation (21), à $a^2 - b^2$. Donc, $\overline{OM}^2 + \overline{ON}^2$ est constant : il a d'ailleurs bien la valeur $2a^2 - (\overline{m_0M}^2 + \overline{n_0N}^2) = 2a^2 - (a^2 - b^2) = a^2 + b^2$: ce qui, au reste, est évident, car les axes forment évidemment un système de diamètres conjugués.

2° Le parallélogramme construit sur deux demi-diamètres conjugués est la projection du carré construit sur deux rayons rectangulaires du cercle C. Son aire est donc égale à a^2 (aire du carré) multiplié par le cosinus de l'angle des deux plans; soit $a^2 . \frac{b}{a} = ab$.

740. Théorème. — *Lorsqu'une droite de longueur constante se déplace de manière que ses deux extrémités décrivent deux droites fixes rectangulaires, un point quelconque de la droite mobile décrit une ellipse ayant ses axes suivant les droites fixes.*

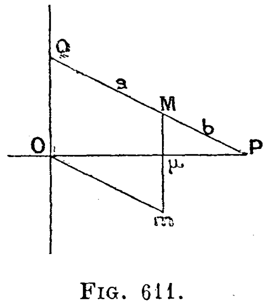

Fig. 611.

Soient PQ la droite mobile, les points P et Q décrivant respectivement les droites perpendiculaires Ox, Oy (*fig.* 611); M, un point de cette droite, tel que $MP = b$, $MQ = a$. Achevons le parallélogramme $OQMm$, dont le côté Mm, parallèle à OQ, coupe Ox en μ. Le point m décrit évidemment une circonférence de centre O et de rayon $Om = MQ = a$. Mais, d'autre part, le rapport $\frac{\mu M}{\mu m}$ est égal à $\frac{PM}{Om}$:

il a donc la valeur constante $\frac{b}{a}$. Le lieu de M est donc bien une ellipse, dont les axes ont pour directrices Ox, Oy, et pour longueurs a et $a\frac{b}{a} = b$.

Remarques. — I. On voit que *le rayon du cercle homographique correspondant à chaque position du point* M *est parallèle à la sécante mobile.*

II. Le raisonnement est le même, que le point M soit sur PQ lui-même (*fig.* 611) ou sur un de ses prolongements (*fig.* 611 *bis*). Une même ellipse admet donc deux modes de génération, les deux sécantes qui donnent un même point de la courbe étant également inclinées par rapport aux axes (PQ, P_1Q_1, *fig.* 611 *bis*).

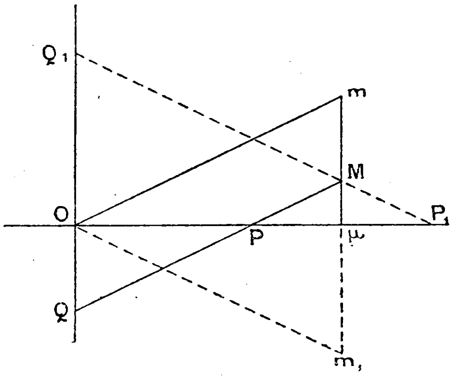

Fig. 611 *bis*.

Ce théorème donne un moyen très simple de construire par points une ellipse : il n'est pas, pour cela, besoin d'autre instrument qu'une *bande de papier* sur laquelle sont reportées, à partir d'un même point (dans le même sens ou en sens contraires) deux longueurs égales aux demi-axes.

On a fondé sur le même principe un *compas elliptique* permettant de tracer la courbe d'un mouvement continu.

741. Normale à l'ellipse.

On peut déduire du théorème qui précède une nouvelle construction de la tangente à l'ellipse :

Théorème. — *La normale à l'ellipse décrite par un point lié à une droite de longueur constante qui glisse entre deux droites rectangulaires fixes, passe par le quatrième sommet du rectangle qui a deux côtés suivant ces deux droites et une diagonale suivant la droite mobile.*

Ceci n'est autre chose que la proposition démontrée au n° **104** (Pl., liv. II). Car la normale au lieu du point P est la perpendiculaire à OP, la normale au lieu du point Q, la perpendiculaire à OQ, et par conséquent *le centre instantané de rotation* est le quatrième sommet R du rectangle qui a trois sommets en O, P, Q.

Le même théorème peut se démontrer directement. On remarquera, pour cela, que la tangente en M est (**736**) parallèle au diamètre conjugué de OM. Or, deux diamètres conjugués correspondent à deux rayons rectangulaires du cercle homographique, donc (n° précéd.) à deux positions rectangulaires de la droite mobile. On obtiendra, par conséquent, le diamètre $O'M'$ conjugué de OM en amenant le rectangle OPQR, par une rotation d'un angle droit autour du point O, à la position $OP'Q'R'$ (*fig.* 612) telle que $OP' = OQ$, $OQ' = OP$, puis prenant sur la nouvelle diagonale PQ', la longueur $P'M' = PM$.

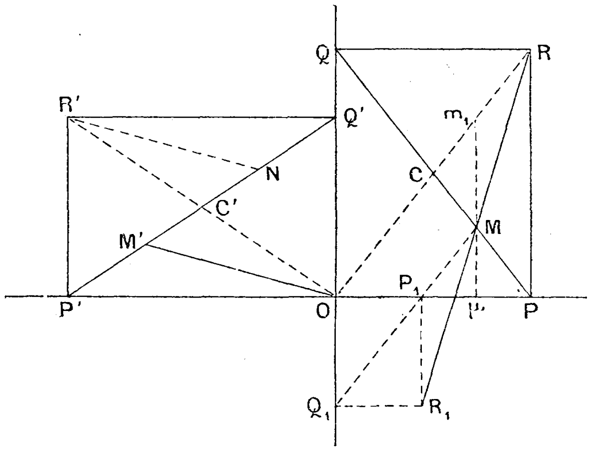

Fig. 612.

Mais si nous prenons, sur cette même diagonale, la longueur $Q'N$ égale à la précédente, la droite $R'N$ sera parallèle à OM' (car ces deux droites sont symétriques l'une de l'autre, par rapport au centre C' du rectangle $OP'Q'R'$). Or $R'N$ est la nouvelle position prise par RM dans la rotation d'un angle droit qui amène OPQR sur $OP'Q'R'$. Donc RM est bien perpendiculaire à OM', c'est-à-dire normal en M.

Remarques. — Dans la figure précédente, *la droite* RM *est égale au demi-diamètre conjugué de* OM : on a bien, en effet, $RM = R'N = OM'$.

Si l'on prolonge cette même droite RM d'une longueur MR_1 égale à elle-même, *le point* R_1 *est sur la droite symétrique de* OR *par rapport aux axes, à une distance du centre* O *égale à* $a - b$ *ou à* $a + b$, *suivant que le point* M *est intérieur ou extérieur au segment* PQ (c'est-à-dire suivant que $OR = PQ$ est lui-même égal à $a + b$ ou à $a - b$).

Car, C étant le centre du rectangle OPQR, la droite CM qui joint les milieux de OR et de RR_1, a une direction symétrique de celle de OR par rapport aux axes et une longueur égale à $\frac{a-b}{2}$ dans le cas où $CP = CQ = \frac{a+b}{2}$.

D'ailleurs on peut voir directement que *le point* R *est le quatrième sommet du rectangle* ($OP_1Q_1R_1$, *fig.* 612) *qu'on obtient en considérant le point* M *comme construit par le second mode de génération* mentionné au n° **740** (Rem. II), c'est-à-dire comme situé sur une droite P_1Q_1, de longueur constante $a - b$ mobile entre les axes, à la distance b du point P_1 et à la distance a du point Q_1 : il suffit de remarquer que la projection du point R_1 sur Ox est symétrique de P par rapport à la projection μ du point M sur la même droite, de sorte que cette projection coïncide avec le point P_1 (un raisonnement analogue s'appliquant à la projection de R_1 sur Oy).

Le point m_1 du cercle homographique que l'on obtient (**740**) en achevant le parallélogramme OQ_1Mm_1, n'est évidemment autre que l'intersection de $M\mu$ avec OR.

742. Les considérations précédentes donnent immédiatement la solution du problème suivant :

Problème. — *Construire les axes d'une ellipse, connaissant deux demi-diamètres conjugués en grandeur et position.*

OM, OM′ étant ces deux demi-diamètres (*fig.* 612) on mènera par M deux droites MR, MR_1 égales à OM′ et perpendiculaires à cette droite. Les axes seront dirigés suivant les bissectrices des angles formés par OR, OR_1 et leurs longueurs seront données par les relations $OR = a + b$, $OR_1 = a - b$.

743. Le théorème du n° **740** n'est qu'un cas particulier du suivant :

Théorème de *la Hire.* — *Lorsqu'une droite de longueur constante se déplace entre deux droites fixes quelconques, un point quelconque invariablement lié à la droite mobile décrit une ellipse.*

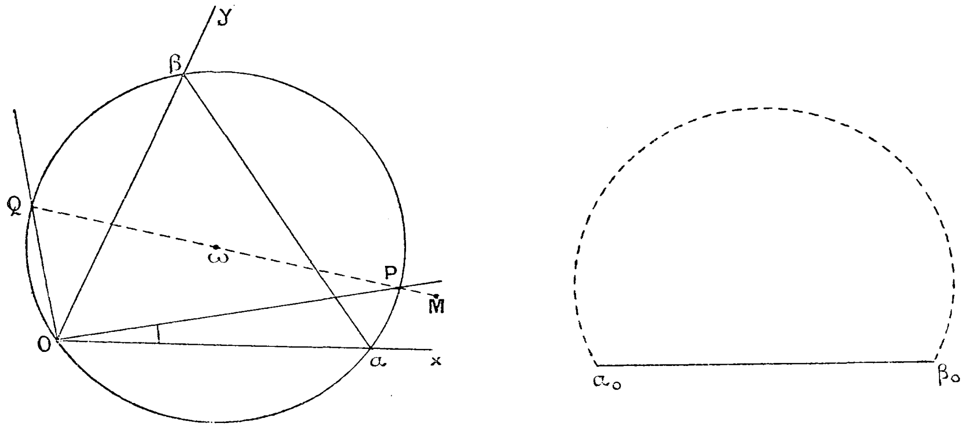

Fig. 613.

Soient αβ (*fig.* 613) une droite, constamment égale à une droite fixe

$\alpha_0\beta_0$, qui se déplace de manière que ses extrémités α, β décrivent respectivement deux droites fixes Ox, Oy ; M, un point qui se meut de manière que la figure $\alpha\beta M$ soit (Pl., **2**) invariable. Circonscrivons un cercle au triangle $O\alpha\beta$: ce cercle aura un rayon constant, celui du segment de cercle décrit sur $\alpha_0\beta_0$ et capable de l'angle $\widehat{xOy}$: il pourra dès lors être considéré comme invariablement lié à la figure mobile $\alpha\beta M$. Si donc nous menons, dans ce cercle, le diamètre PQ qui passe par le point M, les longueurs MP et MQ seront constantes.

Mais la droite OP est de direction fixe : car l'angle $\widehat{xoP}$ a pour mesure la moitié de l'arc constant αP ; et il en est de même de la droite OQ. Ces deux droites étant d'ailleurs rectangulaires, nous sommes revenus au lieu obtenu au n° **740**.

Remarque. — Toutefois, il existe une infinité de positions du point M pour lesquelles le lieu est une portion de droite (ellipse infiniment aplatie) ; ce sont les points de la circonférence $O\alpha\beta$.

744. Propriété des sécantes à l'hyperbole.

Théorème. — *Toute corde d'une hyperbole a même milieu que le segment intercepté sur elle par les asymptotes.*

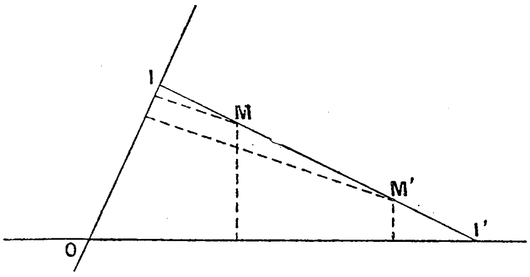

Fig. 614.

Soient MM' la corde considérée ; I, I' les points où elle coupe les asymptotes. Les distances des points M, M' à OI sont entre elles (*fig.* 614) comme les segments IM, IM' ; les distances de ces mêmes points à OI' sont entre elles comme I'M, I'M'. Or le rapport des deux premières distances est inverse du rapport des deux secondes, en vertu du théorème du n° **729**. Donc on a

$$\frac{IM}{IM'} = \frac{I'M'}{I'M}.$$

Cette égalité a d'ailleurs lieu *en grandeur et en signe*, car les points M, M' sont, par rapport aux asymptotes, dans un même angle (auquel cas les rapports $\frac{IM}{IM'}$ et $\frac{I'M'}{I'M}$ sont tous deux positifs ; *fig.* 614) ou dans deux angles opposés par le sommet (les rapports $\frac{IM}{IM'}$, $\frac{I'M'}{I'M}$ étant alors tous deux négatifs ; *fig.* 614 *bis*).

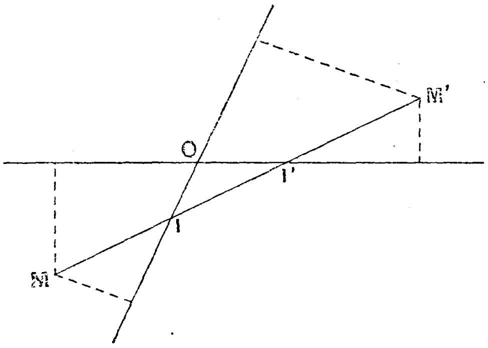

Fig. 614 *bis*.

Or il n'y a qu'un point qui divise MM' dans un rapport $\frac{IM}{IM'}$ égal en grandeur et en signe à $\frac{I'M'}{I'M}$, c'est le symétrique de I' par rapport au milieu de MM'.

Ce théorème donne un moyen simple de construire par points une hyperbole (dont on connaît les asymptotes et un point.) Il suffit de faire passer par ce point une série de sécantes (*fig.* 615) et de déterminer le second point M' où chacune d'elles coupe la courbe en portant, à partir du point d'intersection avec une des asymptotes, un segment égal à celui qui est intercepté entre la seconde asymptote et le point connu.

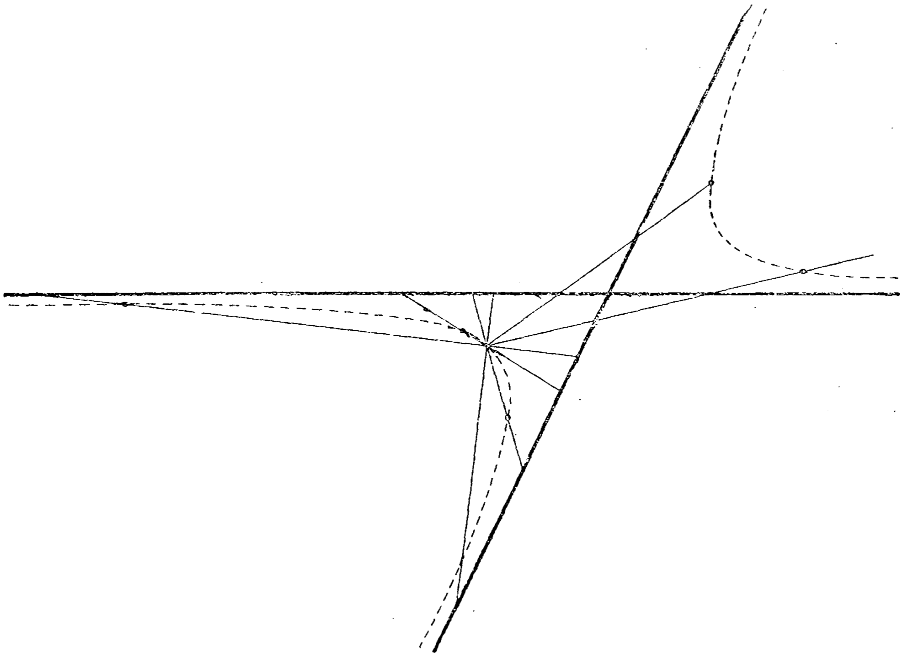

Fig. 615.

Tout point ainsi construit appartient d'ailleurs bien à l'hyperbole, comme on le voit en reprenant en sens inverse les raisonnements précédents.

745. Diamètres de l'hyperbole.

Théorème. — *Dans une hyperbole, le lieu des milieux des cordes parallèles à une direction donnée est une droite passant par le centre.*

Car le lieu des milieux des segments interceptés, sur des droites parallèles à une même direction, par les côtés de l'angle fixe, formé par les asymptotes, est évidemment une droite passant par le sommet de cet angle.

Le lieu ainsi défini se nomme le *diamètre* conjugué de la direction de cordes considérée.

746. On nomme diamètres *conjugués* l'un de l'autre deux diamètres tels que le premier soit parallèle à la direction conjuguée du second.

Théorème. — *Deux diamètres conjugués forment avec les asymptotes un faisceau harmonique et réciproquement.*

Car les parallèles à l'un des rayons d'un tel faisceau sont divisées en deux parties égales par les trois autres.

Corollaires. — I. *Si un diamètre est conjugué d'un autre, réciproquement celui-ci est conjugué du premier.*

II. *Les diamètres conjugués sont des rayons correspondants d'une même involution* (**655**).

III. *Dans l'hyperbole équilatère, les diamètres conjugués sont également inclinés sur les asymptotes* (Pl., **201**).

Un diamètre passe par les points de contact des tangentes parallèles à la direction conjuguée de ce diamètre (si ces tangentes existent).

Car, les deux points d'intersection d'une tangente étant tous deux confondus avec le point de contact, il en est de même du milieu de la corde interceptée.

On voit, de plus, qu'*une tangente est divisée en deux parties égales par son point de contact et les asymptotes.*

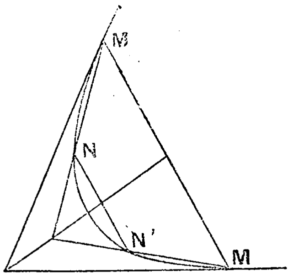

Fig. 616.

747. *Un diamètre passe par le point de rencontre des tangentes aux extrémités d'une corde conjuguée.*

Car soient MM′ (*fig.* 616) une telle corde, NN′ une corde parallèle à la première. La droite qui joint les milieux de MM′, NN′ n'est autre que le diamètre considéré : or cette droite passe (Pl., **121**) par le point d'intersection de MN, M′N′. Le diamètre passe donc aussi par l'intersection des tangentes en M, M′, car celles-ci sont les limites vers lesquelles tendent MN, M′ N′, lorsque la seconde corde se rapproche indéfiniment de la première.

748. *Deux cordes supplémentaires* (c'est-à-dire deux cordes qui ont une extrémité commune et leurs secondes extrémités diamétralement opposées) *sont parallèles à deux diamètres conjugués.* En effet (*fig.* 617), soient les deux cordes supplémentaires MN, MN′. Ces deux cordes sont respectivement parallèles aux droites qui joignent le centre O de l'hyperbole aux milieux m, m' de MN, MN′. Or Om est le diamètre conjugué de la direction MN.

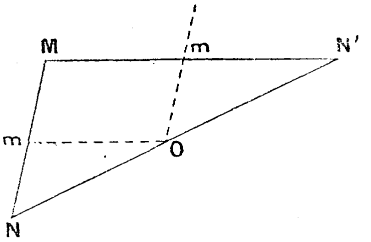

FIG. 617.

REMARQUE. — Les théorèmes que nous venons de démontrer depuis le nº **745** sont entièrement analogues à ceux que nous avons rencontrés dans la théorie de l'ellipse (**735-738**).

Des théorèmes tout semblables (sauf ceux qui regardent les diamètres conjugués) ont été également démontrés pour la parabole (**532**, **532** *bis*).

749. *De deux diamètres conjugués, il y en a toujours un qui coupe la courbe et l'autre qui ne la coupe pas.* Car deux diamètres conjugués, formant avec les asymptotes un faisceau harmonique, sont situés dans des angles différents par rapport à ces droites.

Si un diamètre d'une hyperbole ne rencontre pas la courbe, il rencontre toujours l'hyperbole conjuguée. On convient alors d'appeler *longueur* de ce diamètre la longueur b interceptée sur lui par l'hyperbole conjuguée. Les longueurs ainsi définies pour les diamètres non transverses donnent lieu à des énoncés analogues à ceux qui concernent les diamètres de l'ellipse, mais à condition de changer toujours b'^2 en $-b'^2$, comme nous l'avons déjà indiqué pour l'axe non transverse (**507**). C'est, par exemple, ce qui arrive pour les théorèmes d'Apollonius (ex. 1057) et pour l'*équation* de l'hyperbole, rapportée à deux diamètres conjugués (ex. 1058 *bis*).

EXERCICES

1045. Lieu des points qui divisent dans un rapport donné les cordes d'un cercle parallèles à une direction fixe.

1046. L'ellipse et son cercle principal sont deux figures homologiques avec centre à l'infini.

1047. Construire une ellipse, connaissant deux sommets opposés et un point ou une tangente.

1048. La corde qui joint les extrémités de deux diamètres conjugués de l'ellipse est tangente à une ellipse fixe. Lieu du point qui divise cette corde dans un rapport donné quelconque.

1049. Inscrire à l'ellipse un triangle d'aire maximum. Il y a une infinité de triangles inscrits qui ont l'aire maximum.

Même problème pour un polygone d'un nombre quelconque de côtés.

1050. Circonscrire à l'ellipse un triangle comprenant la courbe à son intérieur et d'aire maximum.

1051. Deux demi-diamètres quelconques d'une ellipse ou d'une hyperbole forment avec les tangentes menées à l'extrémité de chacun d'eux deux triangles équivalents (utiliser la symétrie oblique de la courbe par rapport à chacun de ses diamètres).

1051 *bis*. Les tangentes menées d'un point à une ellipse ou à une hyperbole sont entre elles comme les diamètres qui leur sont parallèles.

Il en est de même des cordes des arcs qu'interceptent entre elles deux sécantes parallèles.

1052. Si deux ellipses homothétiques se coupent et que, par un point de la corde commune prolongée, on leur mène des tangentes, celles-ci sont entre elles comme les diamètres de l'une des courbes qui leur sont parallèles.

1053. Quand un parallélogramme est circonscrit à une ellipse, les diagonales sont deux diamètres conjugués de la courbe. Démontrer le même théorème pour l'hyperbole.

1054. La projection parallèle d'une hyperbole sur un plan quelconque est une hyperbole.

1055. Deux hyperboles conjuguées sont obliquement symétriques l'une de l'autre par rapport aux asymptotes : c'est-à-dire (voir exercice 604) que chaque point M de l'un correspond à un point M' de l'autre, de manière que la droite MM' soit parallèle à une asymptote et coupée en son milieu par l'autre. Les points M et M' sont les extrémités (**749**) de deux diamètres conjugués.

1056. Construire les axes d'une hyperbole connaissant en grandeur et position deux demi-diamètres conjugués.

1057. Le parallélogramme construit sur deux demi-diamètres conjugués d'une hyperbole a une aire constante.

La différence des carrés de ces deux demi-diamètres est également constante.

1058. Si a', b' sont les longueurs de deux demi-diamètres conjugués de l'ellipse, l'équation de la courbe rapportée à ces deux demi-diamètres est $\frac{x^2}{a'^2} + \frac{y^2}{b'^2} = 1$.

1058 *bis*. Si a', b' sont les longueurs de deux demi-diamètres conjugués de l'hyperbole, l'équation de la courbe rapportée à ces deux demi-diamètres est

$$\frac{x^2}{a'^2} - \frac{y^2}{b'^2} = 1.$$

On prouvera que la base et la hauteur du parallélogramme dont l'aire est constante, en vertu du n° **729**, sont proportionnelles, l'une à $\frac{x}{a'} - \frac{y}{b'}$, l'autre à $\frac{x}{a'} + \frac{y}{b'}\Big)$.

1059. Si x, y sont les coordonnées de l'extrémité d'un diamètre d'une ellipse rapportée à ses axes, dont les longueurs sont a et b, les extrémités du diamètre conjugué ont leurs coordonnées x', y' données par les formules

$$\frac{x'}{a} = \pm \frac{y}{b}, \qquad \frac{y'}{b} = \mp \frac{x}{a}.$$

Trouver un énoncé analogue pour l'hyperbole.

1060. Lieu des milieux des cordes d'une conique qui passent par un point fixe. Cas de la parabole.

Lieu des points M tels qu'en les joignant à un point fixe A du plan, le segment compris entre M et chacun des points d'intersection de AM avec une conique donnée, soit égal au segment compris entre A et l'autre point d'intersection. Montrer que ce lieu ne change pas si on remplace le point A par un point déterminé quelconque du lieu.

1061. On donne un angle xOy et un point A. Lieu du point obtenu en prenant sur une sécante quelconque menée de A, à partir du point où cette sécante rencontre Ox, un segment qui soit dans un rapport donné avec le segment intercepté, sur la même sécante, entre le point A et la droite Oy.

1062. Le lieu des points qui divisent dans un rapport donné les segments interceptés par un angle fixe sur les droites issues d'un point fixe est une hyperbole passant par le point fixe et ayant ses asymptotes parallèles aux côtés de l'angle (se ramène au précédent).

1063. Trouver, sur une hyperbole donnée, deux points qui forment avec le centre de la courbe un triangle semblable à un triangle donné.

Même problème pour l'ellipse.

1064. Une tangente mobile d'une ellipse intercepte, sur deux tangentes fixes parallèles entre elles, à partir des points de contact, des segments dont le produit est constant.

Deux tangentes parallèles mobiles interceptent, sur une tangente fixe, des segments dont le produit est constant.

Étendre ces théorèmes à l'hyperbole (ex. 1052).

1065. Réciproquement, quand une droite varie de manière à intercepter, sur deux droites parallèles données, à partir de deux points donnés sur ces droites, des segments dont le produit est constant, elle est tangente à une ellipse ou à une hyperbole fixe.

1066. Sur deux parallèles données, respectivement, on prend deux points M et N tels que leurs distances à deux points fixes A et B du plan soient liées par la relation $\overline{AM}^2 - K^2 . \overline{BN}^2 =$ constante (K étant un nombre donné). Montrer que MN est tangente à une conique fixe (se ramène, en général, au précédent). Qu'arrive-t-il pour $K = 1$?

1067. Ramener le problème du n° **742** (recherche des axes d'une ellipse dont on donne en grandeur et direction deux demi-diamètres conjugués) à l'exercice 903.

La construction à laquelle on arrive est la suivante: On construit un carré ayant pour sommets opposés les extrémités A, B des deux demi-diamètres donnés. La circonférence qui passe par les deux autres sommets de ce carré et le centre donné de l'ellipse coupe la droite AB en deux points diamétralement opposés, par lesquels passent respectivement les deux axes cherchés.

1068. Les droites qui joignent deux points fixes d'une hyperbole à un point variable de la courbe interceptent sur une asymptote un segment de longueur constante et égale à celle qu'interceptent, sur la même asymptote, les parallèles à l'autre asymptote menées par les points fixes.

1069. Trouver les diamètres conjugués communs à deux coniques concentriques.

Ces diamètres existent toujours si les coniques ne sont pas toutes deux des hyperboles.

1070. Construire les directions des axes d'une conique, connaissant en direction deux couples de diamètres conjugués.

1071. Trouver, dans l'ellipse ou dans l'hyperbole, deux diamètres conjugués faisant entre eux un angle donné.

1072. Trouver, dans l'ellipse, deux diamètres conjugués égaux. Montrer que ces diamètres sont les diamètres conjugués qui font entre eux l'angle maximum.

1073. Deux diamètres conjugués d'une hyperbole équilatère sont symétriques l'un de l'autre par rapport aux asymptotes.

1074. Lieu d'un point M d'un plan tel que les droites qui le joignent à deux points donnés soient également inclinées sur une direction donnée.

1075. Par deux points fixes du plan, respectivement, on mène des parallèles à deux diamètres conjugués d'une conique donnée. Quel est le lieu du point d'intersection de ces deux droites?

1076. Deux hyperboles équilatères concentriques et qui ont leurs asymptotes à 45° les unes sur les autres, se coupent à angle droit en tous leurs points communs.

1077. On multiplie les coordonnées des points d'une ellipse E (ou d'une hyperbole) rapportée à ses axes, respectivement par des coefficients donnés.

1° Le lieu du point dont les coordonnées sont mesurées par les nombres ainsi obtenus est une nouvelle ellipse (ou hyperbole) E';

2° Si les coefficients choisis sont tels que E et E' soient homofocales et que M, N soient deux points quelconques de E; M′, N′, les points correspondants de E′, la distance MN′ est égale à la distance M′N.

(Cette proposition (ou plutôt son analogue en géométrie à trois dimensions) se présente dans une question de Mécanique céleste).

1078. La normale à une ellipse est divisée par les deux axes dans un rapport constant.

Trouver le lieu des points qui divisent l'un des segments ainsi obtenus dans un rapport donné quelconque.

1079. La perpendiculaire au milieu d'une corde quelconque de l'ellipse divise en deux parties égales le segment compris entre les sommets des rectangles OPQR (n° **741**) correspondant respectivement à ces points (Pl., **102**). Elle divise également en deux parties égales le segment intercepté sur un axe par les normales en ces points (Pl., ex. 356).

1080. Par deux points A, B d'une hyperbole, on mène des parallèles aux asymptotes. Prouver :

1° Que la seconde diagonale du parallélogramme ainsi formé passe par le centre de la courbe ;

2° Que la moitié de cette seconde diagonale est moyenne proportionnelle entre les distances du centre du parallélogramme au point où elle rencontre la tangente en A et au centre de la courbe ;

3° Que cette même moitié est moyenne proportionnelle entre les distances du centre du parallélogramme aux points où la seconde diagonale rencontre la courbe.

1081. Un demi-diamètre d'une ellipse est moyen proportionnel entre les segments déterminés, à partir du centre, par une corde conjuguée à ce diamètre et le point de concours des tangentes aux extrémités de cette corde.

1082. Même proposition pour l'hyperbole (imiter la méthode du n° **536** : on est ramené aux théorèmes des transversales). Qu'arrive-t-il si le diamètre considéré est non transverse ?

1083. Les définitions étant les mêmes qu'à l'exercice 876 :

1° Une hyperbole ayant ses asymptotes parallèles aux côtés de l'angle donné est le lieu des points tels que leurs distances hyperboliques, d'espèce déterminée, au centre de la courbe soient constantes ;

2° La tangente à cette hyperbole est hyperboliquement perpendiculaire au diamètre du point de contact ;

3° Les deux tangentes menées d'un point à cette hyperbole ont même longueur hyperbolique ;

4° Deux sécantes parallèles interceptent entre elles, sur cette hyperbole, deux arcs dont les cordes ont même longueur hyperbolique ;

5° Dans un quadrilatère circonscrit à cette hyperbole, la somme des longueurs hyperboliques de deux côtés est égale à la somme des longueurs hyperboliques des deux autres ;

6° Si on appelle *angle hyperbolique* ou *pseudo-angle hyperbolique* de deux directions, le logarithme du rapport anharmonique formé par ces directions et celles des côtés de l'angle donné, ou le logarithme de la valeur absolue de ce rapport anharmonique, suivant que ce rapport anharmonique (pris dans un ordre tel qu'il soit égal à 1 quand les deux directions coïncident), est positif ou négatif (c'est-à-dire suivant que ces directions sont celles de deux longueurs hyperboliques de même espèce ou de deux longueurs hyperboliques d'espèces différentes), et si un triangle a deux côtés de longueurs hyperboliques égales (et de même espèce), les angles ou pseudo-angles) hyperboliques opposés à ces côtés sont aussi égaux ;

7° Si les côtés d'un triangle sont de même espèce, mais que le côté AB ait une longueur hyperbolique plus grande que AC, l'angle hyperbolique ACB opposé à AC est aussi plus grand que l'angle hyperbolique ABC opposé à AC. Mais il n'en est pas de même si, les côtés AB et AC étant de même espèce, le côté BC est d'espèce différente ;

8° Une hyperbole H ayant ses asymptotes parallèles aux côtés de l'angle donné, est le lieu des points M tels que l'angle hyperbolique des droites qui joignent chacun d'eux à deux points A et B de la courbe soit constant.

Évaluer les angles hyperboliques d'un triangle, connaissant les longueurs hyperboliques de ses côtés (on commencera par le cas particulier où deux de ces côtés sont hyperboliquement perpendiculaires).

1084. Si un quadrilatère est circonscrit à une ellipse ou à une hyperbole, la somme de deux des triangles qui ont pour sommet commun le centre et pour base les côtés, est équivalente à la somme des deux autres.

Le lieu des centres des coniques inscrites à un quadrilatère est la droite qui passe par les milieux des diagonales (Pl., ex. 371).

1085. Deux sécantes parallèles à une hyperbole coupent cette courbe en quatre points tels que leurs distances à une des asymptotes soient en proportion.

1086. Le produit des segments interceptés, sur une droite, entre une hyperbole et ses deux asymptotes est égal et de signe contraire au carré du diamètre parallèle à la droite.

1087. Le produit des segments interceptés, à partir d'un point fixe, sur une sécante issue de ce point, par une hyperbole, est au produit des segments interceptés, à partir du même point, par les asymptotes, dans un rapport qui ne dépend pas de la direction de la sécante.

(Appliquer le théorème des transversales et l'ex. 1068).

1088. Théorème de *Newton*. Si, par deux points O, O′ du plan d'une ellipse, on mène deux sécantes parallèles, dont l'une coupe la courbe en m, n, l'autre en m', n', le rapport $\frac{Om \cdot On}{O'm' \cdot O'n'}$ est indépendant de la direction commune des sécantes.

Si, autour du point O, on fait pivoter une sécante, le produit des segments Om, On, interceptés par la courbe sur cette sécante, est dans un rapport constant avec le carré du demi-diamètre parallèle à la sécante.

Lieu de l'extrémité d'une longueur portée à partir de O sur la sécante et moyenne proportionnelle entre Om et On.

1089. Mêmes questions pour l'hyperbole (utiliser ex. 1087).

1090. Une corde focale d'une conique (c'est-à dire une corde passant par le foyer) est proportionnelle au carré du diamètre qui lui est parallèle.

La somme ou la différence de deux cordes focales parallèles à deux diamètres conjugués est constante.

1091. On circonscrit un cercle à un triangle inscrit dans une ellipse. Montrer que le rayon R du cercle est donné par la formule

$$R = \frac{\delta\delta'\delta''}{ab}$$

où $\delta, \delta' \delta''$ sont les demi-diamètres parallèles aux côtés du triangle; a, b, les demi-axes de l'ellipse.

(Appliquer Pl., **130** *bis* au triangle considéré et au triangle (inscrit au cercle de rayon a), dont le premier est la projection).

On suppose que les trois sommets du triangle tendent simultanément vers un même point de la courbe. Montrer que le cercle circonscrit tend vers une position limite déterminée (cercle *osculateur*) indépendante de la loi suivant laquelle les trois sommets se rapprochent de M. Construire cette position limite.

1092. Trouver le lieu du centre du cercle inscrit au triangle qui a pour sommets un point quelconque M d'une ellipse donnée et les deux foyers (exercice 1077).

Montrer que si M′ est un autre point de la courbe, C′ le cercle analogue à C construit à l'aide de M′, les droites qui joignent chacun des points M, M′ au centre du cercle correspondant ont même projection sur M M′ (ex. 1079).

En conclure que l'axe radical des cercles C, C′ passe par le milieu de M M′. La puissance de M par rapport au cercle C′ est égale à la puissance de M′ par rapport au cercle C.

CHAPITRE VIII

QUADRATURE DES CONIQUES

750. Aire de l'ellipse.

Théorème. — *L'ellipse d'axes* $2a$ *et* $2b$ *a pour aire* πab.

En effet, cette ellipse est la projection d'un cercle de rayon a et d'aire par conséquent égale à πa^2. Le cosinus de l'angle des deux plans est d'ailleurs égal (**733**, Rem.) à $\frac{b}{a}$; l'aire projetée est donc (1) (**606**. Coroll. II) $\pi a^2 \times \frac{b}{a} = \pi ab$.

Remarque. — Le même raisonnement s'applique *au secteur d'ellipse*, c'est-à-dire à la portion d'ellipse comprise entre deux demi-diamètres, car cette aire est manifestement la projection d'un secteur circulaire. On peut, dès lors (comparer Pl., **263**), évaluer toute aire limitée par des droites, des arcs de cercles et des arcs d'ellipses.

751. Aire du secteur d'hyperbole.

Nous nommons *secteur d'hyperbole* (*fig.* 618) l'aire comprise entre un arc d'hyperbole MN et les rayons qui joignent ses extrémités au centre.

On démontre (2) que la définition de l'aire (Pl., **260**) s'applique à la portion de plan ainsi définie, c'est-à-dire qu'en substituant à l'arc d'hyperbole une ligne brisée inscrite (*fig.* 619), on obtient une aire polygonale qui tend vers une limite déterminée lorsque le nombre des côtés de la ligne brisée va en augmentant indéfiniment et chacun d'eux en tendant vers zéro suivant une loi quelconque.

---

(1) Le raisonnement du n° **606** démontre l'existence de l'aire de la portion projetée, en même temps qu'il en établit l'expression.

(2) Il suffit (Pl. **260**, note 1, page 252) de montrer que la distance d'une corde au point de rencontre des tangentes en ses extrémités tend vers zéro avec la longueur de la corde : ce qu'on déduira aisément de l'exercice 1080.

Nous allons apprendre à évaluer l'aire ainsi définie. Nous pouvons d'ailleurs remarquer que cette aire est équivalente à celle qui est délimitée par l'arc MN, une des asymptotes, et les parallèles Mm,Nn (*fig.* 618) menés par les points MN à l'autre asymptote. En effet, ces deux aires s'obtiennent respectivement en retranchant de l'aire mixtiligne $OMNn$ les deux triangles rectilignes OMm,ONn, lesquels sont équivalents entre eux comme moitiés de parallélogrammes équivalents.

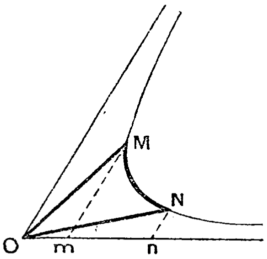

FIG. 618.

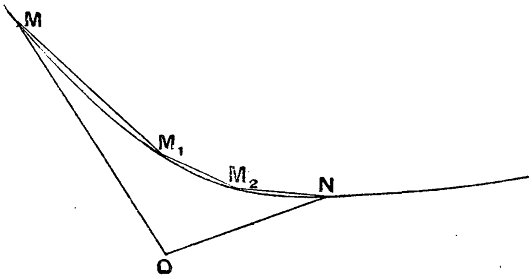

FIG. 619.

Les droites Mm,Nn sont les ordonnées des points M et N, lorsque l'hyperbole est rapportée à ses asymptotes.

Théorème. — *Dans une même hyperbole supposée rapportée à ses asymptotes, l'aire d'un secteur est proportionnelle au logarithme du rapport des abscisses des extrémités de l'arc correspondant.* Comme dans d'autres démonstrations analogues, nous prouverons tout d'abord les deux points suivants :

1° *A deux valeurs égales du rapport des abscisses correspondent des secteurs équivalents.* — Soient les deux arcs MN,M′N′ tels que le rapport des abscisses Om,On (*fig.* 620) des points M,N soit égal au rapport des abscisses Om',On' des points M′,N′. Entre M et N, pre-

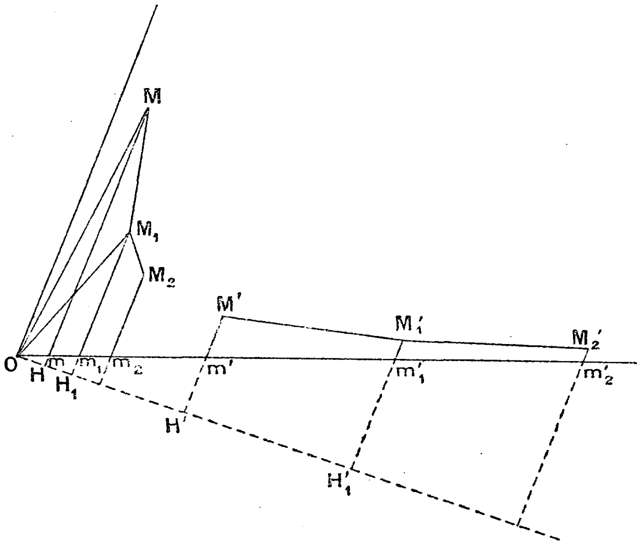

FIG. 620.

nons sur la courbe les points $M_1, M_2, \ldots$; entre M′ et N′ les points $M'_1, M'_2, \ldots$, tels que les abscisses $Om'_1, Om'_2, \ldots$ de $M'_1, M'_2, \ldots$ soient respectivement aux abscisses $Om_1, Om_2, \ldots$ de $M_1, M_2, \ldots$ comme Om' est à Om. Si nous démontrons que le secteur polygonal $OMM_1M_2\ldots N$ est équivalent à $OM'M'_1M'_2\ldots N'$, il sera établi que le secteur hyperbolique OMN est équivalent au secteur hyperbolique OM′N′, car le secteur hyperbolique OMN est, par définition, la limite du secteur polygonal $OMM_1M_2\ldots$ N lorsque les points $M, M_1M_2, \ldots$ vont en se rapprochant indéfiniment les uns des autres.

Comme tout à l'heure, le triangle OMM_1 est équivalent au trapèze MM_1mm_1 (parce que le triangle OMm est équivalent à OM_1m_1), et, de même, le triangle $OM'M'_1$ au trapèze $M'M'_1m'm'_1$. Le trapèze MM_1mm_1 a pour mesure le demi-produit de la somme $Mm + M_1m_1$ par la hauteur, que nous compterons en HH_1 (*fig.* 620) sur la perpendiculaire aux deux bases menées par le point O, et le trapèze $M'M'_1m'm'_1$ a pour mesure le demi-produit de la somme $M'm' + M'_1m'_1$ par la hauteur $H'H'_1$ comptée sur la même perpendiculaire.

Or les rapports $\frac{M_1m_1}{Mm}, \frac{M'_1m'_1}{M'm'}$ sont respectivement inverses des rapports $\frac{OH_1}{OH}, \frac{OH'_1}{OH'}$ (puisque le triangle OMm est équivalent à OM_1m et le triangle $OM'm'$ à $OM'_1m'_1$); ces rapports sont égaux entre eux, puisque l'on a $\frac{Om_1}{Om} = \frac{Om'_1}{Om'}$. On peut écrire :

$$\frac{M'm' + M'_1m'_1}{Mm + M_1m_1} = \frac{M'm'}{Mm}.$$

Quant aux hauteurs $H'H'_1$, HH_1, elles sont entre elles comme OH′ est à OH, à cause de l'égalité $\frac{OH'_1}{OH'} = \frac{OH_1}{OH}$.

Donc les trapèzes en question sont entre eux comme les produits $Mm \times OH$ et $M'm' \times OH'$, c'est-à-dire comme les triangles OMm, $OM'm'$; ces trapèzes, et aussi les triangles $OMM_1, OM'M'_1$, sont, par conséquent, équivalents entre eux.

De même, le triangle $OM'_1M'_2$ sera équivalent à OM_1M_2, et ainsi de suite. La conclusion est donc démontrée.

2° *Si l'on donne au rapport des abscisses trois valeurs telles que la troisième soit le produit des deux premières, on obtient trois secteurs* *tels que le troisième soit équivalent à la somme des deux premiers.* — C'est ce qui est évident si les deux premiers secteurs ont pour base deux arcs consécutifs MN, NP (*fig.* 621), le troisième secteur ayant pour base l'arc total MP. Mais, d'autre part, il est clair qu'on peut ramener tout autre cas à celui-là, en vertu de 1°.

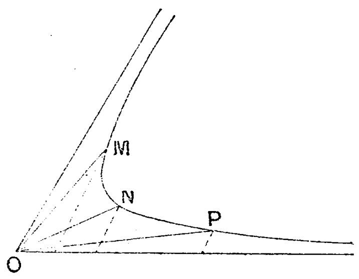

Fig. 621.

Par conséquent, *si le logarithme du rapport des abscisses prend trois valeurs telles que la troisième soit la somme des deux premières, le troisième secteur obtenu est équivalent à la somme des deux premiers :* cet énoncé revient au précédent, puisque la somme des logarithmes de deux nombres est égale au logarithme de leur produit (¹).

Des deux propositions qui viennent d'être démontrées résulte, ainsi qu'il a été expliqué à plusieurs reprises, le théorème énoncé.

752. Nous venons d'apprendre à comparer deux secteurs correspondant à une même hyperbole. Comparons maintenant deux secteurs empruntés à deux hyperboles différentes.

Nous rapporterons chacune des hyperboles à ses asymptotes. L'aire du parallélogramme ayant un sommet en un point quelconque d'une de ces hyperboles et deux côtés suivant les asymptotes de cette courbe, est une constante que nous appellerons, pour abréger, la *constante relative* à l'hyperbole considérée.

Cela posé, on aura le théorème suivant :

Théorème. — *Dans deux hyperboles dont chacune est rapportée à ses asymptotes, deux secteurs correspondant à la même valeur du rapport des abscisses sont entre eux comme les constantes relatives aux deux courbes.*

En effet, si O, O' sont les centres des deux courbes, M, M_1 deux points de la première; M', M'_1 deux points de la seconde, tels que leurs abscisses $O'm'$, $O'm'_1$ soient entre elles comme les abscisses Om, Om_1 des points M, M_1 (*fig.* 622), on démontrera, comme au numéro précédent (1°), que les triangles OMM_1, $O'M'M'_1$ sont entre eux

---

(1) Voir Bourlet, *Leçons d'Algèbre*, livre V, ch. III, n° **137**, page 426.

comme OMm, O$'$M$'m'$, c'est-à-dire comme les constantes relatives aux deux courbes. Dès lors, la même conclusion s'étendra (toujours comme au numéro précédent, 1°) au rapport de deux secteurs OMN, O$'$M$'$N$'$ tels que les abscisses des points M$'$,N$'$ soient entre elles comme celles des points M, N.

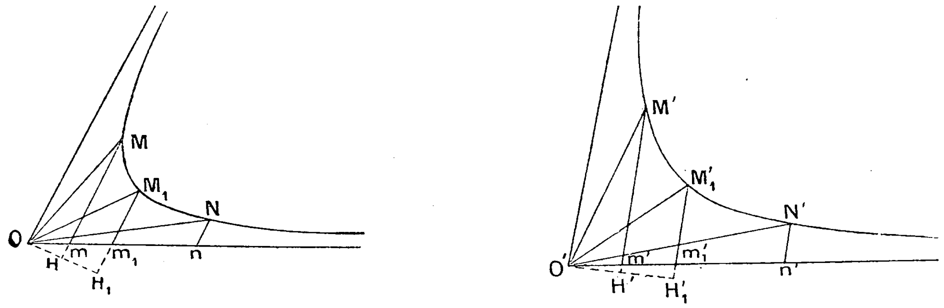

FIG. 622.

Des deux théorèmes précédents résulte :

Théorème. — *L'aire du secteur correspondant à l'arc compris entre deux points d'une hyperbole quelconque est proportionnelle au produit de la constante relative à la courbe par le logarithme du rapport des abscisses de ces deux points.*

En effet, nous venons de voir que cette aire est proportionnelle : 1° au logarithme du rapport des abscisses ; 2° à la constante relative à la courbe, lorsque ces deux quantités varient séparément : elle est donc proportionnelle à leur produit.

752 *bis*. **Corollaire.** — Tout ce que nous venons de dire subsiste quel que soit le système de logarithmes employés.

Prenons maintenant pour base du système de logarithmes le rapport des abscisses de deux points M, N, pris sur une même branche d'hyperbole et tels que l'aire du secteur compris entre ces deux points soit égale à la constante relative à la courbe. Alors l'aire d'un secteur d'hyperbole quelconque sera *égale* au produit de la constante relative à la courbe par le logarithme de rapport des abscisses correspondantes, car cette propriété a lieu pour le secteur particulier que nous venons de définir et s'étend, par suite, à tous les autres secteurs d'hyperboles, en vertu des théorèmes précédents.

Le système de logarithmes ainsi obtenu n'est autre que le système des logarithmes *népériens*, le premier qui ait été inventé (¹). Sa base est désignée ordinairement par la lettre e : les premières décimales de ce nombre sont $e = 2,7182818...$

Le nombre e n'est pas constructible à l'aide de la règle et du compas : c'est-à-dire qu'on ne peut construire à l'aide de la règle et du compas deux lignes dont le rapport soit égal à e. Plus généralement, il n'existe aucun secteur d'hyperbole tel qu'on puisse construire géométriquement le carré qui lui est équivalent, en même temps que les asymptotes de la courbe et les extrémités de l'arc qui sert de base au secteur (²).

Remarque. — *L'aire d'un secteur d'hyperbole augmente indéfiniment lorsqu'une des extrémités de l'arc correspondant s'éloigne à l'infini, l'autre restant fixe,* puisque le logarithme de l'abscisse variable augmente indéfiniment.

753. Aire du segment de parabole.

Le *segment de parabole* est l'aire comprise entre un arc de parabole et sa corde. Contrairement à ce qui a lieu pour l'ellipse et l'hyperbole, on peut construire avec la règle et le compas un carré équivalent à un segment de parabole donné quelconque.

Théorème. — *Un segment de parabole équivaut aux deux tiers du triangle formé par la corde du segment et les tangentes à ses extrémités* (³).

---

(1) Bourlet, *Leçons d'Algèbre*, page 428.

(2) Les Mathématiques supérieures permettent d'établir, entre les nombres e et π, une relation qui fait intervenir les qualités imaginaires et dont nous ne pouvons par conséquent donner une idée ici, mais dont l'existence ne doit pas surprendre, puisque l'un de ces nombres est lié à l'aire de l'ellipse (**750**) et l'autre à l'aire de l'hyperbole.

Le théorème relatif à l'impossibilité de construire le nombre e (ou plutôt une proposition plus étendue dont ce théorème découle (voir note E à la fin du volume)), est dû à M. Hermite (1874) : c'est le résultat auquel nous avons fait allusion au liv. III (Pl., page 181, note 2). Le théorème plus général que nous énonçons ensuite est celui qui a été déduit des travaux de M. Hermite par M. Lindemann. En vertu de la relation, mentionnée tout à l'heure, qui existe entre les nombres e et π, ce théorème entraîne l'impossibilité de la quadrature du cercle.

(3) Ce théorème et le mode de démonstration que nous en donnons sont dus à *Archimède*.

La démonstration suppose que les polygones inscrits se succèdent suivant une loi déterminée (chaque polygone ayant pour sommets les sommets du précédent et les points de la courbe situés sur les diamètres conjugués des côtés de ce précédent). Pour démontrer que la limite obtenue est la même, quelle que soit la loi d'inscription (pourvu que chaque côté tende vers zéro), il suffit (Pl., page 252, note 1) de faire voir que la distance d'une corde au point d'intersection des tangentes en ses extrémités tend vers zéro avec la longueur de la corde. Or, c'est ce qui résulte aisément du n° **536**.

Soit le segment de parabole déterminé par la corde aa' (*fig.* 623), les tangentes menées à la courbe en a, a' se coupant en A. Soit S l'aire du triangle Aaa'.

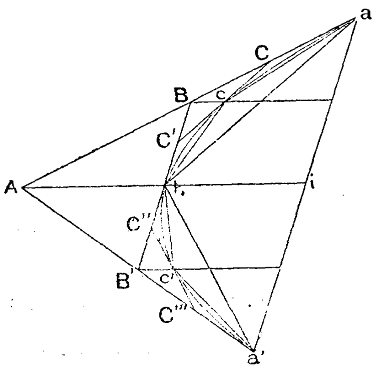

FIG. 623.

Le diamètre qui passe en A coupe la courbe en un point b où la tangente est parallèle à aa' ; soient B, B' les points où cette tangente coupe respectivement Aa et Aa'. Le diamètre Ab est divisé Ab, en deux parties égales par les points et le point i où il coupe aa' (**526**). Si donc nous joignons ab et $a'b$, les triangles iab et $ia'b$ sont respectivement les moitiés de iaA et de $ia'A$, donc, le triangle $aa'b$ a pour aire $\frac{S}{2}$. Le triangle ABB', qui est semblable à Aaa', avec le rapport de similitude $\frac{1}{2}$, a pour mesure $\frac{S}{4}$, de sorte que la somme des deux triangles bBa et $bB'a$ est égale ment $\frac{S}{4}$.

Menons maintenant les diamètres des points B et B' lesquels coupent respectivement la courbe en c, c' : les tangentes en ces points sont respectivement parallèles à ab et $a'b$; la première coupe aB en C et Bb en C' ; la seconde coupe bB' en C'' et $B'a'$ en C'''. Si nous joignons ac, cb, bc', $c'a'$, nous constaterons, comme tout à l'heure : 1° que le triangle acb est la moitié du aBb et le triangle $bc'a'$, la moitié du triangle $bB'a'$; 2° que les deux triangles BCC' et B'C''C''' sont respectivement les quarts de Bab et $B'ba'$. Dès lors, il est clair que la somme des deux triangles inscrits acb et $bc'a'$ est égale à $\frac{S}{8}$, de sorte que le polygone inscrit $acbc'a'$ a pour aire $\frac{S}{2}+\frac{S}{2\times 4}$.

En même temps on voit que la somme des deux triangles circonscrits BCC' et B'C''C''' est $\frac{S}{16}$. De plus, les deux polygones $acbc'a'$ et ACC'C''C''' sont séparés par quatre triangles intermédiaires aCc, $cC'b$, $bC''c'$, $c'C'''a'$, ayant pour somme $\frac{S}{4^2}$.

Nous continuerons de même en menant les diamètres des points C, C′, C″, C‴. Les points où ces diamètres couperont la courbe formeront, avec les points précédemment obtenus, a, c, b, c', a', les sommets d'un nouveau polygone inscrit dont l'aire sera $\frac{S}{2}+\frac{S}{2\times 4}+\frac{S}{2\times 4^2}$; l'espace compris entre ce polygone inscrit et le polygone circonscrit correspondant sera $\frac{S}{4^3}$.

Si l'on continue ainsi indéfiniment, on voit que l'aire d'un quelconque des polygones inscrits successifs est mesurée par une expression de la forme $\frac{S}{2}+\frac{S}{2\times 4}+\frac{S}{2\times 4^2}+\ldots\ldots+\frac{S}{2\times 4^m}$, c'est-à-dire par la somme d'un certain nombre de termes de la progression géométrique qui a pour premier terme $\frac{S}{2}$ et pour raison $\frac{1}{4}$. Lorsque m augmente indéfiniment, cette expression tend (¹) vers une limite égale à $\frac{S}{2\left(1-\frac{1}{4}\right)}=2\frac{S}{3}$. Le théorème est donc démontré.

L'aire compris entre un polygone inscrit et le polygone circonscrit correspondant est d'ailleurs égale à $\frac{S}{4^m}$ et tend bien vers zéro lorsque m augmente indéfiniment.

EXERCICES

1093. L'aire d'un triangle inscrit à une parabole est double de celle du triangle circonscrit formé par les tangentes en ses sommets.

Proposition analogue pour un polygone inscrit d'un nombre quelconque de côtés. En déduire l'aire du segment de parabole.

1094. Deux diamètres conjugués divisent une ellipse en quatre parties équivalentes.

1095. On mène, dans une ellipse, deux demi-diamètres tels que le secteur compris entre eux et la courbe ait une aire constante. Montrer 1° que la corde qui joint les

---

(1) Bourlet, *Leçons d'Algèbre*, livre V, ch. II, n° **133**, p. 414.

extrémités de ces deux demi-diamètres est tangente à une ellipse fixe, qui la touche en son milieu;

2° Que le segment compris entre la courbe et cette corde a également une aire constante;

3° Qu'il en est de même du triangle qui a pour côtés cette corde et les tangentes menées à ses extrémités. Lieu du point de concours de ces tangentes.

1095 *bis*. Étant donnée une ellipse, quel est le lieu d'un point pour lequel le rayon du cercle considéré à l'exercice 757 est constant?

1096. Deux sécantes parallèles interceptent sur l'hyperbole des arcs qui servent de bases à des secteurs équivalents. Démontrer cette proposition sans se servir des théorèmes sur l'aire du secteur (n^{os} **751-752** *bis*) et en utilisant seulement le théorème sur les diamètres de l'hyperbole (**745**). En déduire à nouveau l'aire du secteur d'hyperbole (ex. 1085).

1097. Résoudre, pour l'hyperbole, l'exercice 1095.

1098. En adoptant les définitions des exercices 876 et 1083 :

1° Si deux lignes brisées L et L′, terminées aux mêmes extrémités, ont tous leurs côtés de même espèce, et que L enveloppe L′, laquelle est convexe, la somme des longueurs hyperboliques des côtés de L est *plus petite* que la somme correspondante relative à L′;

2° Dans une hyperbole H ayant ses asymptotes parallèles aux côtés de l'angle donné, le rapport de la longueur hyperbolique d'une corde AB à la somme des longueurs hyperboliques des tangentes AB, BC menées en ses extrémités et terminées à leur point de rencontre C tend vers l'unité lorsque la corde tend vers zéro (mener le diamètre du point C et appliquer exercices 1080, 1083);

3° Si on inscrit à un arc AB de l'hyperbole H une ligne brisée dont le nombre des côtés augmente indéfiniment de manière que chacun d'eux tende vers zéro, la somme des longueurs hyperboliques de ces côtés tend vers une limite l, qu'on peut appeler la longueur hyperbolique de l'arc AB;

4° Deux arcs de l'hyperbole H, qui ont même longueur hyperbolique, sont vus du centre sous des angles hyperboliques égaux et correspondent à des secteurs d'hyperbole équivalents.

Plus généralement, l'aire d'un secteur de l'hyperbole H est proportionnelle à la longueur hyperbolique de l'arc qui lui sert de base, ou à l'angle hyperbolique des deux rayons qui le limitent.

1099. Si on joint un point variable d'une ellipse à deux points fixes de la courbe et qu'on mène, par le centre, des parallèles aux droites ainsi tracées, on détermine, dans l'ellipse, un secteur d'aire constante et égale à la moitié de l'aire du secteur formé par les demi-diamètres qui aboutissent aux deux points fixes.

Même problème dans l'hyperbole.

1100. Trouver le lieu d'un point tel que le segment de parabole compris entre la courbe et la corde de contact des tangentes issues de ce point ait une aire constante. Montrer que ce lieu est une parabole qui se déduit de la parabole donnée par translation. La projection de la corde de contact sur la directrice est constante (employer une remarque analogue à celle de l'exercice 1096).

1101. Mener, par un point intérieur à une conique, une corde qui détache le plus petit segment possible.

1102. Diviser un secteur d'ellipse en deux parties équivalentes par un diamètre. Même problème pour un secteur d'hyperbole (¹).

1103. Circonscrire à un triangle la plus petite ellipse possible.

(On étudiera (ex. 1049) le rapport de l'aire d'un triangle à celle d'une ellipse circonscrite et l'on en cherchera le maximum).

1103 *bis*. Inscrire, à un triangle donné, la plus grande ellipse possible (parmi celles qui sont comprises à l'intérieur du triangle).

(Même méthode).

1104. Lieu du centre d'une hyperbole qui passe par deux points fixes A, B, de manière que le secteur compris entre la courbe et les demi-diamètres aboutissant en ces points ait une aire donnée, la constante relative à la courbe étant également donnée. Montrer que les asymptotes passent chacune par un point fixe. Trouver le lieu de l'intersection des tangentes à l'hyperbole en A et B.

1105. Une ellipse varie de manière que ses axes restent dirigés suivant deux droites fixes et que son aire reste constante. Montrer que cette ellipse est tangente à une hyperbole équilatère fixe. Généraliser au cas où l'ellipse, gardant toujours une aire constante, a deux diamètres conjugués suivant deux droites données.

1106. Calculer l'aire du triangle qui a pour sommets le centre d'une hyperbole et deux points de la courbe, connaissant la constante relative à l'hyperbole et le rapport des abscisses des deux points (lorsqu'on rapporte la courbe à ses asymptotes).

1107. Montrer que le logarithme de $(1 + a)$, dans le système dont la base est le nombre e, est la limite, pour n infini, de l'expression

$$a\left(\frac{1}{n} + \frac{1}{n+a} + \frac{1}{n+2a} + \dots + \frac{1}{n+na}\right)$$

(On remarquera que cette expression représente une aire polygonale formée à l'aide d'un contour inscrit à l'hyperbole).

---

(1) Le problème de diviser un secteur d'ellipse ou d'hyperbole en un nombre de parties équivalentes qui n'est pas une puissance de 2 n'est pas résoluble par la règle et le compas.

L'introduction des imaginaires permet de réunir en un seul et même problème la question précédente relative à l'ellipse et la question relative à l'hyperbole, quoique ces deux questions soient d'apparence très différentes. (L'une conduit à la division d'un angle en un nombre quelconque de parties égales; l'autre, à trouver deux lignes dont le rapport soit $\sqrt[m]{\frac{a}{b}}$, où a et b sont deux lignes données.)

NOTE E

SUR LA RÉSOLUBILITÉ DES PROBLÈMES DE GÉOMÉTRIE

788. Ainsi que nous avons eu l'occasion de le faire remarquer à plusieurs reprises, les divers problèmes de construction que l'on peut rencontrer en géométrie sont loin de pouvoir être tous résolus comme nous l'avons indiqué au livre II de la Géométrie plane, c'est-à-dire uniquement par le moyen de la règle et du compas.

A quels caractères peut-on reconnaître si un problème donné quelconque admet une solution de cette nature? Nous ne pouvons donner à cet égard que quelques indications, car, ainsi que nous allons le voir, les méthodes qui permettent de répondre à cette question appartiennent au domaine de l'algèbre.

Nous avons vu, en effet, au livre X, comment une figure plane quelconque peut être considérée comme déterminée par des données numériques convenablement choisies : c'est ce que nous avons appelé faire le *levé* de la figure en question. Nous avons même vu qu'on peut, pour ces données, choisir exclusivement des mesures de longueur (levé à la chaîne seule, ou à la chaîne et à l'équerre). *Nous supposerons essentiellement, dans ce qui va suivre, que cette dernière précaution ait été prise:* si, par exemple, la figure considérée contient un angle, il est entendu que la détermination de cet angle sera ramenée à celle des trois côtés d'un triangle dont il fait partie.

789. Il est vrai que ces données numériques, nécessaires pour déterminer la figure, sont quelquefois en nombre infini : c'est ce qui arrive si cette figure contient des lignes de forme quelconque qu'il faut construire par points, ceux-ci étant en nombre infini. Mais ce cas ne se présentera pas dans les problèmes dont nous nous occuperons. Nous supposerons, en effet, que les figures considérées sont de celles que l'on peut reproduire à l'aide de la règle et du compas — et cela, par un nombre fini d'opérations : autrement dit, ces figures se composeront toujours de points, de droites et de cercles en nombre fini.

Par exemple, si, parmi les données de la question, figure une ellipse, il ne faudra pas supposer cette ellipse tracée — puisqu'on ne peut le faire d'un mouvement continu, en n'employant que la règle et le compas —

mais donnée par ses foyers et son grand axe, ou par cinq points (¹), ou par toutes autres données équivalentes à celles-là. De même, si une ellipse figure parmi les inconnues, il est clair qu'on ne pourra demander qu'elle soit tracée : elle devra être regardée comme obtenue lorsqu'on en connaîtra cinq points.

Toute figure satisfaisant à la condition précédente sera déterminée par un nombre fini de points, puisqu'une droite est déterminée par deux points et un cercle par trois.

790. Pour déterminer la situation d'un point, nous pourrons prendre, en particulier, les *coordonnées* de ce point (**533**), un système d'axes, que nous supposerons rectangulaires, ayant été choisi dans le plan de la figure : la connaissance de celle-ci sera alors fournie par la connaissance des coordonnées d'un certain nombre de points.

791. Soit maintenant un problème de construction, ayant pour objet la recherche d'une figure F′ ayant avec une figure donnée F des relations données.

Si nous voulions déterminer la figure F par des mesures de longueur, autrement dit en faire le levé (à la chaîne seule, ou à la chaîne et à l'équerre, bien entendu), nous obtiendrions une certaine série de nombres N. De même, le problème étant supposé résolu et la figure F′ construite, le levé de la figure formée par l'ensemble de F et de F′ conduirait à adjoindre aux nombres N d'autres nombres que nous désignerons par N′.

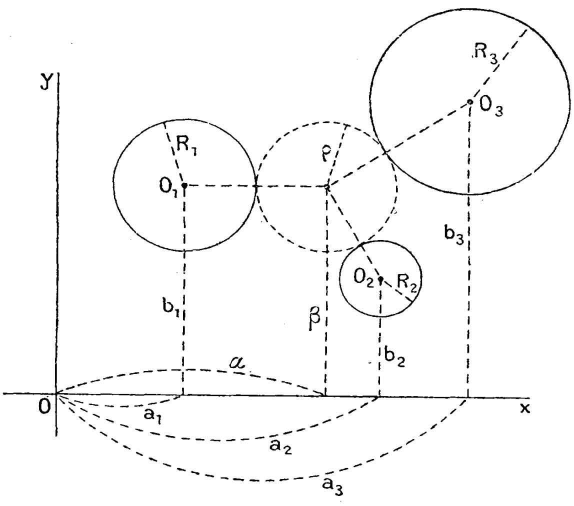

Fig. 643.

Exemple. — Dans le problème du *cercle tangent à trois cercles donnés*, les nombres N seront les coordonnées a_1, b_1; a_2, b_2; a_3, b_3 des centres de trois cercles et leurs rayons R_1, R_2, R_3 : ces nombres détermineront entièrement la figure formée par ces trois cercles (*fig.* 643). Les nombres N′ seront les coordonnées α, β du centre du cercle cherché et le rayon ρ de ce cercle.

On pourra encore considérer les distances mutuelles O_2O_3. O_3O_1, O_1O_2 (*fig.* 643) des centres des cercles donnés et les rayons R_1, R_2, R_3, comme constituant les quantités N, car ces longueurs suffisent à faire le levé de la figure formée par les cercles donnés. Les nombres N′ seront alors, par exemple, les distances x, y, z du centre du cercle cherché aux points O_1, O_2, O_3, et le rayon ρ du même cercle.

Cela posé, imaginons pour un instant qu'au lieu de *construire* la figure

---

(1) Ces deux manières de donner une conique sont équivalentes au point de vue qui nous occupe, car on peut (ex. 1175) construire, par la règle et le compas, les foyers d'une conique dont on connaît cinq points.

F′, on se propose de *calculer* les nombres N′ en supposant donnés les nombres N.

Dans ce but, il faudra former les conditions auxquelles doivent satisfaire les nombres N et N′ pour que les figures F et F′ aient entre elles les relations indiquées dans l'énoncé du problème : on aura ainsi un certain nombre d'équations qu'il faudra *résoudre* par rapport aux nombres N′. Cette résolution est un problème d'algèbre.

La condition nécessaire et suffisante pour que la figure cherchée F′ *puisse se construire à l'aide de la règle et du compas est que le calcul des nombres* N′ *puisse être effectué en ne résolvant que des équations du premier et du second degré, à une inconnue chacune* (ces équations successives étant d'ailleurs en nombre quelconque), *les coefficients de chacune d'elles étant supposés formés rationnellement avec :* 1° *des nombres* N ; 2° *des nombres déjà calculés à l'aide des équations précédentes ;* 3° *des nombres* **entiers** *connus* (¹).

Par exemple, le côté du pentagone régulier inscrit à un cercle de rayon donné R peut être construit à l'aide de la règle et du compas. Or ce côté est mesuré (Pl., **170**) par $\frac{R}{2}\sqrt{10 - 2\sqrt{5}}$ autrement dit sa valeur x est donnée par la résolution successive des équations du second degré :

$$(10\,R - z)^2 = 20\,R^2$$
$$\text{d'où } z = R\left(10 - 2\sqrt{5}\right)$$
$$4x^2 = Rz,$$

dont la première ne contient, dans ses coefficients, que le rayon donné R et les nombres entiers 10 et 20 ; la seconde, que le nombre z déjà calculé, le rayon R et l'entier 4.

792. Dans un grand nombre de cas, on trouve plus ou moins aisément (²) les conditions auxquelles doivent satisfaire les nombres N et N′ et on constate que ces conditions sont *algébriques*, c'est-à-dire s'expriment par un certain nombre d'équations de la forme

$$P = 0, \tag{23}$$

P désignant chaque fois un polynôme entier par rapport aux nombres N et N′, dont les coefficients sont des nombres entiers.

Exemple. — Dans le cas du problème des cercles tangents, les nombres cherchés α, β, ρ (voir au numéro précédent) seront déterminés par les équations

$$\begin{cases} (\alpha - a_1)^2 + (\beta - b_1)^2 = (R_1 \pm \rho)^2 \\ (\alpha - a_2)^2 + (\beta - b_2)^2 = (R_2 \pm \rho)^2 \\ (\alpha - a_3)^2 + (\beta - b_3)^2 = (R_3 \pm \rho)^2 \end{cases}$$

Si, au contraire, on s'est donné (comme nous l'avons supposé en second lieu) les

---

(1) Nous avons donné, en Géométrie plane (**155**), le moyen de construire une longueur donnée par une équation du second degré.

(2) Cette partie du problème est, en général, du ressort de la géométrie analytique.

distances mutuelles des points O_1, O_2, O_3, au lieu des coordonnées de ces mêmes points, on écrira les relations de contact

$$(24) \qquad x = \pm R_1 \pm \rho, \quad y = \pm R_2 \pm \rho, \quad z = \pm R_3 \pm \rho,$$

auxquelles on devra adjoindre l'équation obtenue en subtituant x, y, z, O_2O_3, $O_3 O_1$, $O_1 O_2$dans la relation (5′) (nº **612**).

On obtient bien ainsi quatre équations de la forme (23).

793. Si, après avoir formé ces équations, on réussit à les résoudre par le moyen d'équations du premier et du second degré satisfaisant aux conditions précédemment indiquées, on aura décidé dans le sens de l'affirmative la question posée : *Peut-on construire la figure* F′ *à l'aide de la règle et du compas?*

EXEMPLE. — Dans le problème des cercles tangents, si l'on remplace x, y, z (notations des deux numéros précédents) par leurs valeurs $\pm R_1 \pm \rho$, $\pm R_2 \pm \rho$, $\mp R_3 \pm \rho$ tirées de l'équation (24) et que l'on reporte ces valeurs dans l'équation (5′) du nº **612**, on aura pour ρ une équation du second degré (¹).

Le problème est donc bien résoluble.

Si, au contraire, les divers essais auxquels on peut se livrer pour effectuer cette solution échouent, cela peut provenir de ce que l'on a mal opéré ou, au contraire, de ce que cette résolution est impossible à obtenir. Rien, au premier abord, ne force à considérer l'une des deux explications comme la véritable plutôt que l'autre.

Il est clair que le problème qui consiste à décider entre ces deux explications est des plus difficiles. Il existe, en effet, une infinie variété de méthodes que l'on peut essayer d'appliquer à la résolution proposée, une infinité de manières dont on peut combiner des équations du premier et de second degré pour arriver à cette résolution, et il s'agit de savoir si *aucune* de toutes ces méthodes ou de ces combinaisons *imaginables* ne permet d'atteindre le but.

Aussi la réponse n'a-t-elle pu être fournie que dans ce siècle, par le moyen de la théorie des groupes (²) : cette théorie permet de décider en toute certitude la question précédente (toutes les fois que les conditions qui déterminent les N′ sont algébriques) : autrement dit, elle permet, — ou bien d'opérer la résolution demandée, — ou bien de démontrer en toute rigueur que cette résolution est impossible.

Parmi les problèmes dont l'impossibilité (au point de vue de la construction par la règle et le compas) a pu être ainsi démontrée, nous citerons :

(¹) C'est ce que l'on reconnaît en formant d'abord les binômes $y^2—z^2$, $z^2—x^2$, $x^2—y^2$ (qui figurent dans la relation du nº **612**) et constatant qu'ils sont du premier degré en ρ.

(²) La notion de *groupe* a été introduite, précisément en vue du problème dont nous parlons en ce moment et de problèmes analogues, par divers mathématiciens du commencement de ce siècle; mais les découvertes capitales sur ce sujet sont dues à GALOIS (savant français, mort à vingt ans (1826-1846)), qui a pu, grâce à elles, résoudre complètement les problèmes en question. En même temps, il reconnaissait l'importance générale de la notion de groupe, qui, depuis ses travaux, tend à jouer un rôle prépondérant dans toutes les parties des mathématiques.

Le problème de la *trisection de l'angle*, qui consiste à diviser un angle, donné arbitrairement, en trois parties égales (ou plus généralement, en un nombre quelconque de parties égales, ce nombre n'étant pas une puissance de 2);

Le problème de la *duplication du cube*, ou problème *délique* (¹), qui consiste à trouver un cube dont le volume soit double de celui d'un cube donné, — ou, d'une manière générale, à trouver deux lignes dont le rapport soit égal à $\sqrt[3]{n}$, n étant le rapport de deux lignes données (²) ;

Le problème de l'inscription du polygone régulier de N côtés, lorsque N n'appartient pas à l'une des catégories énumérées au n° **173** de la Géométrie plane;

La recherche des points communs à deux coniques données quelconques (³), ou (ce qui revient au même) celle de leurs sécantes communes ou celle de leurs pôles doubles;

La recherche des plans de symétrie et des sections circulaires d'un cône ayant pour base une conique (**757**) (⁴).

794. Problèmes transcendants.

L'impossibilité du problème est démontrée à plus forte raison, si l'on constate que les relations données ne peuvent pas s'exprimer par des équations algébriques à coefficients entiers (de la forme (23)) entre les données N et les inconnues N′. Le problème est alors dit *transcendant*.

Seulement, on peut se trouver en présence d'une difficulté tout analogue à celle que nous avons rencontrée tout à l'heure. Pour affirmer qu'un problème est transcendant, il faut *prouver* qu'il est impossible de déterminer les inconnues du problème par des équations algébriques de la forme indiquée.

On ne possède pas de méthode entièrement générale pour triompher de cette dernière difficulté.

Mais elle a pu être surmontée pour les deux principaux problèmes transcendants que nous ayons rencontrés en géométrie élémentaire, ceux qui sont relatifs aux nombres e et π. Les découvertes de MM. Hermite et Lindemann à cet égard ont précisément consisté à démontrer que *l'un comme l'autre de ces nombres n'est racine d'aucune équation algébrique à coefficients*

---

(1) La légende raconte qu'Apollon, pour faire cesser la peste qui ravageait l'île de Délos, aurait demandé que l'on doublât le volume de l'autel élevé en son honneur, et qui était de forme cubique : d'où le nom donné à ce problème.

(2) Ainsi que nous l'avons dit (ex. 1102, note), on est conduit, en algèbre, à réunir en une seule cette question et celle de la trisection de l'angle.

(3) On suppose, bien entendu, que les coniques sont données ainsi qu'il est expliqué au n° **789**. On voit ici qu'il n'est pas indifférent de savoir si l'on applique ou non la règle formulée en cet endroit : car si les coniques étaient entièrement tracées, le problème qui consiste à trouver leurs intersections serait tout résolu.

(4) Nous avons indiqué (particulièrement au livre II) un certain nombre de problèmes ayant pour objet la construction d'un triangle déterminé par trois éléments. Si l'on choisit ces trois éléments de toutes les façons possibles parmi les côtés, les hauteurs, les médianes, les bissectrices intérieures ou extérieures, les rayons des cercles circonscrits, inscrits et exinscrits, on obtient 244 questions (en ne comptant que celles qui sont véritablement distinctes les unes des autres). Sur ces 244, on constate que 69 au moins ne sont pas résolubles par la règle et le compas (*Korselt*, Archiv. der Math. und Phys., Leipzig, 1900.)

entiers. Par conséquent aussi il est impossible de construire avec la règle et le compas deux lignes dont le rapport soit égal à e ou deux lignes dont le rapport soit égal à π: c'est de là que ressort l'impossibilité de la quadrature du cercle.

La recherche de la longueur d'un arc de cercle donné quelconque est également un problème transcendant : il n'existe pas d'angle que l'on puisse construire avec la règle et le compas, en même temps que la longueur de l'arc qu'il intercepte sur un cercle de rayon donné.

795. Constructions effectuées par la règle seule.

Quels sont les problèmes de construction que l'on pourrait résoudre si, au lieu d'une règle et d'un compas, on ne pouvait employer que la règle ?

Avant de répondre à cette question, il est nécessaire de spécifier comment l'on entend l'emploi de la règle. Nous supposerons que celle-ci ait un bord rectiligne *et un seul*, l'instrument étant, dans tous les autres sens, terminé par des bords de forme inconnue, dont on s'interdit, d'ailleurs, de faire usage, de quelque façon que ce soit, au cours des constructions. Autrement dit, les seules opérations que nous pourrons effectuer avec notre règle seront les suivantes :

1° Tracer la droite qui passe par deux points donnés ;

2° Marquer le point commun à deux droites données.

Cela posé, nous considérerons encore la figure donnée F et la figure cherchée F′ comme déterminées par des nombres. Mais le choix entre les différents modes de levé possibles, choix qui était indifférent dans le cas où l'on pouvait se servir de la règle et du compas, ne l'est plus ici : nous supposerons essentiellement que les longueurs mesurées, pour déterminer les deux figures ne soient autres que les coordonnées de leurs différents points (voir n° **790**) par rapport à deux axes déterminés.

Dans ces conditions, *il faudra que les nombres inconnus* N′ *soient déterminés exclusivement par des équations du premier degré* formées rationnellement à l'aide des nombres connus N et de nombres entiers.

Cette condition est nécessaire ; mais elle n'est pas suffisante. Par exemple, le problème de *mener par un point donné* A, *une parallèle à une droite donnée* D, satisfait à cette condition (¹) : il est aisé, cependant, de voir que ce problème ne peut pas être résolu à l'aide de la règle seule.

Supposons, en effet, que l'on ait pu obtenir la solution dans ces conditions. Faisons la perspective de la figure considérée sur un autre plan P′ : le point A aura pour perspective un point A′ et la droite D, une droite D′.

Or les deux opérations précédemment indiquées comme exécutables avec la règle, sont toutes deux projectives. Par conséquent, la série des constructions effectuées dans le plan P, à partir du point A et de la droite

---

(1) C'est-à-dire qu'étant données les coordonnées du point A et celles de deux points de la droite D, on peut déterminer, par des équations du premier degré, les coordonnées d'un second point de la parallèle cherchée.

D aura pour image, sur le plan P′, une série de constructions toutes semblables effectuées à l'aide du point A′ et de la droite D′. Cette dernière série de constructions devrait dès lors fournir la parallèle menée par le point A′ à la droite D′ : ce qui est absurde, puisque nous savons que cette parallèle n'*est pas* la perspective de la parallèle menée par A à D.

Il est clair qu'on peut raisonner de même dans tout autre cas analogue, et que la conclusion est la suivante : *pour qu'un problème soit résoluble à l'aide de la règle seule, il faut que son énoncé ne contienne* (ou tout au moins *puisse être amené à ne contenir*) *que des propriétés projectives*, du moins *tant qu'on ne connaît, entre les éléments de la figure donnée, aucune relation non projective.*

796. Inversement, l'ensemble des deux conditions que nous venons d'indiquer : à savoir, *que le problème soit du premier degré* et *qu'il soit projectif*, est *suffisant* pour que la construction soit possible par la règle seule. C'est ainsi que l'on peut construire, avec la règle, l'homologue d'un point quelconque, dans une homographie déterminée par trois couples de points homologues (**645**) ; le conjugué harmonique d'un point d'une droite par rapport à un segment de cette droite (Pl., **203**) ; le second point d'intersection d'une conique avec une droite menée par un point connu de la courbe ; etc.

797. Ainsi que nous l'avons spécifié dans l'énoncé qui vient d'être donné, la conclusion peut se trouver modifiée si l'on connaît entre les éléments de la figure donnée une relation non projective.

Supposons, par exemple, que l'on donne quelque part dans le plan de la figure un parallélogramme. Alors on pourra mener, par un point quelconque, une parallèle à une droite quelconque (1) (voir ex. 895) ; par suite aussi, on peut (Pl., **151**) diviser une droite en segments proportionnels à des segments donnés *d'une même droite*, ou encore (en combinant cette construction avec l'exercice 129) diviser une droite donnée en un nombre quelconque donné de parties égales. D'une manière générale, on peut résoudre, dans ces conditions, *tout problème du premier degré dont l'énoncé se conserve par projection parallèle.*

798. Enfin si, dans le plan du dessin, on se donne un carré, il n'y a plus de condition de projectivité : il suffit que le problème soit du premier degré (exemple : mener d'un point une perpendiculaire sur une droite) (2).

---

(1) La possibilité de ce problème, dans les conditions indiquées, résulte de ce que le problème suivant : *mener, par un point donné, une droite coupant une droite donnée L en un point situé sur une droite* Δ *non directement donnée, mais qui passe par l'intersection de deux droites données* A, B *et par l'intersection de deux droites données* C, D, est possible par la règle seule (car il est du premier degré et projectif). Lorsque A et B sont parallèles entre elles ainsi que C, D, la droite Δ est la droite de l'infini, et on retombe sur le problème proposé. La seule difficulté nouvelle provient de ce qu'ici la droite Δ ne peut être tracée. On a vu, à l'exercice 895, que cette difficulté peut être tournée en construisant une figure homographique de la première et où l'homologue de Δ soit à distance finie.

(2) On peut concevoir que ce problème soit résoluble dans ces conditions par la règle seule, si l'on remarque que son énoncé peut être mis sous la forme suivante. *Étant donnés un*

799. On peut se demander également quelles constructions sont possibles à l'aide du compas seul. La réponse peut se donner en un mot : *on peut résoudre, par le compas seul, les mêmes problèmes qu'avec la règle et le compas* (1).

800. Admettons enfin qu'on n'ait à sa disposition qu'une règle, mais que cette règle ait *deux bords* que l'on sache *rectilignes et parallèles entre eux*. On démontre également que l'*usage de cet instrument remplace entièrement celui de la règle et du compas*. Il en est de même si, outre la règle (à un seul bord), on a à sa disposition une équerre, même si l'angle de cette équerre n'est pas droit, pourvu que ses bords soient bien rectilignes.

801. Enfin, rappelons que, dans ce que nous avons dit précédemment sur l'usage de la règle, nous avons supposé (d'une manière analogue à ce qui a été dit au n° **789** pour les problèmes constructibles par la règle et le compas) que les données comprenaient exclusivement des figures exécutables avec la règle seule, autrement dit, des droites et des points : les conclusions précédemment énoncées ne sont nécessairement vraies que moyennant cette restriction. C'est ainsi que nous avons appris (Pl., **211**) à tracer par la règle seule les tangentes menées d'un point à un cercle, problème qui n'est pas du premier degré : seulement le cercle était tracé d'avance.

On démontre qu'il suffit d'avoir tracé, une fois pour toutes, *un seul* cercle dont le centre soit connu, pour que tout problème constructible par la règle et le compas puisse être ensuite construit à l'aide de la règle seule.

NOTE F

SUR LA DÉFINITION DES VOLUMES

802. Nous avons admis dans le texte (liv. VI) qu'à chaque polyèdre on peut faire correspondre une grandeur appelée *volume*, possédant les deux propriétés suivantes :

I. *Deux polyèdres égaux ont le même volume, quelles que soient leurs situations dans l'espace.*

---

point P *et sept droites* A, A′, B, B′ (les côtés du carré), C, D (les diagonales), L (la droite donnée), *mener par le point* P *une droite* M, *telle que, sur la droite* Δ (ici, droite de l'infini) *qui joint le point d'intersection de* A, A′ *au point d'intersection de* B, B′, *les droites* A, B ; C, D ; L, M *interceptent trois segments en involution*. La difficulté provenant de ce que Δ ne peut être tracée se tourne comme précédemment (voir note précédente).

(1) Toutefois, bien entendu, si la figure cherchée comprend des droites, on doit considérer une de ces droites comme obtenue dès qu'on en connaît deux points.

II. *Le polyèdre* P'', *somme de deux polyèdres adjacents* P *et* P', *a pour volume la somme des volumes de* P *et de* P'.

Nous allons montrer qu'on peut effectivement réaliser une pareille correspondance. La marche suivie à cet effet sera toute semblable à celle que nous avons adoptée en Géométrie plane (note D), ce qui nous dispensera d'insister sur certains points que nous avons développés en cet endroit.

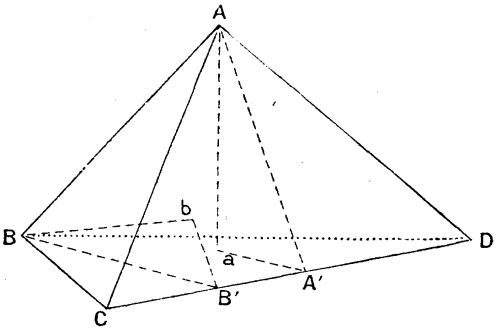

FIG. 644.

Théorème. — *Dans tout tétraèdre, chaque face, multipliée par la hauteur correspondante, donne le même produit.*

Considérons, dans le tétraèdre ABCD (*fig.* 644), les deux faces BCD, ACD, auxquelles correspondent respectivement les hauteurs Aa, Bb. Les deux triangles BCD, ACD, ayant la base commune CD, ont entre eux le même rapport que leurs hauteurs BB', AA'. Il suffit de montrer que ce rapport est inverse du rapport $\frac{Aa}{Bb}$, c'est-à-dire que l'on a

$$\frac{AA'}{Aa} = \frac{BB'}{Bb}.$$

Or c'est ce qui se voit dans les triangles AaA', BbB', rectangles, l'un en a, l'autre en b, et qui ont tous deux un angle aigu égal au dièdre A.CD.B, ou à son supplément (comparer **360**).

Donc on a aussi : $$\frac{\text{surf. BCD}}{\text{surf. ACD}} = \frac{Bb}{Aa}$$

ou $$Aa \times \text{surf. BCD} = Bb \times \text{surf. ACD}.$$

C. Q. F. D.

La valeur commune des produits précédents, multipliée par une constante numérique *K* dont nous choisirons la valeur un peu plus loin, sera dite le *volume* du tétraèdre. Ce volume est nul si les quatre points A, B, C, D sont dans un même plan, et dans ce cas seulement.

803. Nous allons maintenant démontrer la proposition qui correspond à celle que nous avons établie au n° **315** (Pl., note D). Mais, afin de ne pas avoir à distinguer un grand nombre de dispositions de figures, nous considérerons les volumes comme affectés de signes, d'après la convention suivante :

Nous désignerons par (ABCD) le volume du tétraèdre ABCD, précédé du signe + ou du signe —, suivant que ce tétraèdre est *direct* ou *rétrograde*, c'est-à-dire suivant que le trièdre A.BCD est direct ou rétrograde. Le signe de l'expression (ABCD) dépend évidemment de l'ordre dans lequel on nomme les quatre points A,B,C,D; il est aisé de voir qu'il change quand on permute deux d'entre eux (1).

804. Le signe de l'expression (ABCD) change lorsque A, B, C restant fixes, le point D change de côté par rapport au plan ABC, car alors le dièdre C.AB.D change le sens. Ce signe change dès lors aussi lorsque l'un quelconque des quatre points, A, par exemple, change de côté par rapport au plan des trois autres qui restent fixes, puisque (ABCD) est égal et de signe contraire à (DBCA).

Le point A restant fixe ainsi que le plan BCD, le signe de l'expression (ABCD) dépend (Pl., **20**) du sens de rotation du triangle BCD dans ce plan.

805. Théorème. — A, B, C, D, E *étant cinq points quelconques de l'espace, on a toujours*

$$(EBCD) + (AECD) + (ABED) + (ABCE) = (ABCD). \qquad (25)$$

1° Nous traiterons d'abord le cas particulier où le point E est dans le plan ABC (*fig.* 645). Le volume du tétraèdre EABC est alors nul et l'équation précédente pourra s'écrire (2)

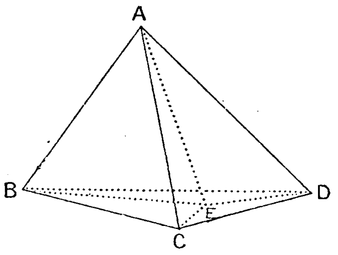

Fig. 645.

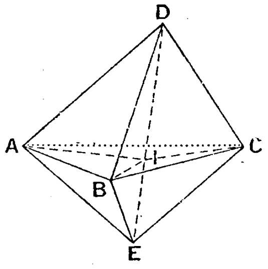

Fig. 646.

$$(EBCD) + (ECAD) + (EABD) = (ABCD).$$

Or les quatre tétraèdres EBCD, ECAD, EABD, ABCD ont la hauteur abaissée du point D commune. Leurs volumes seront donc proportionnels à leurs bases et les expressions (EBCD), (ECAD), (EABD), (EBCD) seront proportionnelles à ces mêmes bases affectées des signes + ou — suivant leurs sens de rotation (puisque ceux-ci correspondent (n° précédent) aux dispositions des tétraèdres). Or, dans ces conditions, nous savons que la base ABC est la somme algébrique des bases EBC, ECA, EAB (Pl., **315**).

---

(1) Cela est évident (**371**) si, parmi les sommets permutés ne figure pas A ; d'autre part, si A est permuté avec C, par exemple, le dièdre B.AC.D changera de sens (puisque, les faces étant les mêmes et nommées dans le même ordre, on aura changé le sens choisi sur l'arête) : or le sens de ce dièdre décide de la disposition du trièdre A.BCD.

(2) L'expression (ECAD), par exemple, est égale à (AECD), car toutes deux sont (**803**) égales et de signe contraire à (EACD).

2° Passons maintenant au cas général. Soit I le point de rencontre de la droite DE et du plan ABC (*fig.* 646); on aura (1°)

$$(26) \qquad (IBCD) + (AICD) + (ABID) = (ABCD).$$

Mais, E étant dans les plans ADE, BDI, CDI, ABC, on a aussi

$$\begin{aligned} (IBCD) &= (EBCD) + (IECD) + (IBED) + (IBCE) \\ (AICD) &= (EICD) + (AECD) + (AIED) + (AICE) \\ (ABID) &= (EBID) + (AEID) + (ABED) + (ABIE) \\ 0 = (ABCI) &= (EBCI) + (AECI) + (ABEI) + (ABCE) \end{aligned}$$

Portant ces valeurs dans l'équation (26), il vient bien

$$(ABCD) = (EBCD) + (AECD) + (ABED) + (ABCE)$$

[Tous les autres termes se détruisent deux à deux comme dérivant l'un de l'autre par permutation des lettres I et E (par exemple (IECD) et (EICD)].

806. Corollaire. — Si l'on convient d'appeler *additif* ou *soustractif* (comparer Pl., **315**) chacun des tétraèdres EBCD, AECD, ABED, ABCE, suivant qu'il est ou non du même côté que le tétraèdre ABCD, par rapport à la face commune, le volume du tétraèdre ABCD est égal à la somme des volumes des tétraèdres additifs, diminuée de celle des tétraèdres soustractifs.

En effet, dans l'équation (25), supposons que l'ordre des points ABCD ait été pris tel que le tétraèdre ABCD soit direct. Les expressions (EBCD),... seront positives ou négatives suivant que la disposition des tétraèdres correspondants sera ou non la même que celle du tétraèdre ABCD, c'est-à-dire suivant qu'ils seront additifs ou soustractifs.

Inversement, le théorème du n° **315** donne, entre quatre points d'un plan, la relation

$$(OBC) + (OCA) + (OAB) = (ABC)$$

où (ABC) est l'aire du triangle ABC précédée du signe + ou du signe —, suivant le sens de rotation de ce triangle.

807. On appellera *volume d'une pyramide quelconque* le produit de la base par la hauteur et par la constante K. Il est évident que ce volume est la somme des tétraèdres obtenus en décomposant la base en triangles d'une façon quelconque.

808. Théorème. — *Soient un polyèdre décomposé, d'une façon quelconque, en un nombre quelconque de tétraèdres, et un point quelconque O de l'espace, que l'on joint à tous les sommets. Une quelconque des pyramides qui ont pour sommet commun O et pour bases respectives les faces du polyèdre étant considérée comme additive ou comme soustractive, suivant qu'elle est ou non du même côté que le polyèdre, par rapport à la face commune, la différence S entre la somme des volumes des pyramides additives et la somme des volumes* *des pyramides soustractives* (s'il en existe) *est égale à la somme* Σ *des tétraèdres en lesquels le polyèdre a été décomposé.*

Corollaire. — *La quantité* S *est indépendante du choix du point* O *et la quantité* Σ, *du mode de décomposition du polyèdre en tétraèdres.*

Démonstrations calquées sur celles du n° **316**.

La quantité ainsi définie sera dite le *volume* du polyèdre : elle possède les deux propriétés fondamentales énoncées tout à l'heure (comparer **317**).

Les volumes ainsi définis coïncident avec ceux que nous avons mesurés dans le texte, lorsqu'on prend $K = \frac{1}{3}$: c'est la valeur que doit avoir cette constante pour que le cube d'arête 1 ait son volume égal à l'unité. Les raisonnements donnés dans le texte prouvent qu'il n'y a qu'une seule manière de déterminer les volumes de manière à satisfaire à cette condition et à celles que nous avions imposées en commençant.

Il est impossible de décomposer un polyèdre en polyèdres partiels qui, autrement assemblés, forment un polyèdre intérieur au premier. Cette proposition résulte des raisonnements que nous venons de présenter et non de ceux du livre VI (comparer **318**).

NOTE G

SUR LES NOTIONS DE LONGUEUR, D'AIRE ET DE VOLUME RELATIVES A DES LIGNES ET A DES SURFACES QUELCONQUES

809. Longueur d'un arc de courbe gauche.

Un arc AB d'une courbe gauche (C) étant donné, projetons-le orthogonalement sur un plan quelconque, suivant un arc *ab* (*fig*. 643) d'une courbe (*c*). Supposons que la définition de la longueur d'une courbe plane donnée dans la note de la page 173 (Pl., liv. III) s'applique à la courbe (*c*) : on pourra, en d'autres termes, mesurer la longueur d'un arc quelconque de (*c*). Si les hypothèses énumérées dans la note en question sont vérifiées, le rapport d'un arc de (*c*) à sa corde tendra vers l'unité quand l'arc tendra vers zéro ; et même, $1 + \alpha$ étant un nombre aussi peu supérieur qu'on le veut à 1, on pourra toujours (¹) trouver un nombre ε tel que, pour tous

---

(¹) En effet la longueur d'un arc *pq* faisant partie de *ab* est (la courbe *ab* étant supposée convexe le long de cet arc) plus petite que la somme des tangentes en *p* et en *q*, prolongées jusqu'à leur point d'intersection et les hypothèses faites à l'endroit cité de la Géométrie plane les arcs faisant partie de l'arc ab et dont la corde est moindre que ε, ce rapport soit plus petit que $1 + \alpha$. Nous pourrons développer sur un plan (**538**) le cylindre qui projette la courbe AB, celle-ci venant suivant une nouvelle courbe A_1B_1 et sa projection ab suivant un segment de droite a_1b_1 (*fig.* 647) égal à la longueur de l'arc ab. Supposons que la définition de la longueur d'un arc de courbe plane s'applique également au développement de (c) et soit l la longueur de l'arc A_1B_1.

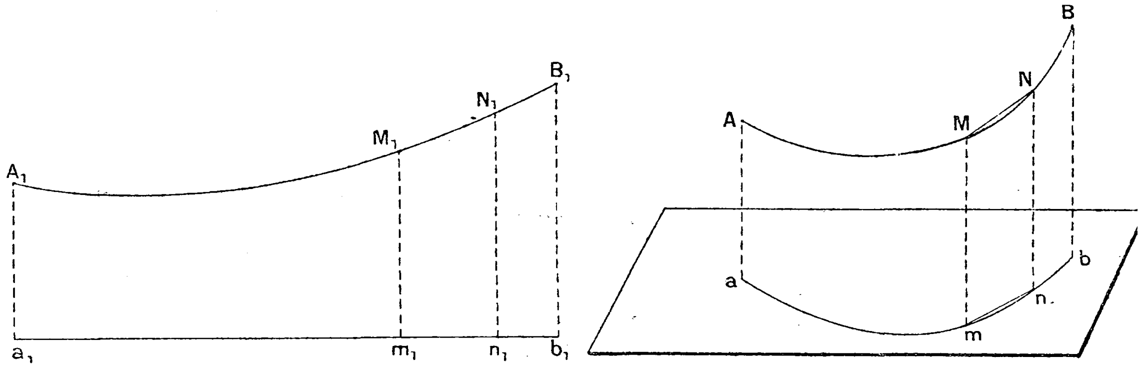

FIG. 647.

Dans ces conditions, je dis que le *périmètre d'une ligne polygonale inscrite à l'arc* AB *et ayant ses extrémités en* A *et* B *tend vers* l, *lorsque le nombre des côtés de cette ligne brisée augmente indéfiniment de manière que chacun d'eux tende vers zéro.*

Soient, en effet, M, N deux sommets consécutifs de la ligne polygonale ; m, n leurs projections sur le plan de (c) ; M_1, N_1, m_1, n_1, les points correspondants à M, N, m, n dans le développement du cylindre. On a $m_1M_1 = mM$; $n_1N_1 = nN$; mais mn, corde d'un arc de (c), est plus petit que m_1n_1 (lequel est égal à la longueur de cet arc).

Portons le trapèze $mMnN$ en $m_1M_1n'N'$ sur le trapèze $m_1M_1n_1N_1$ (*fig.*643 *bis*) de manière que mM vienne suivant m_1M_1 et mn suivant la direction m_1n_1. On aura évidemment $MN = M_1N' < M_1N_1$; mais *le rapport* $\frac{M_1N_1}{M_1N} = \frac{M_1N_1}{MN}$ *sera plus petit que le rapport* $\frac{m_1n_1}{m_1n'}$ (c'est-à-dire que $\frac{m_1n_1}{mn}$). Car $\frac{M_1N_1}{M_1N'} - 1$ ou $\frac{M_1N_1 - M_1N'}{M_1N'}$ est plus petit que $\frac{N\,N'}{M_1N'}$, lequel est à son tour plus petit que $\frac{nn'}{m_1n'}$, c'est-à-dire que $\frac{m_1n_1}{m_1n'} - 1$.

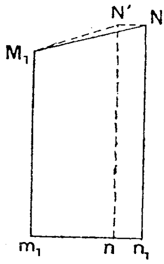

FIG. 647 *bis*.

Or nous avons vu que l'on pouvait rendre le rapport $\frac{m_1n_1}{mn}$ plus petit que $1 + \alpha$, quel que soit le nombre positif α, et qu'il suffisait, pour cela, de

consistent précisément à admettre que le rapport de cette somme à la corde pq devient plus petit que $1 + \alpha$, toutes les fois que l'arc pq, intérieur à ab, a une corde inférieure à une quantité convenablement choisie ε.

prendre mn inférieur à une certaine quantité ε. Si donc nous avons pris tous les côtés MN de la ligne polygonale (et par conséquent, *a fortiori*, toutes les cordes mn) inférieures à ε, tous les rapports tels que $\frac{M_1N_1}{MN}$ sont plus petits que $1 + \alpha$: d'après une proposition souvent rappelée d'arithmétique, il en est de même du rapport formé avec la longueur de la ligne brisée $A_1 \dots M_1N_1 \dots B_1$, somme de toutes les cordes M_1N_1, et la longueur de la ligne polygonale A... MN... B, dont nous sommes partis et qui est la somme des cordes telles que MN.

Autrement dit (puisque α peut être pris aussi petit qu'on veut) le rapport $\frac{A_1 \dots M_1N_1 \dots B_1}{A. \; M\,N \dots B}$ tend vers 1, lorsque les côtés de la ligne polygonale A,.. M N... B tendent tous vers zéro.

Or le numérateur tend, par hypothèse, vers l : il en est donc de même du dénominateur. C. Q. F. D.

Il résulte de là, en particulier, qu'en projetant la courbe (c) sur un plan différent du premier et répétant les mêmes opérations dans ces nouvelles conditions, la longueur l trouvée ne pourrait avoir une valeur autre que la première.

La longueur l, limite vers laquelle tend le périmètre d'un polygone inscrit à l'arc AB et dont tous les côtés tendent vers zéro, est dite la *longueur de l'arc de courbe* AB. Il est clair, d'après ce qui précède, que, *si on développe un cylindre sur un plan, toute ligne tracée sur la surface a même longueur que son développement.*

La ligne droite est, dans l'espace, le plus court chemin d'un point A *à un autre* B. Car tout autre chemin est, soit une ligne brisée, plus longue que la ligne droite, soit une ligne courbe dont la longueur est la limite d'une ligne brisée (¹).

Le rapport d'un arc de courbe gauche à sa corde tend vers l'unité lorsque l'arc tend vers zéro, car l'arc MN de la courbe AB (*fig.* 647) est égal à l'arc M_1N_1 de la courbe A_1B_1 ; le rapport $\frac{\text{arc } M_1N_1}{\text{corde } M_1N_1}$ tend vers l'unité et nous avons vu qu'il en est de même pour le rapport $\frac{\text{corde } M_1N_1}{\text{corde } MN}$.

810. Plus court chemin d'un point à un autre sur la sphère.

Appliquons ce qui précède à une ligne sphérique AB. Inscrivons dans cette ligne le polygone A... MN... B, puis remplaçons chaque côté par l'arc de grand cercle qui a mêmes extrémités : nous obtenons ainsi une ligne composée d'arc de grands cercles successifs, ou *ligne brisée sphérique*.

Lorsque les côtés du polygone tendent vers zéro, le rapport de chaque

---

(1) La longueur de la ligne courbe ne peut être *égale* à celle de la ligne droite, car, si C est un point extérieur à la droite, mais situé sur la courbe, celle-ci est au moins égale à AC + BC, lequel est plus grand que la droite AB.

arc de grand cercle à la corde correspondante tend vers 1, et il en est de même, par conséquent, du rapport de la ligne brisée sphérique à la ligne brisée rectiligne, de sorte que ces deux quantités ont même limite. Ainsi *la longueur d'une courbe sphérique est la limite vers laquelle tend la longueur d'une ligne brisée sphérique inscrite, dont tous les côtés tendent vers zéro.*

L'arc de grand cercle qui joint A et B est plus court que toute ligne brisée sphérique joignant les mêmes points. Il est donc aussi plus court que toute courbe sphérique allant de A en B : *l'arc de grand cercle est le plus court chemin entre deux points de la sphère.*

811. Considérons un cône quelconque, ou la portion d'un cône comprise entre deux génératrices OA, OB (*fig.* 648). Une sphère quelconque décrite du sommet O comme centre coupera ce cône suivant une ligne sphérique AB. Ayant décrit dans un plan, d'un point quelconque O_1 comme centre, un cercle de même rayon que la sphère, et pris sur la circonférence un point arbitraire A_1, nous ferons correspondre, à un point quelconque M de la ligne sphérique, le point M_1 pris sur la circonférence de manière que l'arc de cercle A_1M_1 ait même longueur que l'arc AM de la ligne sphérique; puis à chaque point P de la surface conique, le point P_1 pris à une distance de O_1 égale à OP, sur un rayon tel que son extrémité M_1 corresponde (au sens que nous venons d'indiquer) au point M où la génératrice OP coupe la sphère.

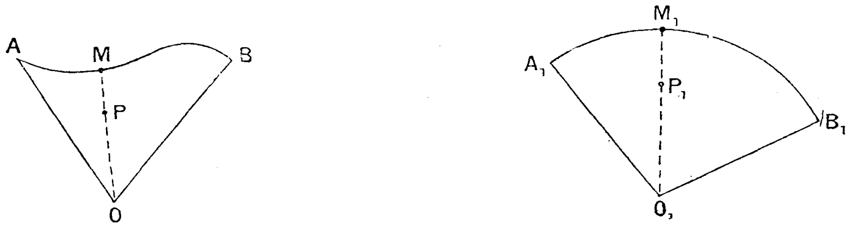

Fig. 648.

La figure formée par les points tels que P_1 est dite le *développement* de la surface conique. Le lecteur démontrera aisément, par des procédés analogues à ceux que nous avons employés pour le cylindre : 1° que *toute ligne tracée sur le cône a même longueur que son développement ;* 2° que *deux lignes se coupent sous le même angle que leurs développements.*

812. On dit qu'une surface est *développable* lorsqu'on peut faire correspondre ses points à ceux d'un plan de manière que les lignes qui se correspondent aient même longueur de part et d'autre. C'est ce qui a lieu pour le cylindre et le cône. Il existe une infinité d'autres surfaces développables. Mais il faut se garder de croire que cette propriété appartienne à une surface quelconque : pour une surface prise au hasard, au contraire, elle n'a, en général, pas lieu. La sphère, par exemple, ne la possède pas.

C'est ce dont on peut se rendre compte en considérant les angles que font entre elles les lignes tracées sur une surface développable.

Soient S une telle surface ; Ax, Ay (*fig.* 649) deux lignes concourantes de S, auxquelles correspondent, lorsque cette surface est développée sur un plan (ce que nous supposons possible), les deux lignes A_1x_1, A_1y_1. Coupons Ax, Ay par une troisième ligne BC, ayant pour développement B_1C_1 et supposons que les points B et C se rapprochent indéfiniment du point A. Dans ces conditions, les directions des lignes AB, AC ; A_1B_1, A_1C_1 tendent respectivement vers celles des tangentes aux lignes Ax, Ay, A_1x_1, A_1y_1 en A et en A_1. De plus, les rapports des arcs AB, AC, A_1B_1, A_1C_1 aux cordes correspondantes tendront vers l'unité.

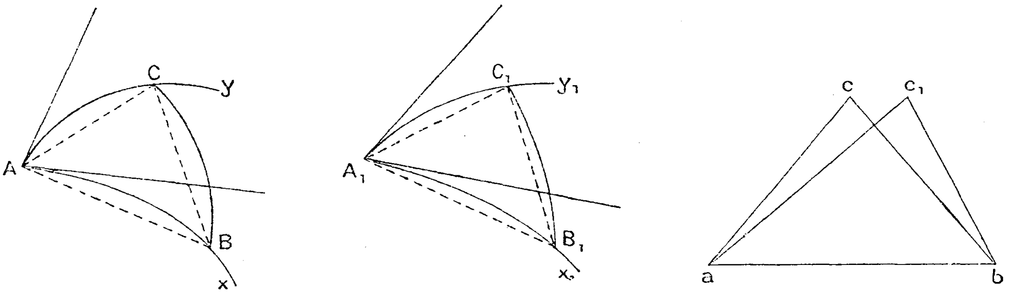

FIG. 649.

Nous ne pouvons pas étendre cette conclusion aux arcs BC, B_1C_1, puisque les courbes BC et B_1C_1 sont variables. Mais on démontre que, moyennant certaines restrictions simples imposées à S, on peut choisir les courbes variables BC, B_1C_1, de manière que les rapports des arcs BC, B_1C_1 à leurs cordes respectives tendent vers 1 et que, de plus, le rapport $\frac{AB}{AC}$ tende vers une limite.

En tout cas, si S était une sphère, un tel choix serait assurément possible : il suffirait de prendre pour BC un arc de grand cercle(1).

Mais d'après l'hypothèse, les arcs AB et A_1B_1 ont même longueur, de même que AC, A_1C_1 et BC, B_1C_1. Donc le rapport de la corde AB à la corde A_1B_1 tend vers l'unité, et il en est de même pour chacune des cordes AC, BC et sa correspondante.

Par conséquent, si, sur une droite fixe ab comme base, nous construisons un triangle abc semblable à ABC et un triangle abc_1 semblable à $A_1B_1C_1$, le point c tendra vers une position limite (puisque les rapports $\frac{AC}{AB}$, $\frac{BC}{AB}$ admettent chacun une valeur limite) et le point c_1 tendra vers la même limite (puisque $\frac{ac}{ac_1} = \frac{AC}{A_1C_1} : \frac{AB}{A_1B_1}$ tend vers l'unité, et de même $\frac{bc}{bc_1}$). Donc l'angle $\widehat{bac} = \widehat{BAC}$ tend vers la même limite que $\widehat{bac_1} = \widehat{B_1A_1C_1}$: autrement dit, l'angle des deux courbes A_1x_1, A_1y_1 est égal à celui des deux courbes Ax, Ay. Ainsi, il devra toujours arriver (comme nous l'avons trouvé dans les cas du cône et du cylindre) que l'angle de deux courbes quelconques de la surface soit égal à celui de leurs développements.

---

(1) On va voir, au numéro suivant que, dans ces conditions, B_1C_1 est un segment de droite.

813. Cela posé, admettons que la surface S soit une sphère. Alors la ligne la plus courte entre deux points de la sphère devra évidemment avoir pour image la ligne la plus courte entre deux points du plan : autrement dit, les grands cercles de la sphère auront pour images les droites du plan et un triangle sphérique aura pour image un triangle rectiligne du plan. Or cela est absurde, puisque la somme des angles d'un triangle rectiligne est égale à deux droits et celle des angles d'un triangle sphérique, toujours plus grande que deux droits.

Donc la sphère, ou même n'importe quelle aire sphérique, si petite qu'elle soit (puisqu'on pourra toujours y trouver un triangle sphérique), ne pourra jamais être développée sur le plan (1).

814. Volumes limités par des surfaces courbes.

Soit une portion d'espace S limitée par des surfaces quelconques.

Supposons que nous puissions trouver deux séries indéfinies de polyèdres $P_1, P_2, \ldots, P_n, \ldots$; $Q_1, Q_2, \ldots, Q_n, \ldots$ satisfaisant aux conditions suivantes :

1° Quel que soit n, le polyèdre (2) P_n n'a aucun point extérieur à S (tout ou partie des sommets, ou des arêtes ou même des faces de P_n pouvant faire partie des surfaces limites de S);

2° Quel que soit n, l'espace S n'a aucun point extérieur à Q_n (une partie quelconque de la surface limite de S pouvant être sur la surface de Q_n);

3° La différence $Q_n - P_n$ des volumes des deux polyèdres de même indice tend vers zéro lorsque cet indice n augmente indéfiniment; ou encore, le rapport $\frac{Q}{P_n}$ tend vers l'unité dans les mêmes conditions.

Alors je dis que *les volumes* P_n, Q_n *tendent vers une limite commune* V.

Pour le démontrer, je remarque tout d'abord que tout polyèdre Q_n de la seconde série renferme tout polyèdre P_n de la première à son intérieur et que, par conséquent, tout volume de la seconde série est plus grand que n'importe quel volume de la première.

Cela posé, supposons d'abord que, parmi les P_n, il y en ait un, P_α, plus grand que tous les suivants (ou au moins égal à l'un quelconque d'entre eux)

Alors, lorsque l'indice n est plus grand que α, les quantités Q_n, P_n comprennent entre elles P_α et comme leur différence tend vers zéro ou leur rapport vers 1, il est évident qu'elles tendent vers la limite commune P_α.

Supposons, en second lieu, que jamais une des quantités P_n ne soit plus grande que toutes les suivantes : autrement dit, si nous prenons une quelconque d'entre elles, soit P_α, il en existera une suivante, P_β, plus grande que P_α; puis une autre, P_γ, suivant P_β, et plus grande que P_β ; et ainsi de suite indéfiniment.

---

(1) De même, deux sphères de rayons différents ne sont pas *applicables* l'une sur l'autre, c'est-à-dire qu'il est impossible de faire correspondre point par point une portion de l'une à une portion de l'autre, de manière que les lignes qui se correspondent aient même longueur.

(2) Nous ne supposerons pas que le polyèdre P_n soit nécessairement d'un seul tenant : on pourra prendre, pour P_n, l'ensemble de plusieurs polyèdres non contigus, pourvu que ces polyèdres et leur volume total vérifient les conditions indiquées dans le texte. Nous aurons plus loin (**815** *bis*) à utiliser cette remarque.

Puisque les quantités P_α, P_β, P_γ, ... vont en croissant et qu'elles restent inférieures à une quantité déterminée (à savoir l'une quelconque des Q_n), elles tendent vers une limite V, et les quantités Q_α, Q_β, Q_γ, ... tendent également vers V (puisque les différences $Q_\alpha - P_\alpha$, $Q_\beta - P_\beta$, $Q_\gamma - P_\gamma$, ... ont pour limite zéro ou que les rapports $\frac{Q_\alpha}{P_\alpha}$, ... ont pour limite 1).

V est au moins égal à chacun des P_n (puisqu'il est la limite de la suite Q_α, Q_β, Q_γ, ..., dont tous les termes sont supérieurs à P_n) et au plus égal à chacun des Q_n (comme limite de la suite P_α, P_β, P_γ, ...). Donc il est la limite commune de P_n et de Q_n, puisqu'il est constamment compris entre ces deux quantités, dont la différence tend vers zéro ou le rapport vers 1.

C. Q. F. D.

De plus, *si on forme, d'une manière quelconque, deux autres séries de polyèdres,* P'_n *et* Q'_n, *satisfaisant* (*comme* P_n et Q_n) *aux conditions précédemment indiquées par rapport à la même portion d'espace* S, *la limite commune de* P'_n *et de* Q'_n *aura la même valeur* V *que la limite commune de* P_n *et de* Q_n.

Cette proposition n'est pas distincte de la précédente : car on peut former une suite comprenant alternativement des polyèdres P_n et des polyèdres P'_n, ainsi qu'une composée des polyèdres Q_n et Q'_n correspondants : ces deux suites mixtes satisferont aux mêmes conditions que les premières et auront, par conséquent, une limite commune, ce qui ne se peut que si P_n et P'_n, Q_n et Q'_n ont la même limite.

La quantité V, limite des volumes P_n et des volumes Q_n, et indépendante (d'après ce que nous venons de constater) de la manière dont on choisit ceux-ci (pourvu que les uns comprennent S, que les autres soient compris dans S et que la différence des uns et des autres tende vers zéro ou leur rapport vers 1) est dite le *volume* de l'espace S. Il est clair que la notion de volume, une fois définie, possédera les propriétés indiquées au livre VI (**397**) ; c'est-à-dire que deux espaces égaux ont le même volume et que l'espace formé par la réunion de deux espaces contigus aura un volume égal à la somme de leurs volumes (¹).

815. Il reste à savoir si, une portion d'espace S étant donnée, on peut trouver les polyèdres P_n et Q_n satisfaisant aux conditions indiquées.

Supposons que, à l'intérieur de S, on puisse trouver un point O tel que la droite qui le joint à un point quelconque de la surface limite de S (cette droite n'étant pas prolongée au delà de O) ne perce cette surface limite en aucun point. Soit S' l'homothétique de S par rapport au point O, avec un rapport d'homothétie $1 - \varepsilon$ plus petit que l'unité; S'', l'homothétique de S par rapport au centre O, avec le rapport de similitude $1 + \varepsilon$: il est clair

---

(1) Sur ce dernier point, voir plus loin, **815** *bis*.

que chacun des solides S′, S, S″ est entièrement intérieur au suivant. Soit alors R un polyèdre intérieur à S″, mais comprenant S′ à son intérieur. L'homothétique P de R par rapport à O avec le rapport d'homothétie $\frac{1}{1+\varepsilon}$ sera intérieur à S (puisque R est intérieur à S) ; et l'homothétique Q de R par rapport à O, avec le rapport d'homothétie $\frac{1}{1-\varepsilon}$ comprendra S à son intérieur (puisque R comprend S″). D'ailleurs le rapport des volumes de P et de Q est (**431**) égal à $\left(\frac{1-\varepsilon}{1+\varepsilon}\right)^3$ et tend vers 1 lorsque ε tend vers zéro.

Dès lors, si on donne à ε une série de valeurs qui tendent vers zéro, et si, pour chacune de ces valeurs, on construit le polyèdre R et, par conséquent, les polyèdres P et Q, on a une double série de polyèdres remplissant toutes les conditions demandées.

815 *bis*. Si la forme de la région S est telle que le raisonnement précédent ne s'y applique pas, on pourra, en général, la décomposer en deux ou plusieurs régions partielles auxquelles il soit applicable. On formera alors chaque polyèdre P avec l'ensemble des polyèdres P relatifs à ces régions partielles (¹) et le polyèdre Q avec l'ensemble des polyèdres Q relatifs à ces mêmes régions.

816. Soit *d* la distance minima de la surface limite de S à celle de S′ et à celle de S″, c'est-à-dire une quantité telle que tout point de la première soit au moins à la distance *d* de tout point de la seconde et au moins à la distance *d* de tout point de la troisième.

Inscrivons à la surface limite de S un polyèdre comprenant le point O à son intérieur et tel que la plus grande dimension de chaque face soit inférieure à *d*. Alors la surface de ce polyèdre ne pourra évidemment avoir aucun point commun avec la surface de S″, ni avec la surface de S′, ni même avec l'intérieur de S′. Donc ce polyèdre est compris dans S″ et comprend S′ : on peut le prendre pour le polyèdre R du numéro précédent, et si l'on forme de pareils polyèdres pour des valeurs de plus en plus petites de ε, leurs volumes tendent vers V.

Comme ε tend vers zéro avec *d*, on voit que, *si l'on inscrit à la surface limite de* S *un polyèdre* (*comprenant toujours à son intérieur un point déterminé intérieur à* S) *et tel que la plus grande dimension de chacune de ses faces tende vers zéro, le volume de ce polyèdre tendra vers le volume de* S. On voit d'ailleurs immédiatement que cette conclusion s'étend au cas où l'on ne peut appliquer directement le raisonnement du n° **815** et où on est obligé de décomposer S en deux ou plusieurs parties comme il est expliqué au n° **815** *bis*.

Lorsqu'il s'agit de la sphère, on peut prendre pour le point O le centre et les solides S′ S″ seront des sphères concentriques à la première. La distance *d* sera la différence des rayons de S et de S′ et on pourra prendre,

---

(1) Voir la note 2, page 535.

pour R, tout polyèdre inscrit dont les dimensions sont toutes plus petites que cette différence (1).

817. Dans le cas du cône ou du cylindre, la définition précédente concorde avec celles que nous avons données au livre VIII. Prenant, par exemple, le cas du cylindre, il est clair que les prismes inscrits et circonscrits sont précisément des polyèdres P_n et Q_n tels que nous les avons introduits au n° **815**.

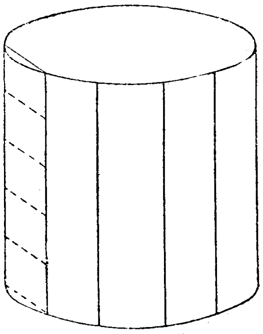

Fig. 651.

D'ailleurs, le prisme inscrit tel que les côtés de sa base tendent vers zéro, peut être considéré comme un polyèdre inscrit dans lequel la plus grande dimension de chaque face tend vers zéro. Il suffira, à cet effet, de diviser chaque arête latérale du prisme en un certain nombre de parties égales, lequel nombre ira en augmentant indéfiniment en même temps que le nombre des côtés de la base (*fig.* 651). Les points de division feront partie, comme les sommets extrêmes eux-mêmes, de la surface cylindrique, et, par conséquent, les petits rectangles qu'ils forment (*fig.* 651) pourront être considérés comme faces d'un polyèdre inscrit, — plusieurs de ces faces étant seulement en prolongement les unes des autres, ce qui ne change rien à la validité des raisonnements.

Des considérations toutes semblables s'appliquent évidemment au cône.

818. Considérons, de même, le volume V engendré par un polygone plan tournant autour d'un axe situé dans son plan et qui ne le traverse pas.

Considérons p positions du polygone, ABCD, A′B′C′D′ (*fig.* 652) étant,

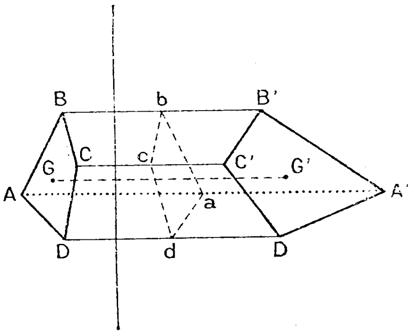

Fig. 652.

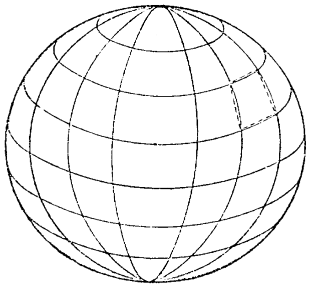

Fig. 650.

---

(1) Par exemple, on pourra diviser la sphère par des méridiens et des parallèles (*fig.* 650) dont les longitudes ou les latitudes diffèrent entre elles d'une quantité λ telle que l'arc de grand cercle d'angle au centre λ ait une longueur inférieure à d. Les points d'intersection de ces méridiens et de ces parallèles seront les sommets d'un polyèdre inscrit dont toutes les faces, qui seront des trapèzes ou des triangles, auront leurs dimensions plus petites que d.

par exemple, deux consécutives d'entre elles. Les polygones ABCD, A'B'C'D' sont symétriques l'un de l'autre par rapport à un plan, le plan bissecteur du dièdre dans les faces duquel ils sont respectivement contenus. Il existe donc un tronc de prisme qui a pour base ces deux polygones, les arêtes étant perpendiculaires à ce plan de symétrie. Considérons le polyèdre formé par l'ensemble des troncs de prismes qui ont ainsi pour bases les couples de positions consécutives du polygone. Si nous augmentons indéfiniment le nombre de ces positions de manière que les dièdres successifs que forment entre elles leurs plans tendent vers zéro, le volume du polyèdre dont nous venons de parler tendra vers V, ainsi qu'il résultera de considérations toutes pareilles à celles que nous venons de présenter au n° précédent.

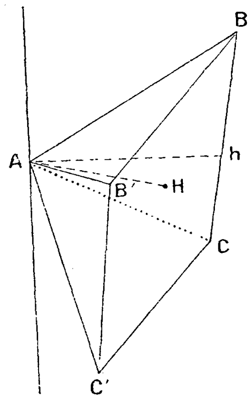

Fig. 653.

Cette remarque permet de démontrer très simplement certaines propositions importantes. Supposons, par exemple, que le polygone considéré soit un triangle ABC ayant son sommet A sur l'axe, alors les troncs de prismes se réduiront à des pyramides telles que ABCB'C' (*fig.* 653).

Chacune de ces pyramides a pour mesure le tiers du produit de sa base BCB'C' par sa hauteur AH, de sorte que leur somme est égale au tiers de la somme des bases multipliée par une quantité intermédiaire entre la plus petite et la plus grande des hauteurs. Or, lorsqu'on augmente indéfiniment le nombre des positions successives du triangle, la somme des trapèzes BCB'C' tend vers la surface engendrée par BC dans sa révolution autour de l'axe, et quant à la hauteur AH, elle tend vers la hauteur A*h* du triangle ABC, car la distance *h*H, qui est la distance du point H à la droite BC, tend vers zéro.

Nous avons donc immédiatement le théorème du n° **485** : *le volume engendré par un triangle tournant autour d'un axe situé dans son plan, passant par son centre et ne le traversant pas, est égal à la surface engendrée par le côté opposé au sommet situé sur l'axe, multipliée par le tiers de la hauteur correspondante.*

819. Revenons au cas où le polygone tournant est quelconque : la remarque précédente nous donne encore (du moins pour le cas d'un polygone) le *théorème de Guldin.*

Théorème. — *Le volume engendré par une aire plane qui tourne autour d'un axe situé dans son plan et ne le traversant pas, est égal au produit de cette aire par la circonférence que décrit son centre de gravité.*

Soient, en effet, G le centre de gravité du polygone ABCD, G' le centre de gravité de la position suivante A'B'C'D' (*fig.* 652).

Le tronc de prisme ABCDA'B'C'D' a pour mesure (**608**) le produit de sa section droite par la distance GG'.

Or la section droite, qui n'est autre que la section par le plan bissecteur du dièdre formé par les bases, tend vers le polygone ABCD lui-même et, d'autre part, la somme de toutes les longueurs telles que GG' tend vers la longueur de la circonférence décrite par le point G. Donc le théorème est démontré.

820. Nous avons défini le volume V d'un solide quelconque par cette propriété que deux volumes polyédraux P_n et Q_n, dont le premier est intérieur au solide et dont le second comprend ce solide, tendent vers V lorsque leur différence tend vers zéro. Mais il est clair, une fois V défini, que deux volumes quelconques, polyédraux ou non, tendront vers V s'ils satisfont aux autres conditions imposées à P_n et à Q_n, puisque l'un sera toujours plus petit que V et l'autre plus grand que V.

Soit, par exemple, une aire plane curviligne A tournant autour d'un axe qui est situé dans son plan et ne la traverse pas. Inscrivons et circonscrivons à cette aire des polygones qui auront A pour limite commune. Ces polygones, en tournant autour de l'axe, engendreront des volumes dont les uns seront inscrits au volume V engendré par A, les autres circonscrits au même volume, et la différence entre les volumes inscrits et les volumes circonscrits tendra vers zéro (1). Donc ces volumes auront V pour limite.

On voit par là que la définition des volumes du secteur sphérique et de la sphère, telle que nous l'avons donnée au livre VIII (chap. v), concorde avec la définition actuelle.

On voit aussi que le théorème de Guldin, démontré au numéro précédent pour les polygones, est également vrai pour les aires planes curvilignes, si l'on admet que le centre de gravité de l'aire plane considérée est la position limite vers laquelle tend le centre de gravité d'un polygone inscrit dont tous les côtés tendent vers zéro. Alors, en effet, dans l'égalité exprimée par ce théorème, les deux membres sont les limites de quantités analogues dans lesquelles l'aire curviligne est remplacée par un polygone inscrit.

821. Soit encore un volume quelconque que nous couperons par des plans parallèles à une même direction, la distance de deux plans successifs ne dépassant pas une certaine longueur h. Soient s la portion du solide comprise entre deux consécutifs de ces plans; C un cylindre ayant ses bases dans les plans en question et compris dans s; C' un cylindre ayant ses bases dans les mêmes plans et comprenant s à son intérieur (si les deux courbes de section du solide par les deux plans considérés sont telles que la projection de l'une d'elles sur le plan de l'autre comprenne celle-ci, on pourra prendre pour C et C′ les cylindres droits qui ont respectivement ces courbes pour bases).

---

(1) En effet, cette différence a pour mesure le produit de l'aire annulaire comprise entre un polygone inscrit et un polygone circonscrit, — laquelle tend évidemment vers zéro, — par 2π et par la distance de l'axe au centre de gravité de cette aire, laquelle n'augmente pas indéfiniment (ex. 870).

Dans tous les solides que l'on a habituellement à considérer, on peut prendre h assez petit pour que, quels que soient les deux plans, pourvu que leur distance ne dépasse pas h, le rapport $\frac{C}{C'}$ soit compris entre l'unité et un nombre $1 - \alpha$ aussi voisin qu'on le veut de l'unité (ou, s'il n'en est pas ainsi, le solide peut être décomposé en parties dont chacune satisfasse à cette condition).

Dès lors, le solide étant décomposé en plusieurs portions par une série de plans parallèles entre eux dont les distances successives ne dépassent pas h, formons, pour chacune de ces portions les cylindres C et C′ et appelons P le solide formé par l'ensemble des cylindres C, Q le solide formé par l'ensemble des cylindres C′. D'après ce que nous venons de dire, le rapport de chaque cylindre C au cylindre C′ correspondant et, par conséquent aussi, le rapport $\frac{P}{Q}$, seront compris entre 1 et $1 - \alpha$. Le nombre α pouvant être choisi aussi petit qu'on veut si h est suffisamment petit, on voit que lorsque h tend vers zéro, les volumes P et Q tendent simultanément vers le volume du solide, puisque le rapport $\frac{P}{Q}$ tend vers 1 et que P est intérieur à ce solide, lequel est intérieur à Q.

822. Aire d'une surface courbe.

La définition de l'aire d'une portion de surface courbe offre de beaucoup plus grandes difficultés que les précédentes. Si, en effet, on considère une surface polyédrale inscrite à la surface courbe et qu'on suppose seulement, comme nous l'avons fait, que la plus grande dimension de chaque face diminue indéfiniment, sans ajouter à cette supposition d'autres hypothèses convenablement choisies sur la loi de variation de la surface polyédrale, il n'arrive pas nécessairement que l'étendue de celle-ci tende vers une limite déterminée : il peut même arriver que cette étendue augmente indéfiniment.

Nous nous bornerons à définir l'aire d'une surface fermée convexe.

Dans ce but, nous établirons d'abord les deux lemmes suivants :

Lemmes. — I. *Une face d'un polyèdre quelconque est plus petite que la somme des autres.*

Projetons, en effet, toutes ces autres faces sur le plan de la première. L'ensemble de ces projections recouvrira évidemment toute cette première face (il pourra même arriver qu'il la dépasse, ou en recouvre tout ou partie plusieurs fois). Or, chaque face est (**606**) plus grande que sa projection.

II. *La surface d'un polyèdre convexe est plus petite que celle d'un polyèdre enveloppant quelconque.*

Soient S la surface du polyèdre convexe, S′ la surface du polyèdre enveloppant. Celle-ci pourra avoir une ou plusieurs faces communes (1) avec la première (pourvu qu'elle n'ait aucune partie intérieure à la première) : soit n le nombre des faces non communes sur S. Si $n = 1$, le théorème est démontré, car l'unique face non commune de S est plus petite que la somme des faces non communes de S′, lesquelles forment avec elle un polyèdre.

Si n est différent de 1, prolongeons le plan P d'une des faces non communes de S : nous partageons ainsi S′ en deux parties, l'une S'_1, située par rapport à P du même côté que S, l'autre S'_2 située du côté opposé. Nous diminuerons cette dernière (lemme précédent) en la remplaçant par la portion du plan P terminée au même contour. Or, nous obtenons ainsi un nouveau polyèdre enveloppant S, mais avec lequel ce dernier aura une face commune de plus.

Il est clair qu'en continuant cette réduction, nous serons finalement ramenés au cas de $n = 1$. La proposition est donc démontrée.

Remarque. — Une proposition toute semblable s'appliquerait (avec le même mode de démonstration) à une surface polyédrale convexe ouverte et à une surface polyédrale enveloppante terminée au même contour.

823. Cela posé, soit une surface fermée convexe S. Nous considérerons encore des polyèdres P_n et Q_n dont les uns seront intérieurs à S et les autres la comprendront à leur intérieur. Mais nous imposerons cette fois à ces polyèdres *la condition d'être convexes*. Dès lors, en vertu du lemme II, la surface de chaque polyèdre P_n sera inférieure à la surface de n'importe quel polyèdre Q_n. Si donc on suppose que la différence entre la surface de P_n et celle de Q_n tend vers zéro (ou que leur rapport tend vers 1), ces surfaces auront une limite commune, indépendante de la manière dont on aura choisi les P_n et les Q_n pourvu que ceux-ci remplissent les diverses conditions que nous venons d'énumérer. Il n'y a, à cet égard, rien à changer aux raisonnements du n° **814**.

On obtient d'ailleurs des polyèdres P_n et Q_n par le même procédé qui a été expliqué au n° **815**, en ayant soin, toutefois, de prendre pour R un polyèdre convexe. En particulier, on verra, exactement comme au n° **816**, *qu'une surface fermée convexe est la limite d'un polyèdre convexe inscrit, dans lequel la plus grande dimension de chaque face tend vers zéro.*

824. Lorsqu'il s'agit de la longueur d'un arc de courbe plane, on peut, en général, si l'arc n'est pas convexe, le décomposer en arcs convexes. Il importe de remarquer que ce mode de raisonnement n'est pas applicable ici. On rencontre, et cela parmi les surfaces usuelles, des surfaces dont aucune portion, si petite qu'elle soit, n'est convexe et dont, en un quelconque de leurs points, on ne peut pas dire qu'elles tournent leur convexité dans un sens ou dans l'autre. C'est, par exemple, le cas de la *surface gauche de révolution* (ex. 1031) dont la forme générale est représentée fig. 654 (¹).

---

(1) Une face de S sera considérée comme commune avec S′ si elle est située dans le plan d'une face de S′.

825. Dans le cas du cylindre, du cône ou du tronc de cône, la définition précédente coïncide avec celles que nous avons données au livre VIII : on peut, en effet, évaluer la surface *totale* de l'un de ces corps comme limite de la surface totale des prismes, pyramides ou troncs de pyramides inscrits (comparer **817**) et comme les surfaces de bases de ces polyèdres tendent vers les surfaces de bases des corps ronds correspondants, il en est de même des surfaces latérales.

On peut également raisonner sur la surface engendrée par une ligne brisée tournant autour d'un axe extérieur à elle et situé dans son plan, comme nous avons raisonné au nº **818** sur le volume engendré par un polygone : il est clair qu'en appliquant, non plus le théorème du nº **608**, mais l'exercice 871, nous obtiendrons (du moins pour une ligne brisée tournante) le second *théorème de Guldin :*

Théorème. — *La surface engendrée par une ligne qui tourne autour d'un axe situé dans son plan et ne le traversant pas, est égale au produit de la longueur de cette ligne par la circonférence que décrit son centre de gravité.*

Ce théorème s'étendra d'ailleurs à une ligne courbe tournante, par voie de passage à la limite : les considérations qui précèdent permettent de faire cette extension par une voie analogue à celle que nous avons employée au nº **820**, toutes les fois qu'il s'agit d'une ligne convexe tournant sa concavité vers l'axe.

825 *bis*. Nous pouvons encore définir l'aire de la zone, puisque nous pouvons définir l'aire totale du segment sphérique ; et cette définition concorde (comparer **820**) avec celle du nº **482**.

On remarquera que ces définitions permettent d'obtenir immédiatement les théorèmes relatifs aux volumes sphériques.

Si, en effet, nous considérons un polyèdre convexe inscrit à la sphère, ce polyèdre sera décomposable en pyramides ayant pour

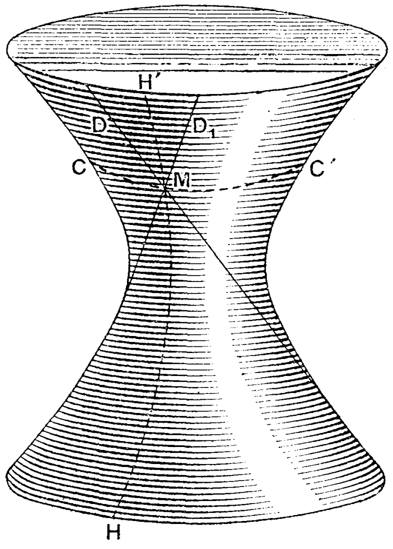

Fig. 654.

(¹) M étant un point quelconque de la surface, le plan tangent en M coupe la surface suivant deux droites (ex. 1273) MD, MD_1, lesquelles partagent celui-ci en quatre parties dont deux opposées l'une à l'autre (celles qui contiennent le méridien HH' (*fig.* 654)) sont, par rapport au plan tangent, du côté extérieur, et les deux autres (celles qui contiennent le parallèle CC') du côté intérieur.

bases les différentes faces et pour sommet commun le centre. Son volume sera égal au tiers de la somme des bases, — c'est-à-dire de la surface, — multipliée par une quantité intermédiaire entre la plus grande et la plus petite des hauteurs. Or ces dernières tendent toutes vers le rayon, puisque le polyèdre et, par conséquent (puisqu'il est convexe), le plan de chacune de ses faces sont extérieurs (**816**) à une sphère quelconque concentrique à la première et de rayon plus petit. Quant à la surface du polyèdre, elle tend vers celle de la sphère. On a donc bien ce théorème que *le volume de la sphère est égal au produit de sa surface par le tiers du rayon.* Le même raisonnement s'applique d'ailleurs évidemment au secteur sphérique.

826. Lorsqu'une surface S peut être développée sur un plan, on démontre que l'aire de toute figure tracée sur S est égale à celle de son développement (voir exerc. 822).

Bien entendu, la réciproque n'est pas vraie : nous voulons dire que, si l'on a fait correspondre les points d'une surface S aux points d'un plan de manière que les figures qui se correspondent aient même aire, il n'en résulte en aucune façon que S soit développable. Par exemple, dans l'exercice 1301, nous indiquons une correspondance de cette espèce entre une sphère (c'est-à-dire une surface non développable) et un cylindre (lequel peut être étalé sur un plan).

NOTE H

SUR LES POLYÈDRES RÉGULIERS ET LES GROUPES DE ROTATIONS

827. Nous avons démontré, au nº **708**, que *tout polyèdre régulier admet un certain nombre de déplacements,* c'est-à-dire que ces déplacements font coïncider le polyèdre avec lui-même, les sommets venant prendre la place les uns des autres.

Soient R et S deux déplacements qui laissent ainsi inaltéré le polyèdre considéré, ou, plus généralement, qui laissent inaltérée une figure donnée F quelconque. Il est clair que la figure F ne changera pas davantage, si l'on effectue successivement les deux déplacements R et S, autrement dit, si l'on effectue le déplacement RS, *produit* (Pl., **291**) de R et de S.

Par conséquent, en introduisant une définition donnée au nº **291**, si nous considérons l'ensemble des déplacements qui n'altèrent pas la figure F, *ces déplacements forment un groupe*, puisque R et S étant deux quelconques d'entre eux, les produits (¹) RS et SR appartiennent au même ensemble.

Il est bien entendu que S peut n'être autre que R : le produit RR est désigné par la notation R^2 et de même les produits de trois, quatre.... facteurs tous égaux à R sont respectivement désignés par les notations R^3, R^4..., et sont dits les *puissances* successives de R.

Si R est un déplacement hélicoïdal composé d'une rotation d'angle α et d'une translation t parallèle à l'axe de la rotation, on voit immédiatement que R^m (en désignant par m un entier quelconque) sera un déplacement de même axe, composé d'une rotation d'angle $m\alpha$ et d'une translation de grandeur mt.

Il faut observer, d'autre part, que nous comptons parmi les opérations appartenant au groupe celle dans laquelle on ne change rien aux positions des différents points : elle est dite *l'opération identique* et il nous arrivera de la représenter par le chiffre 1. Il est aisé de voir que la conclusion obtenue tout à l'heure (à savoir que si R et S laissent inaltérée la figure F, il en est de même de leur produit) suppose essentiellement la convention qui vient d'être faite, relativement à l'opération identique.

En effet, R étant un déplacement quelconque, qui a pour effet d'amener un point quelconque M de l'espace en une nouvelle position M', soit S le déplacement *inverse* de R, c'est-à-dire celui qui, appliqué au point M', donne pour résultat M (R étant un déplacement hélicoïdal composé d'une translation de grandeur t et d'une rotation d'angle α, le déplacement inverse a le même axe que R, sa translation et sa rotation ayant les mêmes grandeurs t et α, mais étant de sens opposés aux premiers). Si R laisse inaltérée la figure F, il en est de même de S et, par conséquent, si nous voulons pouvoir dire, comme nous l'avons fait tout à l'heure, que les déplacements qu'admet F forment un groupe, il faut compter au nombre de ces déplacements les produits RS et SR. Or chacun de ces deux produits donne, en vertu de la définition de S, l'opération identique (chacune des deux opérations R et S ayant pour effet de ramener à leurs positions primitives les figures transformées par l'autre).

L'opération inverse de R est représentée par le symbole R^{-1}; ses puissances successives, par R^{-2}, R^{-3}.... On voit immédiatement que R^{-k} est inverse de R^k et que l'inverse de RS (en désignant par S une seconde opération quelconque) est $S^{-1}R^{-1}$.

828. Nous venons de remarquer que, *si le groupe des déplacements qu'admet une figure quelconque* F *comprend un déplacement* R, *il comprend aussi le déplacement inverse* R^{-1}.

La même propriété appartient à la plupart des groupes que l'on a à considérer dans les applications de cette notion aux diverses parties des mathématiques. On démontre, en particulier, qu'elle a lieu pour tout

---

(1) Rappelons que les deux produits RS et SR ne sont pas, en général, identiques entre eux (voir Pl., page 276, note 2 et exercice 624).

groupe composé d'un nombre fini de transformations ; nous la démontrerons d'ailleurs, chemin faisant (**830** *bis*), pour les groupes dont nous allons avoir à nous occuper.

Elle entraîne, pour les groupes G qui la possèdent, cette conséquence que *si une figure* F′ *est homologue* (¹) *d'une figure* F (relativement à un groupe G), *réciproquement* F *est homologue de* F′ ; car si R est l'opération du groupe qui transforme F en F′, l'inverse R^{-1} transformera F′ en F.

829. Voici une nouvelle conséquence de la propriété précédente :

Soient R un déplacement (²), composé d'une translation de grandeur t, parallèle à un axe A et d'une rotation d'angle α autour du même axe (t ou α pouvant, bien entendu, être nul), et qui change une figure quelconque f en f' (*fig.* 655); S, un autre déplacement quelconque d'axe B. Appliquons à la figure formée par l'axe A, la figure f et la figure f', le déplacement S : f viendra en f_1, f' en f'_1, l'axe A en A_1. Nous voyons dès lors que le déplacement R_1 qui a pour axe A_1, la translation t et la rotation α étant les mêmes que celles de R, change la figure f_1 (transformée de f' par S) en f'_1 (c'est-à-dire en la transformée de f' par S).

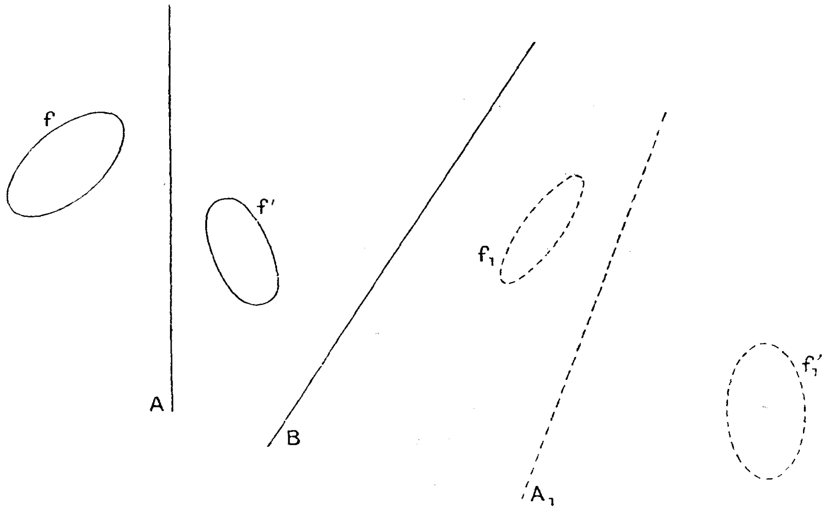

Fig. 655.

On donne à ce nouveau déplacement R_1 le nom de *transformé de* R *par* S. Deux déplacements R, R_1, dont l'un est le transformé de l'autre par un troisième déplacement quelconque, sont dits *semblables*. On voit que deux déplacements semblables ont (en grandeur) même translation et même rotation, et qu'ils sont tous deux *dextrorsum* ou tous deux *sinistrorsum* (**414**, Rem.); ces conditions sont, d'ailleurs, suffisantes, car si elles sont remplies par deux déplacements R, R_1, on les transformera l'un dans l'autre par tout déplacement qui transformera les axes l'un dans l'autre

---

(1) Pour le sens de ce mot, nous renvoyons à la géométrie plane (**293**).

(2) Nous raisonnons ici sur des déplacements, mais la notion d'opérations *semblables* et son application aux groupes subsistent pour des opérations quelconques.

(le sens de translation donné sur le premier axe venant suivant le sens de translation donné sur le second).

Cela posé, admettons que les déplacements R et S, considérés il y a un instant, fassent partie d'un même groupe G, qui comprenne également (d'après la propriété énoncée au n° précédent) R^{-1} et S^{-1}. Alors f et f_1 sont homologues entre eux par rapport à G, de même que f_1 et f'_1; et, comme f et f' sont aussi homologues l'une de l'autre, il en est de même Pl., **293**) pour f_1 et f'_1 ; donc le déplacement R_1, qui change f_1 en f'_1, appartient à G.

Ainsi, *si deux déplacements* R *et* S *appartiennent à un groupe* G, *il en est de même du transformé* R_1 *de* R *par* S.

Les deux déplacements R et R_1 sont dits *homologues* l'un de l'autre par rapport au groupe. Bien entendu, pour que deux déplacements soient homologues, il ne suffit pas qu'ils soient semblables, il faut encore que, parmi les opérations qui les transforment l'un dans l'autre, il y en ait au moins une qui fasse partie du groupe.

---

830. Dans le cas où la figure F est un polyèdre régulier, le nombre des déplacements qu'elle admet est fini.

Nous allons nous proposer de rechercher, d'une manière générale, tous les groupes composés de déplacements en nombre fini. Le nombre N de ces déplacements (le déplacement identique compris, bien entendu), sera dit l'*ordre* du groupe.

Après avoir formé les groupes en question, nous chercherons s'il leur correspond des polyèdres réguliers. Nous nous appuierons, à cet effet, sur le théorème du n° **710.** Par contre, *nos raisonnements seront entièrement indépendants des considérations présentées aux n*^{os} **712-717**; ils nous fourniront, dès lors, une nouvelle démonstration des résultats établis, relativement à l'existence et à la nature des polyèdres réguliers.

Mais l'utilité de la recherche que nous allons entreprendre n'est nullement limitée à l'étude des polyèdres réguliers. D'une part, en effet, on constate que les groupes cherchés jouent un rôle important dans le problème de la résolution des équations (voir note 2 de la page 522); d'autre part, certaines propriétés que nous démontrerons (telles que celle du *domaine fondamental*, n° **845**) se transportent d'elles-mêmes à d'autres groupes analogues, composés d'une infinité d'opérations et dont l'étude est nécessaire à la solution de certaines questions importantes de mathématiques.

Soit G l'un des groupes cherchés. S'il contient un déplacement R, il contiendra aussi ses puissances successives R^2, R^3... Il faudra donc, tout d'abord, que ces puissances ne soient pas en nombre infini.

Dès lors, R *ne peut pas être une translation :* car, si t était la grandeur de cette translation, ses puissances successives seraient des translations de grandeurs respectives $2t$, $3t$,... : de telles translations sont nécessairement toutes distinctes entre elles et en nombre infini.

De même R *ne peut être un déplacement hélicoïdal :* car, si t est la translation qui entre dans R, les déplacements R^2, R^3... comprendraient les translations $2t$, $3t$... et seraient, par conséquent, aussi tous différents les uns des autres.

Donc *le groupe* G *est exclusivement composé de rotations.*

830 *bis.* De plus, soit α l'angle d'une rotation R appartenant à G : les puissances successives de R auront pour angles respectifs 2α, 3α... Pour que ces puissances ne soient pas en nombre infini, il faut qu'une certaine puissance R^p ne soit pas distincte d'une puissance précédente $R^{p'}$. Il est clair que ceci aura lieu lorsque les angles de R^p et de $R^{p'}$ différeront d'un nombre entier de circonférences, et dans ce cas seulement. Donc, *si nous supposons que les angles soient mesurés en prenant pour unité la circonférence entière,* on aura :

$$p\alpha = p'\alpha + m,$$

m étant un entier. Cette équation donne :

$$\alpha = \frac{m}{n}, \tag{27}$$

en posant $p - p' = n$.

On voit alors que la puissance n^{me} de R donnera une rotation composée d'un nombre entier m de circonférences, c'est-à-dire se réduira au déplacement identique : la puissance R^{n+1} ne sera, dès lors, pas distincte de R, la puissance R^{n+2} de R^2....

Nous pouvons d'ailleurs toujours supposer que n ait été choisi le plus petit possible (c'est-à-dire que R^n soit la première puissance de R qui se réduise au déplacement identique). Cela revient évidemment à supposer que la fraction $\frac{m}{n}$ est réduite à sa plus simple expression. Lorsqu'il en est ainsi, on dit que n est l'*ordre* de la rotation R. Par exemple, une rotation d'ordre 2 n'est autre que ce que nous avons appelé précédemment *transposition.*

L'angle $n\alpha$ étant un multiple de la circonférence, la rotation R^{n-p}, laquelle est d'angle $(n - p)\alpha$, revient à une rotation d'angle $p\,\alpha$ effectuée en sens contraire, c'est-à-dire à R^{-p}. En particulier, l'*inverse* $R^{-1} = R^{n-1}$ *de* R *figure parmi les puissances de* R *et, par conséquent, dans le groupe* G.

Enfin, on peut remarquer que si n est l'ordre de R, la rotation ayant pour axe celui de R et pour angle $\frac{1}{n}$ figure également parmi les puissances de R. Car les nombres m et n qui figurent dans la relation (27) étant premiers entre eux, on peut (¹) trouver deux entiers h et k tels que l'on ait

$$km - hn = 1$$

---

(1) TANNERY, *Leçons d'Arithmétique*, page 466.

Cette relation donne

$$k\alpha = \frac{km}{n} = h + \frac{1}{n},$$

et montre, par conséquent, que la rotation R^k a son angle égal au $n^{\text{ème}}$ de la circonférence, à un nombre entier h de circférenee près, lequel peut être laissé de côté.

831. Considérons maintenant deux rotations R et S du groupe.

Leurs axes sont dans un même plan; l'hypothèse contraire serait, en effet, incompatible avec le résultat que nous venons de trouver au n° **829**, en vertu de la proposition que nous énonçons à l'exercice 592.

De plus, *ces axes (s'ils sont distincts) ne peuvent être parallèles*, car, dans ce cas, ou bien R et S auraient leurs angles égaux et de sens contraires, et le déplacement RS serait une translation non nulle (comparer Pl., ex. 94); ou bien les angles de R et de S seraient inégaux (ou égaux et de même sens) et les deux opérations RS et SR seraient deux rotations égales, mais (ex. 623-624) autour d'axes forcément distincts entre eux, de sorte que l'opération $RS(SR)^{-1}$ (ou $RSR^{-1}S^{-1}$) serait une translation non nulle.

Les deux axes (s'ils sont distincts) se coupent donc forcément en un certain point O.

832. Le groupe G renferme d'ailleurs nécessairement une rotation T dont l'axe passe par le point O et est situé en dehors du plan des deux premiers. Si, en effet, R et S sont toutes deux des transpositions, cette rotation T est donnée (**416**) par le produit RS; si, au contraire R, par exemple, n'est pas une transposition, la transformée de S par R a évidemment son axe en dehors du plan qui contient ceux de R et de S.

Dès lors, l'axe de toute rotation U du groupe doit passer par le point O, puisqu'il doit (n° préc.) rencontrer les axes de R, de S et de T.

833. Nous arrivons donc à cette première conclusion :

Tous les déplacements du groupe sont des rotations dont les axes passent par un même point.

Nous prendrons le point O où se coupent tous les axes comme centre d'une sphère Σ : il est clair qu'il suffira, pour étudier les rotations du groupe G, de les appliquer aux seuls points de la sphère Σ.

Chaque axe de rotation coupera Σ en deux points, les seuls que la rotation correspondante laisse inaltérés sur la sphère ; pour abréger, nous donnerons aux points ainsi obtenus le nom de *pôles de rotation.*

Chaque pôle de rotation est, en général, commun à plusieurs rotations du groupe. La plus petite (¹) R d'entre elles a pour angle une partie aliquote de la circonférence : car si cet angle était mesuré par $\frac{m}{n}$ (la fraction $\frac{m}{n}$

---

(1) C'est-à-dire celle dont l'angle est le plus petit, le déplacement identique étant, bien entendu, excepté.

étant irréductible), nous savons que le groupe renfermerait la rotation de même axe et d'angle $\frac{1}{n}$, qui serait plus petite que la première, si m était plus grand que 1 : donc $m = 1$.

D'ailleurs, toutes les autres rotations du groupe ayant les mêmes pôles que R seront des puissances de R : car si l'angle α de l'une d'elles était mesuré par un nombre compris entre $\frac{p}{n}$ et $\frac{p+1}{n}$, en la multipliant par R^{-p}, on obtiendrait évidemment une rotation de même axe et dont l'angle serait plus petit que $\frac{1}{n}$, par conséquent plus petit que celui de R (contrairement à l'hypothèse). Nous dirons que n est l'*ordre du pôle de rotation* considéré.

Un pôle d'ordre n est évidemment commun à $n - 1$ rotations, le déplacement identique non compris.

834. N étant l'ordre du groupe, un point quelconque P de la sphère a N homologues, qu'on obtient en lui faisant subir successivement les N déplacements du groupe (déplacement identique compris). Si P n'est pas un pôle de rotation, ces homologues sont tous distincts entre eux; car si deux ou plusieurs d'entre eux coïncidaient en P', le point P' serait pôle d'une rotation R', et le point P, pôle d'une rotation R homologue de R' (**829**).

Si, au contraire, P est un pôle de rotation d'ordre n, commun à la rotation R $\left(\text{d'angle } \frac{1}{n}\right)$ et à ses puissances $R^2 \ldots$, R^{n-1}, il coïncidera avec $n - 1$ de ses homologues. De plus, soit P' un autre homologue de P, déduit de P par un déplacement S du groupe et ne coïncidant pas avec P : il y aura n homologues de P qui coïncideront avec P'; à savoir, ceux qu'on déduit de P par les rotations S, RS, $R^2S \ldots$, $R^{n-1}S$. Il n'y en aura d'ailleurs pas d'autres : car, sans cela, le point P' serait pôle de rotation d'un ordre n' supérieur à n et le point P serait également, en vertu de ce que nous avons dit au n° **829**, pôle de rotation d'ordre n' et non d'ordre n.

Ainsi, le nombre des homologues de P réunis en P' est exactement n; et, puisque le point P' a été pris quelconque parmi les homologues de P, on peut dire que *les* N *homologues de* P *viennent se confondre entre eux n à n*. On voit, par conséquent, que N est divisible par n et qu'*il y a* $\frac{N}{n}$ *homologues* **distincts** *de* P (le point P lui-même étant compté dans le nombre).

835. Le résultat que nous venons d'obtenir va nous mener à une relation fondamentale entre l'ordre N du groupe et les ordres des différents pôles de rotation.

Soit en effet, P_1 un premier pôle de rotation d'ordre n_1 : nous venons de voir que ce point avait $\frac{N}{n_1}$ homologues distincts. Mais, d'autre part, le pôle

P_1 est commun à $n_1 - 1$ rotations (déplacement identique non compris) : ses homologues seront chacun (**834**) communs à $n_1 - 1$ rotations homologues des premières : soit en tout $\frac{N}{n_1}(n_1 - 1) = N\left(1 - \frac{1}{n_1}\right)$ rotations. Si maintenant, il existe un pôle P_2, non homologue de P_1 et d'ordre (1) n_2, ce point aura $\frac{N}{n_2}$ homologues distincts, fournissant $N\left(1 - \frac{1}{n_2}\right)$ rotations. Un troisième pôle P_3 (s'il en existe), distinct de P_1, de P_2 et de leurs homologues, aura $\frac{N}{n_3}$ homologues fournissant $N\left(1 - \frac{1}{n_3}\right)$ rotations, etc. Nous aurons donc finalement, pour le nombre total de ces rotations, une expression de la forme

$$N\left(1 - \frac{1}{n_1}\right) + N\left(1 - \frac{1}{n_2}\right) + \ldots + N\left(1 - \frac{1}{n_p}\right).$$

Dans ce nombre, le déplacement identique n'est pas compté; mais chacun des $N - 1$ autres déplacements du groupe figure deux fois (et deux fois seulement), une fois pour chacun des deux pôles qu'il possède: d'où la relation à laquelle nous voulions arriver

$$N\left(1 - \frac{1}{n_1}\right) + N\left(1 - \frac{1}{n_2}\right) + \ldots + N\left(1 - \frac{1}{n_p}\right) = 2(N - 1),$$

ou, en divisant par N,

$$(28) \qquad \left(1 - \frac{1}{n_1}\right) + \left(1 - \frac{1}{n_2}\right) + \ldots + \left(1 - \frac{1}{n_p}\right) = 2 - \frac{2}{N}.$$

C'est cette équation que nous allons résoudre par rapport aux entiers positifs (plus grands que l'unité) $n_1, n_2, \ldots, n_p$, N.

Puisque les nombres $n_1, n_2, \ldots, n_p$ sont au moins égaux à 2, chacune des parenthèses du premier membre est au moins égale à $\frac{1}{2}$: donc *le nombre p de ces parenthèses est inférieur* (*et non égal*) *à 4*, car le second membre est plus petit que 2 (l'égalité étant exclue).

D'autre part, le second membre étant au moins égal à 1 (l'égalité n'ayant lieu que pour $N = 2$) pendant que chacune des parenthèses du premier membre est plus petite que 1, on ne peut pas avoir $p = 1$.

836. Si p est égal à 2, l'équation (28) se réduit à

$$\frac{1}{n_1} + \frac{1}{n_2} = \frac{2}{N}$$

et n'a pas d'autres solutions acceptables pour nous que $n_1 = n_2 = N$. Car, il faudrait, sans cela, que l'un des nombres n_1, n_2 fût plus grand que N : ce qui est absurde, puisque N doit être divisible par n_1 et par n_2.

---

(1) Il est bien entendu (voir plus haut, **829**) que n_2 peut être égal à n_1 sans que P_1 et P soient homologues.

$n_1 = n_2 = N$ montre qu'il n'y a que deux pôles de rotation distincts $\left(\frac{N}{n_1} = \frac{N}{n_2} = 1\right)$ et, par conséquent, qu'un seul axe : nous savons qu'alors, les rotations autour de cet axe sont toutes des puissances de l'une d'entre elles. Inversement, il est clair qu'on a bien ainsi un groupe : tel est le groupe des rotations qu'admet (**707**) un angle polyèdre régulier quelconque.

837. Envisageons maintenant le cas de $p = 3$. Dans ce cas, il y a au moins un des nombres n_1, n_2, n_3 qui est égal à 2. Car si on avait $n_1 \geqslant 3$, $n_2 \geqslant 3$, $n_3 \geqslant 3$, chacune des parenthèses du premier membre de l'équation (28) serait au moins égale à $\frac{2}{3}$: leur somme serait donc au moins égale à 2, ce qui ne se peut. Nous prendrons donc $n_3 = 2$, et la relation (28) devient

$$(29) \qquad \frac{1}{n_1} + \frac{1}{n_2} = \frac{1}{2} + \frac{2}{N}.$$

Nous pouvons remarquer tout de suite que cette équation coïnciderait avec l'équation (15′) du n° **715** si l'on changeait n_1, n_2, N, respectivement en m, n, 2A.

Seulement, ici, l'un des nombres cherchés, n_1 par exemple, peut prendre la valeur 2, après quoi l'autre peut être choisi arbitrairement, le nombre N étant égal (comme le montre l'équation (29)) à $2n_2$. Il n'y a alors que deux pôles, et, par conséquent, un seul axe, d'ordre n_2, les rotations qui ne sont pas effectuées autour de cet axe étant toutes des transpositions ; on verra aisément que les axes de celles-ci doivent être perpendiculaires au premier et faire des angles égaux les uns avec les autres.

Les groupes ainsi obtenus ont reçu le nom de *groupes diédraux* (¹) : un tel groupe est celui qu'admet un polygone plan régulier quelconque ou la figure formée par un angle polyèdre régulier et son symétrique, formé en prolongeant les arêtes au delà du sommet.

On notera le cas où n_2 est lui-même égal à 2. Le groupe se compose alors de trois transpositions dont les axes forment un trièdre trirectangle.

Si, maintenant, nous écartons le cas de $n_1 = 2$, les raisonnements du n° **715** sont valables : n_1 est nécessairement à 3 ; n_3 a l'une des valeurs 3, 4, 5. Les valeurs correspondantes de N sont $N = 12, 24, 60$.

838. Démontrons qu'à chacune des combinaisons ainsi obtenues, correspond bien un groupe d'ordre fini (²).

---

(1) Si on divise un grand cercle de la sphère en n parties égales, les n arcs ainsi obtenus peuvent être considérés, à un certain point de vue, comme les côtés (en prolongement les uns des autres) d'un polygone sphérique régulier comprenant un hémisphère entier et la sphère est divisée en deux tels polygones. Le polyèdre correspondant (dièdre) aura deux faces confondues l'une avec l'autre, ainsi qu'il arrivait pour le polygone régulier de deux côtés. (Pl., page 179, note.)

(2) Cela est évident si nous admettons la théorie des polyèdres réguliers, telle qu'elle est exposée aux Compléments, ch. V, puisque nous savons que les cinq espèces de polyèdres réguliers donnent précisément trois groupes qui correspondent aux trois combinaisons en

Les raisonnements sont absolument pareils pour les trois cas : nous traiterons plus particulièrement le plus compliqué, celui de $n_2 = 5$.

Nous savons que le groupe doit comprendre : 1° des rotations d'ordre n_2; 2° des rotations d'ordre $n_1 = 3$; 3° des transpositions. Nous allons trouver une rotation d'ordre 3 et une transposition dont le produit soit une rotation d'ordre n_2.

A cet effet, nous construirons un triangle sphérique (*fig.* 656) ayant pour angles (en A, B, C respectivement) la $n_1^{\text{ème}}$ partie, la $n_2^{\text{ème}}$ partie et la $n_3^{\text{ème}}$ partie de la demi-circonférence (le dernier angle étant droit, puisque $n_3 = 2$). Ce triangle peut être construit, car ses angles satisfont aux conditions de possibilité énoncées au n° **379**. Nous considérerons :

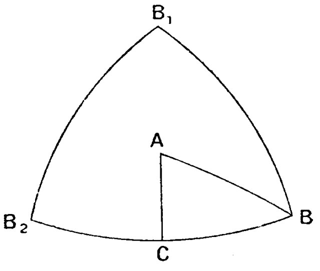

FIG. 656.

1° une rotation R, d'angle égal à la $n_1^{\text{ème}}$ partie de la circonférence, ayant un pôle en A et de même sens que la rotation d'angle égal à BAC $\left(\text{soit à } \frac{1}{2\,n_1}\right)$ qui amènerait le grand cercle AB dans la direction AC;

2° une rotation S, d'angle égal à la $n_2^{\text{ème}}$ partie de la circonférence, ayant un pôle en B et de même sens que la rotation d'angle ABC $= \frac{1}{2\,n_2}$ qui amènerait le grand cercle BA dans la direction BC;

3° une transposition T ayant un pôle en C.

Cette dernière opération transforme B en un point B_2, symétrique de B par rapport au diamètre du point C et par conséquent aussi (puisque l'angle en C est droit) par rapport au plan du grand cercle AC. L'angle sphérique BAB_2 est dès lors mesuré par $\frac{1}{n_1}$ et le point B_2 n'est autre que le transformé de B par R.

Si à ce point B_2, lui-même, on applique la rotation R, on aura un troisième point B_1. Une troisième application de la rotation R ramènerait au point B, car, puisque $n_1 = 3$, on a $R^3 = 1$.

Les triangles sphériques ABB_2, AB_2B_1, AB_1B étant isoscèles et égaux entre eux (1), l'angle sphérique B_1BB_2, double de l'angle à la base du

---

question. Mais, ainsi que nous l'avons dit, nous ne nous appuyons pas sur les résultats des n$^{\text{os}}$ **712-717**, que nous allons, au contraire, démontrer à nouveau dans ce qui va suivre.

(1) Les triangles sphériques ABC, AB_2C sont entièrement extérieurs l'un à l'autre et forment par leur ensemble le triangle sphérique ABB_2. De même les triangles sphériques ABB_2, AB_2B_1. AB_1B sont entièrement extérieurs les uns aux autres et forment par leur ensemble le triangle $BB_1\,B_2$. C'est ce que l'on verra immédiatement en remarquant : 1° que l'on peut construire un triangle sphérique BB_1B_2 ayant ses angles mesurés par $\frac{1}{n_2}$; 2° qu'en divisant ce triangle par les arcs de grands cercles qui joignent le pôle intérieur (**466**) du cercle circonscrit aux sommets et aux milieux des côtés, on obtient des triangles rectangles ayant les angles que nous avons assignés au triangle ABC. Au reste, il importe d'observer qu'aucune de ces remarques n'est nécessaire à la suite de nos raisonnements.

triangle ABB_2, est mesuré par $\frac{1}{n_2}$; donc le point B_2 est le transformé de B_1 par la rotation S.

Mais si nous effectuons successivement les déplacements R et T, le point B reste inaltéré (puisque R l'amène en B_2 et que T ramène B_2 en B) et le point B_1 vient en B_2. Le déplacement RT produit donc sur trois points non en ligne droite (B, B_1 et le centre de la sphère) le même effet que S et, par conséquent (**410**), on a

$$RT = S \tag{30}$$

ce qui peut encore s'écrire

$$S^{-1} = T^{-1}R^{-1} = TR^{-1}, \tag{31}$$

car, T étant une transposition, on a $T^{-1} = T$.

839. Lorsqu'on effectue plusieurs fois de suite la rotation S, le point B_1 a n_2 transformés distincts (le $n_2^{\text{ème}}$ transformé coïncidant avec B_1 lui-même) : soit B_1, B_2, B_3 (*fig.* 657) si $n_2 = 3$; B_1, B_2, B_3, B_4 (*fig.* 658), si $n_2 = 4$; B_1, B_2, B_3, B_4, B_5 (*fig.* 659), si $n_2 = 5$; et les n_2 triangles sphériques $B\,B_1B_2$, $BB_2\,B_3$,.... sont tous équilatéraux et égaux entre eux.

La considération de ces triangles va nous servir à étudier le déplacement

$$U = RTR^{-1}T.$$

Si l'on effectue successivement les déplacements R, T, R^{-1}, T, en partant du point B ou du point B_1, on arrive au point B_3 dans le premier cas, au point B_2 dans le second (¹). Toute rotation, autour d'un axe passant par le centre de la sphère, qui transformera B en B_3 et B_1 en B_2, sera donc (toujours en vertu du n° **410**) identique au déplacement U.

Or, si $n_2 = 3$, la transposition ayant un pôle au milieu C_1 (*fig.* 657) de l'arc de grand cercle BB_3 change bien B en B_3; de plus, le triangle équilatéral BB_3B_1 est changé en un triangle équilatéral égal ayant aussi un côté suivant BB_3, mais placé par rapport à ce côté, dans l'hémisphère où n'est pas B_1 : le troisième sommet de ce triangle, nouvelle position du point B_1, ne peut être autre que B_2.

Donc U est la transposition qui a un pôle en C_1.

Si $n_2 = 4$, le triangle sphérique équilatéral BB_3B_4 (*fig.* 658) (deuxième transformé de $BB_1\,B_2$ par S) admet une rotation d'angle égal à $\frac{1}{3}$ de circonférence, transformée de R par S^2 et dont nous représentons en A_2 (*fig.* 658) le pôle, transformé de A. Cette rotation change B en B_3; en même temps —

(¹) Par exemple, le point B est changé par le déplacement R en B_2, que T change en B, lequel est changé par $R-1$ en B_1, lequel est changé par T en B_3.

le point B_3 venant en B_4 et le point B_4 en B, — le point B_1, symétrique de B_3 par rapport au plan du grand cercle BB_4, vient en un point symétrique de B_4 par rapport au plan du grand cercle BB_3, c'est-à-dire au point B_2. Donc, cette rotation, d'ordre 3, est identique au déplacement U.

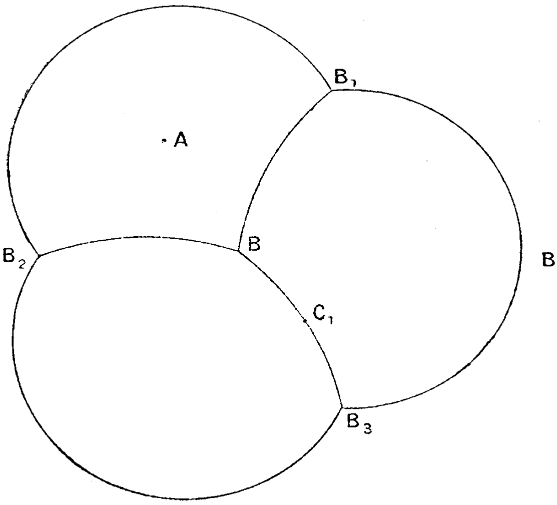

Fig. 657.

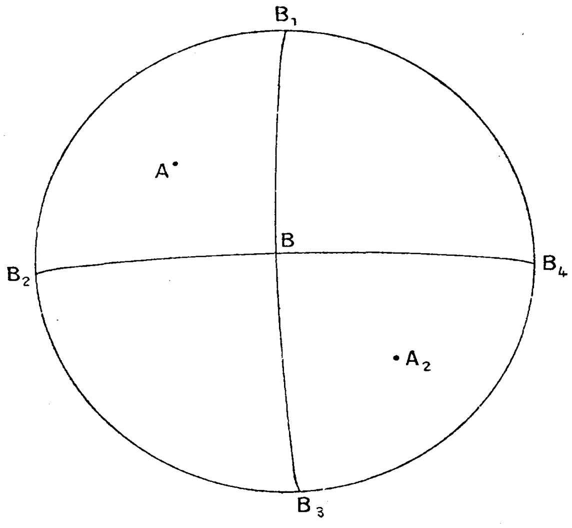

Fig. 658.

Enfin, si $n_2 = 5$, une rotation d'angle égal au $\frac{1}{5}$ de la circonférence, ayant un pôle en B_4 (*fig.* 659), amène B en B_3 (puisque le triangle sphérique BB_3B_4 est équilatéral et a son angle égal à $\frac{1}{5}$); elle amène de même le point B_5 en B et, par conséquent, le point B_1 vient au point B_2, puisque l'un est le symétrique de B_4 par rapport au plan du grand cercle BB_5, et l'autre le symétrique de B_4 par rapport au plan du grand cercle BB_3.

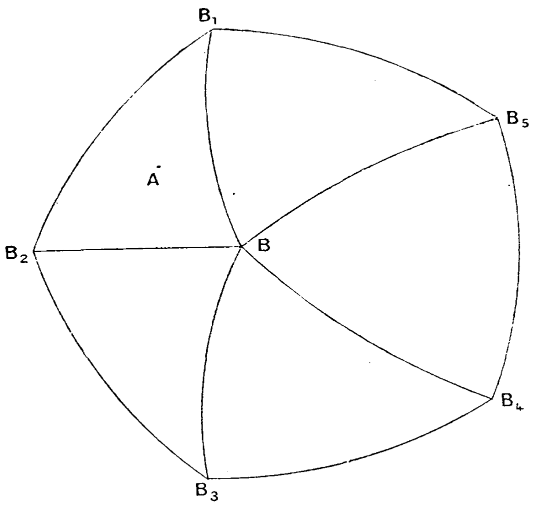

Fig. 659.

Donc, cette rotation d'ordre 5 coïncide avec U.

840. Cela posé, considérons les produits que l'on peut former avec les facteurs R, S, T pris en nombre quelconque et dans tous les ordres possibles. Dans chacun de ces produits, on peut évidemment remplacer plusieurs facteurs *consécutifs* par leur produit effectué, mais il est bien entendu, ainsi que nous l'avons déjà rappelé, que l'on n'a pas, en général, le droit d'intervertir l'ordre des facteurs. Dans ces conditions, il semble que les produits ainsi obtenus soient en nombre infini : nous allons démontrer qu'il n'en est rien et que l'on trouve ainsi des déplacements en nombre limité. Nous aurons ainsi fourni la démonstration demandée, car les produits dont nous parlons forment, d'après la manière même dont il sont définis, un groupe.

Pour arriver à cette démonstration, nous commencerons par remplacer chaque facteur S par sa valeur RT, en vertu de la relation (30). Les symboles que nous aurons à considérer seront donc composés de facteurs R et T. Chaque fois qu'il y aura deux lettres T consécutives, nous pourrons les supprimer, puisque l'on a $T^2 = 1$. De même R^3 étant égal à 1, non seulement nous ne conserverons jamais plus de deux lettres R consécutives, mais lorsqu'il s'en trouvera deux, nous remplacerons leur produit R^2 par R^{-1}. Dans ces conditions, chacun des déplacements en question sera représenté par un symbole composé de lettres T alternant avec des lettres R ou R^{-1}.

Mais un même déplacement peut être représenté par plusieurs symboles de la forme précédente : nous supposerons (ce que nous avons le droit de faire) que, parmi ces symboles équivalents entre eux, ont ait choisi le plus court. Nous considérerons donc un tableau formé de tous les symboles de la forme indiquée tels qu'aucun d'entre eux ne puisse être remplacé par un symbole équivalent, mais plus court; et nous allons montrer que le nombre des symboles du tableau est limité.

841. En premier lieu, la succession RT ne peut figurer plus de deux fois consécutives (pour $n_2 = 5$ ou $n_2 = 4$; plus d'une fois pour $n_2 = 3$) : car la substitution $RT = S$ est d'ordre 5 et, par conséquent, $S^3 = RTRTRT$ peut se remplacer par le symbole le plus court (¹) $S^{-2} = TR^{-1}TR^{-1}$.

De même, le signe R^{-1} (alternant avec T) ne peut figurer plus de deux fois consécutivement : la suite $TR^{-1}TR^{-1}TR^{-1} = S^{-3}$ se remplaçant par $S^{-2} = RTRT$.

Mais il y a plus : la succession RT, par exemple, ne peut figurer deux fois de suite qu'à l'une des extrémités du symbole : en effet, si elle se trouvait deux fois de suite à l'intérieur de ce symbole, elle serait précédée d'une lettre T et suivie du signe R^{-1} (ou exceptionnellement (²) R) ce qui donnerait la succession :

$$\ldots TR\,TR\,TR^{-1}\ldots.$$

(¹) Le symbole ainsi abrégé se réduirait encore, en général, puisque la première lettre T de la succession $TR^{-1}TR^{-1}$ serait en contact avec une lettre T précédente, ce qui permettrait de les supprimer toutes deux, et de même pour la dernière lettre R^{-1} (comparer ci-après).

(²) Cette dernière hypothèse est d'ores et déjà inadmissible si R n'est pas la dernière lettre du symbole, car elle serait suivie d'une lettre T, donnant une troisième fois la succession RT.

Mais si, dans celle-ci, on remplace

$$RTRT = S^2 \text{ par } TR^{-1}TR^{-1}TR^{-1} = S^{-3},$$

il vient

$$\ldots TTR^{-1}TR^{-1}TR^{-1}R^{-1}\ldots\ldots,$$

ce qui (puisque $T^2 = 1$ et $R^{-2} = R$), se réduit à

$$\ldots R^{-1}TR^{-1}TR\ldots,$$

symbole plus court d'une lettre que le premier.

De même, la successsion TR^{-1} ne peut figurer deux fois de suite qu'à l'une des extrémités du symbole.

Par conséquent, sauf aux extrémités, on voit que les lettres R et R^{-1} (entremêlées de lettres T) *alternent régulièrement :* autrement dit que l'ordre est

$$\ldots RTR^{-1}T\,RTR^{-1}T\,RTR^{-1}T\ldots\ldots$$

Mais le produit $RTR^{-1}T$ n'est autre que le déplacement que nous avons nommé U, et nous avons constaté que ce déplacement était d'ordre fini (d'ordre 5, pour $n_2 = 5$).

Dès lors, notre conclusion est établie : notre symbole comprend, au plus, le produit U, écrit une ou deux fois (¹), pouvant être précédé et pouvant être suivi de lettres R ou R^{-1} en nombre au plus égal à 2 (entremêlées de lettres T); et il est clair qu'il n'existe qu'un nombre fini de symboles ainsi formés (en tenant compte des différentes réductions que nous venons d'indiquer, on vérifiera d'ailleurs bien que ce nombre est de 60, et qu'il est de 12 pour $n_2 = 3$, de 24 pour $n_2 = 4$).

842. Nous allons montrer maintenant qu'à chacune des valeurs trouvées pour n_2 ne correspond qu'un seul groupe d'ordre fini (en ne considérant pas comme distincts deux groupes *semblables* entre eux, c'est-à-dire tels que les rotations de l'un soit respectivement les transformées de celles de l'autre par un même déplacement).

Autrement dit, nous montrerons que le groupe correspondant à l'une des combinaisons précédemment obtenues comprend bien trois rotations R, S, T disposées comme nous l'avons indiqué au n° **838** : il comprendra, dès lors, tous les produits qu'on peut former avec les facteurs R, S, T combinés de toutes les façons possibles et coïncidera bien, par conséquent, avec un des groupes qui viennent d'être formés.

Nous prendrons encore $n_3 = 2$, mais nous n'allons pas spécifier, au moins provisoirement, lequel des deux entiers n_1, n_2 est égal à 3 et lequel peut recevoir les valeurs 3, 4 ou 5.

---

(1) Si le produit U figurait trois fois, on le remplacerait (ainsi qu'on a fait pour S^3 par $U^{-2} = TRTR^{-1}\,TRTR^{-1}$, symbole plus court.

Soit alors A un pôle de rotation d'ordre n_1, et considérons, parmi les autres pôles homologues de A, ceux qui sont le plus rapprochés de A : soient A_0 l'un d'eux; A_1, ... , (*fig.* 660) ceux qu'on déduit successivement de A_0 par rotation d'angle $\frac{1}{n_1}$ autour de A.

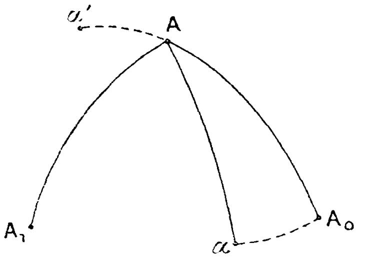

FIG. 660.

Outre ces points A_0, A_1.... il ne saurait exister de point α, homologue de A, aussi rapproché de A que A_1. Car l'arc $A\alpha = AA_0$ devrait tomber dans l'un des angles que font entre eux les arcs AA_0, AA_1..., par exemple, dans l'angle sphérique A_0AA_1 (*fig.* 660) : il devrait alors faire avec l'un des côtés de cet angle, AA_0 par exemple, un angle au plus égal à $\frac{A_0AA_1}{2} = \frac{1}{2\,n_1}\cdot$ Dès lors, dans le triangle isoscèle $AA_0\alpha$, la valeur commune des angles à la base devrait être supérieure à $\frac{1}{2\,n_1}$ (sans quoi la somme des angles serait au plus égale à $\frac{3}{2\,n_1}$, par conséquent — puisque $n_1 \geqslant 3$, — à la demi-circonférence, ce qui est impossible dans un triangle sphérique) et le côté $A_0\alpha$ serait plus petit que AA_0.

Mais il existe une rotation du groupe qui transforme A_0 en A. Cette même rotation transformerait α en un point α' — homologue, lui aussi, de A, — et tel que $A\alpha' < AA_0$, ce qui est contraire à l'hypothèse d'après la quelle A_0 est un homologue de A aussi rapproché que possible de A.

843. Ayant ainsi établi que tout homologue de A, aussi rapproché de A que A_0, est le transformé de A_0 par une puissance convenable de la rotation R qui a pour pôle A et pour angle $\frac{1}{n_1}$, considérons une rotation S du groupe qui transforme A_0 en A. Cette même rotation transformera A en un autre homologue A_1 de A tel que $AA_1 = AA_0$. D'après ce que nous venons de démontrer, A_1 se déduira de A_0 par un déplacement de la forme R^p et on peut évidemment supposer (en multipliant S par une puissance convenable de R) que $p = 1$, de sorte que l'angle sphérique A_0AA_1 sera mesuré par $\frac{1}{n_1}$ (*fig.* 661).

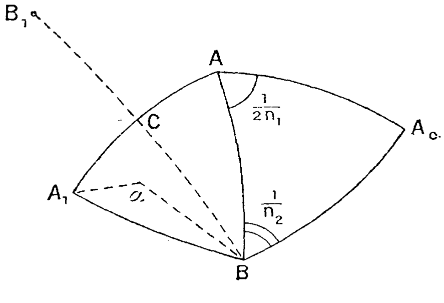

FIG. 661.

Le déplacement S ainsi déterminé aura ses deux pôles de rotation sur le grand cercle qui divise en deux parties égales l'angle A_0AA_1. Soit B celui de ces pôles qui est tel que l'arc de grand cercle AB inférieur à la demi-circonférence soit compris à l'intérieur de l'angle A_0AA_1, de sorte que les deux triangles sphériques isoscèles et égaux AA_0B, AA_1B (*fig.* 661) auront leurs angles à la base mesurés par $\frac{1}{2n_1}$. Ces mêmes triangles auront leur angle au sommet au moins égal à $\frac{1}{n_1}$ ou à $\frac{1}{n_2}$ (n_1 ou n_2 étant l'ordre de la rotation S). Or les nombres $\frac{1}{n_1}$ et $\frac{1}{n_2}$ sont tous deux supérieurs (pour $n_1, n_2 = 3, 4, 5$) à $\frac{1}{2n_1}$: donc on a $AB < AA_0$. Il en résulte (d'après l'hypothèse faite sur A_0) que B n'est pas un homologue de A, autrement dit que S n'est homologue ni de R ni d'une de ses puissances : B est un pôle de rotation d'ordre n_2 (que n_2 soit d'ailleurs égal à n_1 ou différent de n_1) et S a son angle mesuré par $\frac{1}{n_2}$ (¹).

Enfin la rotation $T = R^{-1}S$ transformera A_1 en A et A en A_1 : ce sera donc une transposition ayant un pôle au milieu C de AA_1 ; la relation $T = R^{-1}S$ donne d'ailleurs (en multipliant les deux membres à gauche par R) $S = RT$. En un mot, les rotations R, S, T ont bien entre elles les relations annoncées.

844. Remarquons, de plus, qu'il ne saurait y avoir d'homologue de A plus rapproché de B que A. Si, en effet, α était un tel homologue (par conséquent tel que l'arc de grand cercle $B\alpha$ (*fig.* 661), soit plus petit que BA), il y aurait au moins un des grands cercles BA, $BA_1, \ldots BA_0$, transformés de BA par les puissances successives de S, qui ferait avec $B\alpha$ un angle au plus égal à $\frac{1}{2n_2}$ (comparer **842**) : soit par exemple, BA_1 ce grand cercle. Le plus grand angle du triangle sphérique $BA_1\alpha$ serait alors autre que B_1, sans quoi la somme totale serait au plus égale à $\frac{B}{2n_2}$, par conséquent à la demi-circonférence, ce qui est impossible (comparer encore **842**), et, par conséquent, le côté $A_1\alpha$ serait inférieur au plus grand des deux autres côtés, c'est-à-dire à A_1B, lequel est lui-même (ainsi que nous l'avons vu) plus petit que AA_0. Or ceci ne peut avoir lieu, car une rotation du groupe qui transforme A_1 en A changerait α en un homologue de A plus voisin de ce dernier que A_0 (comparer **842**).

Il ne saurait non plus y avoir d'homologue β de B plus voisin de A que B, sans quoi la rotation qui change β en B changerait A en un homologue α de A tel que $\alpha B < AB$.

La distance AB *est inférieure à un quadrant :* car le point diamétralement

---

(¹) Cet angle ne sera pas un multiple de $\frac{1}{n_2}$, sans quoi la rotation de pôle B et d'angle égal à $\frac{1}{n_2}$ (laquelle appartient au groupe) transformerait A en un de ses homologues plus voisin de lui que A_0, contrairement à l'hypothèse).

opposé à B est un pôle de rotation homologue, soit de A, soit de B : dans les deux cas, nous savons que sa distance à A, est plus grande (¹) que AB.

845. Proposons-nous enfin de faire voir qu'à chacun des groupes obtenus correspondent deux polyèdres réguliers (sauf pour $n_1 = n_2 = 3$, qui ne donne pas deux polyèdres différents) : il nous suffira (**710**) de montrer que ces groupes donnent chacun deux divisions de la sphère en polygones sphériques réguliers et égaux.

A cet effet, considérons un point A de la sphère et appelons *domaine* de ce point la région formée par les points qui sont plus rapprochés de A que d'aucun de ses homologues $A_1 . A_2 \ldots$. Les points de ce domaine sont évidemment ceux qui sont dans le même hémisphère que A, par rapport à chacun des grands cercles perpendiculaires aux milieux de AA_1, de AA_2, etc : le domaine de A est donc un polygone sphérique convexe, limité par des arcs empruntés à tout ou partie des grands cercles en question.

Les points $A_1, A_2, \ldots$ homologues de A, auraient de même leurs domaines respectifs D_1, $D_2 \ldots$. *Tous ces domaines sont extérieurs les uns aux autres et recouvrent, dans leur ensemble, la sphère entière :* en effet, un point quelconque P de la surface appartient toujours à un de ces domaines et, en général, à un seul, à savoir celui qui correspond à l'homologue de A le plus rapproché (²) de P.

Supposons d'abord que le point A ne soit pas un pôle de rotation, de sorte que les points $A_1, A_2 \ldots$, tous distincts entre eux, sont en nombre égal *à* l'ordre N du groupe.

Tous les domaines D, D_1, $D_2 \ldots$, *sont égaux entre eux : chacun d'eux est le transformé de* D *par un déplacement du groupe et par un seul.* Le domaine D_1, par exemple, est le transformé de D par le déplacement qui change A en A_1 : car si P est un point de D, P_1 son transformé, la distance A_1P_1 (égale à AP) est plus petite que la distance du point P_1 à A_2, par exemple (cette distance étant égale à la distance P à l'homologue A' du point A qui est venu en A_2).

Ainsi chacun des domaines D, D_1, $D_2 \ldots$ correspond à un déplacement parfaitement déterminé du groupe.

Tout point P_0 *de la sphère a un homologue et, en général* (³), *un seul dans le domaine* D, puisque P_0 est contenu dans un des homologues de D.

---

(1) Il semblerait que les deux distances puissent être égales. Mais ceci ne pourrait se produire que si le point diamètralement opposé à B était un homologue de B, déduit de B par la rotation de pôle A : il faudrait, pour cela, que cette rotation soit d'ordre pair et l'on peut toujours appliquer le raisonnement du texte au pôle d'ordre 3. Au reste, si la distance AB était d'un quadrant, le triangle BAA_1 aurait ses angles à la base droits, ce qui n'est pas.

(2) S'il existe deux ou plusieurs homologues de A ayant avec P la distance minima, le point P est évidemment mitoyen à plusieurs domaines adjacents entre eux.

(3) Le cas exceptionnel est encore celui où le point P_0 est mitoyen à deux ou plusieurs domaines contigus.

On nomme *domaine fondamental* du groupe G tout domaine qui, comme D, possède cette propriété de renfermer un homologue et un seul de chaque point de la sphère.

846. Supposons maintenant que A soit un pôle de rotation d'ordre (¹) n_1 ou n_2. Alors les points A_1, A_2..., sont en nombre inférieur à N et les domaines D, D_1, D_2,... cessent d'être des domaines fondamentaux. Mais ils sont encore tous égaux entre eux, extérieurs les uns aux autres et recouvrent entièrement la sphère par leur ensemble (les raisonnements présentés tout à l'heure à cet égard continuant à être valables). Nous allons voir que chacun de ces domaines (D, par exemple) est un polygone sphérique régulier.

Pour cela, A étant supposé un pôle d'ordre n_1, reprenons les notations du n° **843** : le point B, pôle d'ordre n_2, sera (**844**) au moins aussi rapproché de A que tout autre homologue de B : chacun des grands cercles limites du domaine D laissera donc A et B dans le même hémisphère ou passera par B : il laissera donc dans le même hémisphère tout point de l'arc de grand cercle (²) AB. Cet arc de grand cercle appartiendra, par conséquent, au domaine D et B, à la frontière de ce domaine. Il en sera de même des points B_1. B_2,..., transformés successifs de B par la rotation R de pôle A et d'angle $\frac{1}{n}$.

Les arcs de grands cercles BB_1, B_1B_2,... déterminent un polygone sphérique régulier, inscrit à un cercle dont A est le pôle intérieur (puisque la distance AB est inférieure à un quadrant). Un grand cercle limite du domaine D ne saurait couper les côtés BB_1, ..., sans quoi il laisserait deux des points B, B_1,.., dans des hémisphères différents, ce que nous savons ne pas être : chacun de ces grands cercles laisse, dès lors, tout le polygone dans un seul et même hémisphère. Donc tout le polygone sphérique BB_1B_2... fera partie du domaine D.

Mais chaque côté de ce polygone est frontière de D : car le symétrique de A par rapport au plan du grand cercle BB_1 est un homologue de A, le point A_1 (*fig.* 661). Donc, notre conclusion est démontrée : le domaine du point A est un polygone sphérique régulier.

Nous aurons bien ainsi deux divisions de la sphère en polygones réguliers égaux : à savoir, les domaines des pôles homologues de A, d'une part; les domaines des pôles homologues de B, de l'autre.

---

(1) Le lecteur étudiera sans difficulté le cas où A est un pôle d'ordre 2, lequel n'offre d'ailleurs aucun intérêt particulier.

(2) Il est bien entendu (**465**) qu'il s'agit de l'arc de grand cercle moindre qu'une demi-circonférence.

- Exercise 4.5.6 corrects the sophism discussed in section 2.2;
- Exercise 4.6.2 completes the section 3.5 coverage of SSA triangle congruence; and
- Exercise 4.8.3 derives the formula for the volume of a sphere mentioned in section 3.14.

Others introduce entirely new subjects: for example,

- Independence proofs for various axioms in section 4.1;
- Arithmetic, geometric, and harmonic means in 4.5 and 4.6; and
- Spherical trigonometry in section 4.9.

There are a few original exercises here. But for most, the author acknowledges debt to his predecessors. Only a few exercises, with clear heritage, are given footnote citations. Others are old gems, whose origin would be hard to establish. The author has used much of this exercise set for decades. Each year new, different, solutions appear. You're encouraged to dive in, try out ideas old and new, and make these problems *your* old friends.

Hints are provided for a few exercises. Sometimes they suggest an appropriate method. Don't feel constrained to follow that, however, since many problems yield to attack from several directions. Other hints are approximate solutions: for example, "the answer is about 14.14." These help you check the feasibility of your solution. But you need to find the *exact* answer, which isn't obvious, even given the approximation. Indeed, 14.14 is *about* the same as both $11 + \pi$ and $10\sqrt{2}$, but those numbers are different.

4.1 Exercises on the incidence and ruler axioms

Concepts

Models of axioms
Finite geometric systems
Independence of the incidence axioms
Four-dimensional simplices
Ruler placement along a line

The incidence axioms of section 3.1 entail only a small part of Euclidean geometry. It's impossible to single out many applications of that material alone, so the exercises in this section are theoretical.

Axiom I5 states roughly that there are enough points to do *some* three-dimensional geometry. It's worded awkwardly. One reason for that was to facilitate the proof of the more informative lemma 3.1.3 and theorem 3.1.4. Exercise 1 explores alternate wordings. Exercise 2 shows that you can't do without I5, because the remaining axioms can be interpreted to describe

Curves, lengths, and curvatures

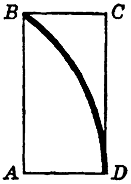

Figure 7.11

7.1 Curves and lengths One of the main purposes of this chapter may seem at first sight to be quite modest. We want to show that the length L of the circular arc of Figure 7.11, in which $ABCD$ is a rectangle and the arc is tangent to CD at D, satisfies the inequality

$$(7.12) \qquad |\overrightarrow{AB}| \leqq L \leqq |\overrightarrow{BC}| + |\overrightarrow{CD}|.$$

Before we ask our little sister to solve the problem, we should ask ourselves a question that shows us that the problem is not completely simple. What is a circular arc, and how do we know that it determines a number that can be called its length? It is clear that we need some definitions before we can do anything.

For an accurate treatment of matters relating to lengths of curves, we need more information about things that are sometimes called curves and are sometimes called oriented curves. A bumblebee can give us preliminary ideas by starting at A, flying to a rose at B, flying on to another rose at C, flying back over the same route to B, and then flying to D and on to E as in Figure 7.13. His total path is a curve, and we get the idea that a curve is not determined by a point set. We cannot know what the curve is until we know the order in which points on the curve were visited. For example, if the bumblebee flies from E back to A by traversing his route in reverse, his path is a new curve which can be called the negative of the original one. While the matter has psychological rather than logical importance to us now, we can feel quite confident that if the bumblebee makes a flight over the interval $t_1 \leqq t \leqq t_2$, and if we introduce an x, y, z coordinate system, then at each time in the interval he is surely someplace and that if we denote his coordinates by $x(t)$, $y(t)$, $z(t)$, then these coordinate functions are continuous functions of t. Of course, the curve does not uniquely determine the coordinate functions because the bumblebee can fly his course at different speeds, but any one set of appropriate coordinate functions does determine the intrinsic curve. The above brief discussion of curves leaves many unanswered questions. It will have served its purpose if it provides a hazy feeling that the following definition uses words in a reasonable way.

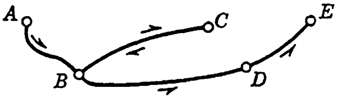

Figure 7.13

Definition 7.14 *If x, y, z are continuous functions of t over an interval, then the ordered set of points*

$$P(t) = P(x(t), y(t), z(t)) \tag{7.141}$$

for which t lies in the interval, and for which $P(t')$ is said to precede $P(t'')$ if $t' < t''$, is a curve (or oriented curve) C.

Professional creators of complicated curves can give an example of a curve in E_3 that is clever enough to "pass through" each point in a given cube or even in the whole E_3. Such curves are space-filling curves. It must not be presumed that all curves are complicated things, however. For example, when $z(t) = 0$ for each t, the curve lies in the xy plane and we omit the $z(t)$ when no confusion can result. We always have the possibility of setting $x(t) = t$ and replacing t by x. This shows that if f is continuous over $a \leqq x \leqq b$, then the set of points $(x, f(x))$ on the graph of $y = f(x)$ becomes a curve when we so order the points that $(x_1, f(x_1))$ precedes $(x_2, f(x_2))$ when $a \leqq x_1 < x_2 \leqq b$. Unless an explicit statement to the contrary is made, it is presumed that the points are ordered in this way whenever the graph of $y = f(x)$ is called a curve. Finally, such things as circles, ellipses, rectangles, and triangles become curves as soon as we think of them as being traversed once in the positive (counterclockwise) or negative (clockwise) direction.

Supposing that C is a given curve for which the interval appearing in Definition 7.14 is a closed interval $a \leqq t \leqq b$, we proceed to define (when it exists) a number $|C|$ which is called the length of C. Let P be a partition of the interval by partition points $t_0, t_1, \cdots, t_n$ for which

$$a = t_0 < t_1 < t_2 < \cdots < t_{n-1} < t_n = b. \tag{7.15}$$

For each $k = 0, 1, 2, \cdots, n$, let P_k be the point on C for which $t = t_k$. Figure 7.151 is a schematic figure that may be helpful, but it is much too simple to show how much care is needed to guarantee that the points are not scrambled in an inappropriate way. The polygon (or broken line) running from P_0 to P_1 to P_2 and so on to P_n is said to be *inscribed* in C. The number S_P defined by

$$S_P = \sum_{k=1}^{n} |\overrightarrow{P_{k-1}P_k}|$$

is the sum of the lengths of the sides of the inscribed polygon. Let S be the set of numbers S_P obtained by making partitions P of the interval $a \leqq t \leqq b$. In case there is no number M such that $S_P \leqq M$ whenever S_P is in S, it is said that C does not have length or that C does not have finite length or that C has infinite length or that $|C| = \infty$. In case there is a number M such that $S_P \leqq M$ whenever S_P is in S, then Theorem 5.46 guarantees existence of a least number $|C|$ such that $S_P \leqq |C|$ whenever S_P is in S. This number $|C|$ is then, by definition, the *length*† of C.

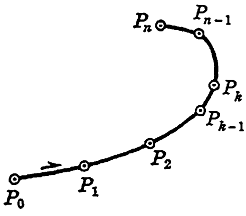

Figure 7.151

For future reference we state without proof the following theorem which involves notation we have been using.

Theorem 7.16 *The curve C has finite length $|C|$ if and only if*

$$|C| = \lim_{|P|\to 0} \sum_{k=1}^{n} |\overrightarrow{P_{k-1}P_k}|.$$

We now use the definition of length to prove the following theorem which gives, as a corollary, the desired result involving Figure 7.11.

Theorem 7.17 *Let f be continuous and monotone increasing (or monotone decreasing) over $a \leqq x \leqq b$. Let C be the graph of $y = f(x)$ so oriented*

---

† In old books particularly, a curve C having finite length is sometimes said to be *rectifiable;* the ancient idea is that if C is a string we could pull on the ends and straighten it out to get a straight string of finite length. We can all know enough about logic to know that if C is not a string, then little credence is placed upon consequences of the false assumption that C is a string.

that $(x_1, f(x_1))$ *precedes* $(x_2, f(x_2))$ *when* $x_1 < x_2$. *Then* C *has finite length* $|C|$ *and*

$$(7.171) \qquad |f(b) - f(a)| \leqq |C| \leqq |b - a| + |f(b) - f(a)|.$$

To prove this, let P be a partition of the interval $a \leqq x \leqq b$, and, for each k, let $P_k = (x_k, f(x_k))$. Let $\Delta x_k = x_k - x_{k-1}$ and let

$$\Delta y_k = f(x_k) - f(x_{k-1}).$$

Then

$$(7.172) \qquad |\overrightarrow{P_{k-1}P_k}| = \sqrt{\Delta x_k^2 + \Delta y_k^2}.$$

But

$$(7.173) \quad \Delta y_k^2 \leqq \Delta x_k^2 + \Delta y_k^2 \leqq |\Delta x_k|^2 + 2|\Delta x_k \, \Delta y_k| + |\Delta y_k|^2 = (|\Delta x_k| + |\Delta y_k|)^2.$$

Therefore,

$$(7.174) \qquad |\Delta y_k| \leqq |\overrightarrow{P_{k-1}P_k}| \leqq |\Delta x_k| + |\Delta y_k|.$$

But the numbers Δx_k are all positive and the numbers Δy_k are all negative (or all positive), and hence (why?) addition gives

$$(7.175) \quad |f(b) - f(a)| \leqq \sum_{k=1}^{n} |\overrightarrow{P_{k-1}P_k}| \leqq |b - a| + |f(b) - f(a)|.$$

Since this inequality holds for each partition P, the curve C has finite length $|C|$. Moreover, the least upper bound of the central sums cannot exceed the particular upper bound in (7.175), and no upper bound can be less than $|f(b) - f(a)|$. This proves Theorem 7.17.

We have been studying lengths of *curves*, that is, lengths of ordered sets of points of special types. There are other (and different) theories involving lengths of unordered sets S in E_3 and E_2 and E_1. We need not be authorities on these matters, but we should have at least a vague idea that, in elementary mathematics, the part of the set S of Figure 7.18 that lies "between" A and B has length L if there is a "natural ordering" of the points of the part that yields a curve C having length L.

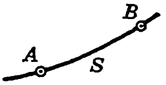

Figure 7.18

Problems 7.19

1 Tell how the length $|C|$ of a curve C is defined.

2 Show that if a curve C having finite length runs from A_1 through A_2 to A_3, then A_2 separates the curve into two parts each having finite length. It is not quite so easy to show that "the whole is equal to the sum of its parts," but it can be done. In particular, the length of a simple polygon is the sum of the lengths of its straight segments.

3 Show that the projection on the xy plane of a curve in E_3 is a curve in E_2.

4 Discover continuous functions x and y such that as t increases over the interval $0 \leqq t \leqq 4$, the point $(x(t), y(t))$ goes once in the positive direction around the square having vertices at the points (0,0), (0,1), (1,1), and (0,1). *Hint:* Write the equations which tell where a pencil point will be at time t if it traverses the square with unit speed. *One ans.:* $x(t) = t$ and $y(t) = 0$ when $0 \leqq t \leqq 1$; $x(t) = 1$ and $y(t) = t - 1$ when $1 \leqq t \leqq 2$; $x(t) = 3 - t$ and $y(t) = 1$ when $2 \leqq t \leqq 3$; $x(t) = 0$ and $y(t) = 4 - t$ when $3 \leqq t \leqq 4$.

5 Let L_1 be the length of the central path from A to B in Figure 7.191 and let L_2 be the length of the upper path. Find $L_2 - L_1$. *Ans.:* $(\pi - 2)h$.

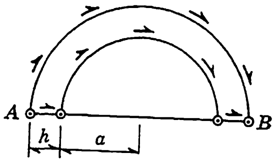

Figure 7.191

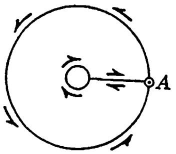

Figure 7.192

6 Supposing that the inner and outer circles of Figure 7.192 have radii ϵ and R, find the length of the curve which begins and ends at A.

7 Draw a square and from each corner draw a line segment toward the center but reaching only halfway to the center. Then insert arrows to specify a curve which forms the boundary of the inner region. Find the length of the curve.

8 This problem requires us to think about and calculate the lengths L_1 and L_2 of two of the paths by which an insect might crawl from the bottom B to the top T of the three-dimensional ring or anchor ring or torus of Figure 7.193. The first path, of length L_1, is a semicircle of radius $b + a$ which lies on the outer circumference of the torus. The second path, of length L_2, consists of a semicircle of radius a, and then a semicircle of radius $b - a$ which lies on the inner circumference of the torus, and finally another semicircle of a radius a. Try to guess which of the paths is shorter and then calculate L_1 and L_2. *Ans.:*

$$L_1 = \pi(a + b), \qquad L_2 = \pi a + \pi(b - a) + \pi a,$$

so the two paths have equal lengths. *Remark:* If a curve G lies in a set S and joins two points P_1 and P_2 of S, and if the length of G is less than or equal to the length of each other curve C in S which joins P_1 and P_2 then G is called a *geodesic* in S. As is easily imagined, the study of geodesics on a torus is an honorable part of an interesting subject.

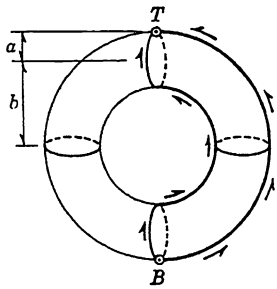

Figure 7.193

9 Creators of interesting tales for children say that, before the time when Columbus sailed across the ocean wet, everybody thought that the earth was flat. It has in fact been widely known for more than two thousand years that the earth is much like a spherical ball, but is not a spherical ball because mountains and valleys are quite noticeable around the Mediterranean sea and some other places. To show that a little information about lengths of arcs can have quite astonishing consequences, we look at the method said to have been used by the industrious Eratosthenes (*c.* 275 B.C. to *c.* 195 B.C.) to find what the radius (a number) of the earth would be if the earth were sandpapered to the shape of a spherical ball. Figure 7.194 shows O, the center of the earth, and a circular arc AB on the surface of the polished earth. The dotted vertical lines represent rays of light coming from the sun, and these rays are so nearly parallel that approximations can be based on a figure in which the rays are parallel to the line OA. Thus an observer at A finds that the sun is at his zenith. At B a pole BC of height h is erected in such a way that an observer at B thinks it is vertical, that is, the points O, B, C lie on the same line. In addition to h, two other lengths are obtained. In the first place, we find the length a of the circular arc DC which has its center at B (the base of the pole BC) and which has a shadow that just covers the pole. In the second place, the length b of the arc AB is obtained by more or less reliable surveyors. Let r be the radius of the earth. Since parallelism of the light rays implies that the angles DBC and AOB are equal, say to θ, we obtain the equation

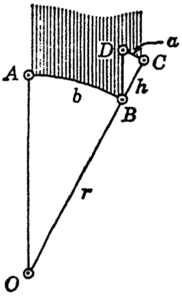

Figure 7.194

$$\frac{a}{h} = \frac{b}{r}$$

from the fact that each of the ratios is equal to θ. From this equation, r is easily calculated. It is not to be presumed that Eratosthenes spoke English and knew about miles, meters, and radians, but it is said that his calculations produced estimates of the radius and circumference of the earth that are almost as good as the estimates (radius 4000 miles, circumference 25,000 miles) that are ordinarily used for rough calculations. The fact that reliability of computed results depends upon accurate surveying is precisely the reason why two men named Mason and Dixon were commissioned to do some accurate surveying.

10 This problem, like some others, does not have a number for an answer. It requires us to think about connections between graphs and curves, and to learn some geometric terminology. The graph of a polynomial of degree n, that is, the graph of an equation of the form

$$y = a_0 + a_1x + a_2x^2 + \cdots + a_nx^n, \tag{1}$$

in which $a_n \neq 0$, used to be (and occasionally still is) called a *parabola of degree n*. For example, a line is a parabola of degree 1 and a cubic is a parabola of degree 3. While this terminology is almost extinct, the graph of the equation

$$y^2 = x^3 \tag{2}$$

still is called a *semicubical parabola*, the old idea being that, when we solve for y, we get an exponent which is not an integer but is half of 3. According to this

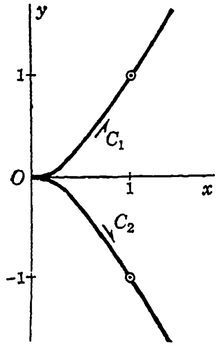

Figure 7.195

terminology, the semicubical parabola is a graph (not necessarily a curve) which is the point set shown in Figure 7.195. The graph has two *branches*, one being the upper branch consisting of points for which $y = x^{3/2}$, and the other being the lower branch consisting of points for which $y = -x^{3/2}$. Each of these branches contains the origin.

When the points on the upper branch are ordered in such a way that $P(x_1,y_1)$ precedes $P(x_2,y_2)$ when $x_1 < x_2$, the branch becomes a curve C_1 in the first quadrant having an end (or end point) at the origin. Similarly, when the points on the lower branch are ordered in such a way that $P(x_1,y_1)$ precedes $P(x_2,y_2)$ when $x_1 < x_2$. this branch becomes another curve C_2 having an end at the origin. With these orderings, the graph consists of the points on the two curves C_1 and C_2, the orderings being indicated by the arrows of Figure 7.195 which lie between the curves and the positive x axis. When $x > 0$, the curve C_1 has a tangent at the point $(x,x^{3/2})$ which has slope $\frac{3}{2}x^{1/2}$, and the curve C_2 has a tangent at the point $(x,-x^{3/2})$ which has slope $-\frac{3}{2}x^{1/2}$. We can observe that C_1 has a forward tangent at the origin whose slope is 0 and that C_2 has a forward tangent at the origin whose slope is 0. Although we have definitions involving tangents to graphs of equations of the form $y = f(x)$ and have definitions involving tangents to curves, we have no definitions which we can apply to decide whether the x axis is tangent to the semicubical parabola at the origin. In accordance with terminology other applications of which are not explained here, we say that the semicubical parabola has a *cusp* at the origin.

11 Prove that the curve C consisting of points P for which

$$\overrightarrow{OP} = t^2\mathbf{i} + t^3\mathbf{j} \tag{1}$$

coincides with the semicubical parabola having the equation $y^2 = x^3$. Sketch a new graph of the semicubical parabola and insert arrows which show how the points on the semicubical parabola are ordered to produce the single curve C. Put (1) in the equivalent form

$$\mathbf{r} = t^2\mathbf{i} + t^3\mathbf{j} \tag{2}$$

and, supposing that a particle moves along C in such a way that its displacement vector at time t is $\mathbf{r}$, find its velocity and acceleration at time t. See what happens when you try to write the equation of the line tangent to C at the point occupied by the particle at time $t = 0$.

12 The *folium of Descartes* is the graph of the parametric equations

$$x = \frac{3at}{1+t^3}, \qquad y = \frac{3at^2}{1+t^3}. \tag{1}$$

The vector $\mathbf{r}$ running from the origin to the point $P(x,y)$ on the folium is

$$\mathbf{r} = 3a\left[\frac{t}{1+t^3}\mathbf{i} + \frac{t^2}{1+t^3}\mathbf{j}\right], \tag{2}$$

there being one such point for each t for which $t \neq -1$. One who has considerable time to study the functions defined by (1) and to make some calculations can discover the manner in which P wanders as t increases. As t increases over the interval $-\infty < t < -1$, P runs over the curve C_1 extending from the origin (but not including the origin) down into the fourth quadrant. As t increases over the interval $-1 < t < \infty$, P traverses the curve C_2 which comes from the third quadrant to the origin and then runs around the loop toward the origin but does not again contain the origin. This problem requires that we obtain some more information without working so hard. Show that if (1) holds, then $y = tx$ and

$$x^3 + y^3 = 3axy. \tag{3}$$

Show that if (3) holds and $y = tx$, then (1) holds. Thus (3) is an equation of the folium. If $P(x,y)$ is a point on the folium, then (3) shows that $P(y,x)$ is also on the folium. Therefore, the line having the equation $y = x$ is an axis of symmetry of the folium. This suggests that we introduce the X, Y axes of Figure 7.196 which bear unit vectors $\mathbf{I}$ and $\mathbf{J}$. Use the formulas

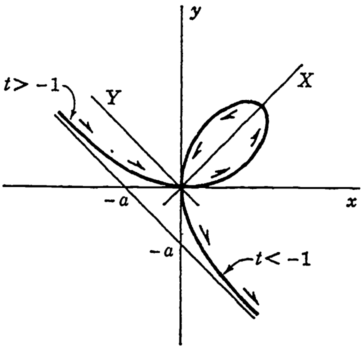

Figure 7.196

$$\mathbf{i} = \frac{1}{\sqrt{2}}(\mathbf{I} - \mathbf{J}), \qquad \mathbf{j} = \frac{1}{\sqrt{2}}(\mathbf{I} + \mathbf{J}) \tag{4}$$

with (2) to obtain the new equation

$$\mathbf{r} = \frac{3a}{\sqrt{2}}\left[\frac{t}{1 - t + t^2}\mathbf{I} + \frac{t(1-t)}{1+t^3}\mathbf{J}\right] \tag{5}$$

of the folium. Treating (5) as an equation of the form $\mathbf{r} = X\mathbf{I} + Y\mathbf{J}$, show that

$$X = \frac{3a}{\sqrt{2}}\frac{t}{1 - t + t^2}, \qquad \frac{dX}{dt} = \frac{3a}{\sqrt{2}}\frac{1 - t^2}{(1 - t + t^2)^2}$$

and use the result to find the minimum and maximum values of X and obtain more information about the folium.

13 Let f be continuous over the interval $0 \leqq x \leqq 1$ and let C be the set of points $(x, f(x))$ so ordered that $(x_1, f(x_1))$ precedes $(x_2, f(x_2))$ if $x_1 < x_2$. We may feel that C must have finite length, and we investigate the matter. Theorem 7.17 shows that C must have finite length if f is piecewise monotone, but we cannot be so sure when C is not piecewise monotone. When p and q are positive integers, the function $\sin^p x^q$ [or the function g for which $g(x) = \sin^p x^q$] is not piecewise monotone over the infinite interval $x > 1$ and the function $\sin^p (1/x^q)$ is not piecewise monotone over the interval $0 < x < 1$. Functions f for which $f(0) = 0$ and

$$f(x) = x^r \sin^p \frac{1}{x^q}$$

are, when $r > 0$, continuous but not piecewise monotone over $0 \leqq x \leqq 1$. Supposing that $p = q = r = 2$, show that $0 \leqq f(x) \leqq 1$ and f is differentiable as well as continuous over $0 \leqq x \leqq 1$. It can be proved that C does not have finite length.

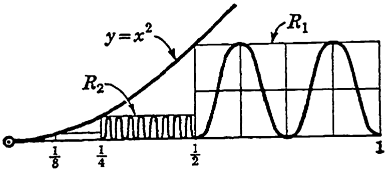

Figure 7.197

14 It is worthwhile to cultivate the ability to understand and even to construct simple examples of curves that have properties of various sorts. Figure 7.197 shows a part of the graph C of a function f, defined over $0 \leqq x \leqq 1$, for which $f'(x)$ exists when $0 \leqq x \leqq 1$ and, moreover, $f(x) = f'(x) = 0$ when $x = 0$, $1, \frac{1}{2}, \frac{1}{4}, \frac{1}{8}, \cdots$. We do not bother to give formulas expressing $f(x)$ in terms of x, being content to describe the graph C. The rectangles have their upper left corners on the graph of the equation $y = x^2$. The part C_1 of the graph in the rectangle R_1 over the interval $\frac{1}{2} \leqq x \leqq 1$ consists of four monotone parts. Show that $1 \leqq |C_1| \leqq 2$. We now turn our attention to the rectangle R_2 which lies above the interval $\frac{1}{4} < x < \frac{1}{2}$ and has height $(\frac{1}{4})^2$. In this rectangle we construct another part C_2 of C, this part consisting of 4^2 monotone parts so that $1 \leqq |C_2| \leqq 2$. Tell how to continue the construction so that the total resulting curve C will not have finite length.

15 Let $x(t)$ and $y(t)$ be continuous over $a \leqq t \leqq b$ so that the set of points $P(t)$ for which $P(t) = (x(t), y(t))$ and $a \leqq t \leqq b$, so ordered that $P(t_1)$ precedes $P(t_2)$ when $t_1 < t_2$, constitutes a curve C in the xy plane. The curve C is said to be a *closed curve* if $P(a) = P(b)$, that is, if the curve ends where it starts. Give some examples of closed curves and some examples of curves that are not closed.

16 A set A in the xy plane is said to be *connected* if to each pair P_1 and P_2 of points in A there corresponds a curve C of the type described in Problem 15 such that $P(a) = P_1$, $P(b) = P_2$, and each point of C is a point of A. Let Γ (capital gamma) be the circle with center at P_0 and radius r. Prove that the set A_1 of points P for which $|\overrightarrow{P_0P}| < r$ (this set being the *interior* of Γ) is a connected set. Prove that the set A_2 of points P for which $|\overrightarrow{P_0P}| > r$ (this being the *exterior* of Γ) is a connected set. Prove finally that if a set A_3 contains a point P_1 for which $|\overrightarrow{P_0P_1}| < r$ and a point P_2 for which $|\overrightarrow{P_0P_2}| > r$ but contains no point of the circle Γ, then A_3 is not a connected set. *Proof of last part:* Suppose, intending to establish a contradiction, that the set A_3 is connected. Then there is a curve C, determined by continuous functions $x(t)$ and $y(t)$ as in Problem 15, such that $P(a) = P_1$, $P(b) = P_2$, and each point of C is a point of A_3. Let

$$f(t) = |\overrightarrow{P_0P(t)}| = \sqrt{(x_0 - x(t))^2 + (y_0 - y(t))^2}$$

so that $f(t)$ is the distance from P_0 to $P(t)$. Then $f(a) < r$ and $f(b) > r$. Since f is a continuous function, it follows from the intermediate-value theorem (Theorem 5.48) that there is a number t^* for which $a < t^* < b$ and $f(t^*) = r$. The point $P(t^*)$ is a point of the circle Γ, so $P(t^*)$ is not in A_3 and we have the required contradiction. *Remark:* The geometrical nature of a circle in a plane is so simple that basic facts involving its interior and exterior are easily described and easily proved. The remaining problems of this list involve more general situations.

17 Sketch some figures to obtain preliminary ideas about matters relating to the following definition. Let S be a given nonempty set in the xy plane and let P' be a point of S. Let S' be the set of points P'' in S that can be connected to P' by curves lying in S. This means that P'' is a point of S' if and only if there exist functions $x(t)$ and $y(t)$ continuous over an interval $a \leqq t \leqq b$ such that $P(x(a), y(a))$ is P', $P(x(b), y(b))$ is P'', and $P(x(t), y(t))$ is a point in S whenever $a \leqq t \leqq b$. The set S' is a connected set because if P_1 and P_2 lie in S', then P_1 and P_2 can be connected to P' by curves C_1 and C_2 lying in S' and these two curves can be combined to give a single curve C connecting P_1 to P_2 and lying in S'. This set S' is the *maximal connected subset* of S that contains P' or, briefly, the *component* of S that contains P'.

18 The curve C of Problem 15 is said to have a *multiple point* at the point Q if there exist two numbers t_1 and t_2 such that $a \leqq t_1 < t_2 < b$ (or $a < t_1 < t_2 \leqq b$) and the two points $P(t_1)$ and $P(t_2)$ coincide with Q. The curve is said to be *simple* (free from multiple points) if it has no multiple points. Give some examples of closed curves that have multiple points and some examples of simple closed curves.

19 The French mathematician Camille Jordan (1838–1922) was the first person to give serious attention to the difficult question whether each simple closed plane curve "separates the plane" into exactly two nonempty components one of which constitutes the outside of the curve and the other of which constitutes the inside. Such curves are called *Jordan curves.* The following theorem is known as the Jordan curve theorem.

Theorem *If C is a simple closed plane curve (or Jordan curve), then the set S of points of the plane which are not points of C contains exactly two (no more and no fewer) nonempty components S_1 and S_2.*

The author now owes his readers an explanation. It never has been and need not be expected that students of elementary calculus know anything about the Jordan curve theorem. Nevertheless, the author insists that each student should have opportunities to pick up ideas about mathematics. We can know that the Jordan curve theorem is so difficult that Jordan never succeeded in proving it and that we must learn more mathematics before we can undertake to understand proofs that have been given or to construct new proofs. We can know that many persons who never generated much interest in additions of fractions become intensely interested in problems involving sets and curves.

7.2 Lengths and integrals

Let x, y, and z be given functions having continuous derivatives over the closed interval $a \leqq t \leqq b$. Let

$$P(t) = P(x(t), y(t), z(t)) \tag{7.21}$$

so that, for each t, $P(t)$ is the point having coordinates displayed in (7.21). Let $\mathbf{r}(t)$ denote the vector running from the origin to $P(t)$ so that, for each t,

$$\mathbf{r}(t) = x(t)\mathbf{i} + y(t)\mathbf{j} + z(t)\mathbf{k}. \tag{7.22}$$

We propose to set up an integral for the length $|C|$ of the curve C traversed by $P(t)$, or by the tip of the vector $\mathbf{r}(t)$, as t increases from a to b. It could be supposed that our main interest is in lengths of curves and that we should get our result as quickly as possible, but this is not true. Integrals are very important things, and we proceed slowly to learn as much as we can about them.

Our first step is to make a partition P of the interval $a \leqq t \leqq b$ having partition points $t_0, t_1, \cdots, t_n$ and to sketch schematic figures showing the partition and points $P_{k-1} = P(t_{k-1})$ and $P_k = P(t_k)$ on C. We then tell ourselves that if $|P|$, the norm of the partition, is small then $|\overrightarrow{P_{k-1}P_k}|$ should be a good approximation to the length of the part of C between P_{k-1} and P_k, so $\Sigma|\overrightarrow{P_{k-1}P_k}|$ should be a good approximation to $|C|$ and hence it should be true that

$$|C| = \lim \Sigma|\overrightarrow{P_{k-1}P_k}|. \tag{7.23}$$

We have employed the fundamental ideas about length given in Section 7.1. The next step is to put the right member into a more useful form. While introduction of the abbreviations may be unwise when acres of paper and blackboard space are available, we simplify our formulas by setting

$$\Delta t_k = t_k - t_{k-1}, \qquad \Delta x_k = x(t_k) - x(t_{k-1}), \qquad \Delta y_k = y(t_k) - y(t_{k-1}),$$
$$\Delta z_k = z(t_k) - z(t_{k-1}).$$

Then (7.23) gives

$$|C| = \lim \Sigma \sqrt{\Delta x_k^2 + \Delta y_k^2 + \Delta z_k^2}. \tag{7.231}$$

We can make this look much more like a limit of Riemann sums by introducing factors Δt_k in numerators and denominators to obtain

$$|C| = \lim \sum \sqrt{\left(\frac{\Delta x_k}{\Delta t_k}\right)^2 + \left(\frac{\Delta y_k}{\Delta t_k}\right)^2 + \left(\frac{\Delta z_k}{\Delta t_k}\right)^2}\, \Delta t_k. \tag{7.232}$$

The possibility of making further progress is provided by the hypothesis that x, y, and z have continuous derivatives.

We should be realistic and realize that there are different ways to proceed. We can cheerfully adopt the view that, however we choose t_k^* in the kth subinterval of our partition, the kth term in (7.232) should be closely approximated by $f(t_k^*)\,\Delta t_k$, where

$$f(t) = \sqrt{[x'(t)]^2 + [y'(t)]^2 + [z'(t)]^2}. \tag{7.233}$$

Thus we can expect that

$$|C| = \lim \Sigma f(t_k)\,\Delta t_k. \tag{7.234}$$

Since our hypothesis guarantees that f is continuous and hence integrable, the Riemann sums do have a limit and we are led to the formula

$$|C| = \int_a^b \sqrt{[x'(t)]^2 + [y'(t)]^2 + [z'(t)]^2}\, dt. \tag{7.24}$$

This is, in fact, a correct and very satisfying formula which treats all coordinates alike and enables us to calculate lengths of curves that wind around through E_3. In case C lies in the xy plane, everything is the same except that $z(t) = z'(t) = 0$ and the formula is thereby simplified. In applications, it often happens that $x(t) = t$ and the formula is written in one or another of the forms

$$(7.241) \quad |C| = \int_a^b \sqrt{1 + [y'(t)]^2 + [z'(t)]^2}\, dt = \int_a^b \sqrt{1 + [y'(x)]^2 + [z'(x)]^2}\, dx = \int_a^b \sqrt{1 + \left(\frac{dy}{dx}\right)^2 + \left(\frac{dz}{dx}\right)^2}\, dx$$

and, for plane curves, we have $z = 0$. It is not easy to be sure that the "cheerful derivation" of (7.24) is slovenly. A person can claim that he will not use the definition of length given in Section 7.1, that he is interested only in curves C for which $x'(t)$, $y'(t)$, and $z'(t)$ are continuous, and that all of the work that he has done merely motivates his definition whereby $|C|$ is *defined* by (7.24). His position is tenable and, so long as he stays in his own garden, it is even reasonable. In fact, many quantities in pure and applied mathematics are defined by integrals, and sometimes the definitions are so well motivated that readers (and even writers) fail to recognize the fundamental fact that it is utterly impossible to *prove* correctness of a formula for something that has not been defined.

We start again with the formula

$$(7.25) \qquad |C| = \lim \sum \sqrt{\left(\frac{\Delta x_k}{\Delta t_k}\right)^2 + \left(\frac{\Delta y_k}{\Delta t_k}\right)^2 + \left(\frac{\Delta z_k}{\Delta t_k}\right)^2}\, \Delta t_k,$$

which is (7.232) brought up where we can see it, but this time our situation is different. We suppose that $|C|$ is *defined* by (7.25), and we want to *prove* that the right side is an integral. For present purposes, the work of the preceding paragraph would be slovenly because nothing was proved. We could try to fix everything by trying to prove that there is a t_k^* such that, with the notation of the preceding paragraph, the kth term of (7.232) is exactly equal to $f(t_k^*)\, \Delta t_k$. We do not try this, however, because of the fear that the process would involve only uninformative hard work. Instead, we start by applying the mean-value theorem (Theorem 5.52) to (7.25). Since x' is continuous, there must be a t_k^* for which $t_{k-1} < t_k^* < t_k$ and

$$(7.251) \qquad \frac{\Delta x_k}{\Delta t_k} = \frac{x(t_k) - x(t_{k-1})}{t_k - t_{k-1}} = x'(t_k^*).$$

Similar formulas involving y and z end with $y'(t_k^{**})$ and $z'(t_k^{***})$, there being no reason for hope that the three numbers t_k^*, t_k^{**}, and t_k^{***} are the same. Thus

$$(7.252)\qquad |C| = \lim \Sigma \sqrt{[x'(t_k^*)]^2 + [y'(t_k^{**})]^2 + [z'(t_k^{***})]^2}\,\Delta t_k.$$

This looks much like a Riemann sum formed for the function f having values

$$(7.253)\qquad f(t) = \sqrt{[x'(t)]^2 + [y'(t)]^2 + [z'(t)]^2},$$

and there is no difficulty in the important special case in which $x(t) = t$ and $z(t) = 0$ for each t. Except in special cases, we must consider consequences of the fact that t_k^*, t_k^{**}, and t_k^{***} may be different. Since difficulties of this nature (and they were real difficulties in the old days) are usually associated with the name of Duhamel (1797–1872), we can call this a Duhamel difficulty. To treat all coordinates alike and to be precise about this matter, we let T_k be the center of the interval $t_{k-1} \leqq t \leqq t_k$. We can then put (7.252) in the form

$$(7.254)\qquad |C| = \lim_{|P|\to 0} \sum_{k=1}^{n} [f(T_k) + \delta_k]\,\Delta t_k,$$

where

$$(7.255)\qquad \delta_k = \sqrt{[x'(t_k^*)]^2 + [y'(t_k^{**})]^2 + [z'(t_k^{***})]^2} - \sqrt{[x'(T_k)]^2 + [y'(T_k)]^2 + [z'(T_k)]^2}.$$

To prove the desired result

$$(7.26)\qquad |C| = \int_a^b f(t)\,dt = \int_a^b \sqrt{[x'(t)]^2 + [y'(t)]^2 + [z'(t)]^2}\,dt,$$

it is therefore sufficient (and also necessary) to prove that

$$(7.261)\qquad \lim_{|P|\to 0} \sum_{k=1}^{n} \delta_k\,\Delta t_k = 0.$$

It is easy to originate the correct idea that the numbers t_k^*, t_k^{**}, and t_k^{***} are all near T_k, that continuity of the functions x', y', z' implies that the two terms on the right side of (7.255) are nearly equal, that the numbers δ_k are all near 0, and hence that the sum in (7.261) is near 0, whenever the norm $|P|$ of P is small. The easy way to make this precise is to use the fact that the first term in the right member of (7.255) is a continuous function of three variables. Using only functions of one variable, we can let $0 < \epsilon' < \epsilon$ and choose a number $\delta > 0$ such that the numbers α, β, and γ defined by

$$(7.262)\qquad [x'(u)]^2 - [x'(v)]^2 = \alpha, \qquad [y'(u)]^2 - [y'(v)]^2 = \beta, \qquad [z'(u)]^2 - [z'(v)]^2 = \gamma$$

all have absolute values less than ϵ' when $|u - v| < \delta$. When $|P| < \delta$, the right member of (7.255) then has the form

$$\delta_k = \sqrt{A_k \pm h} - \sqrt{A_k}, \tag{7.263}$$

where the quantities under the radicals are nonnegative and $0 \leqq h \leqq 3\epsilon'$. It follows that $|\delta_k| \leqq \sqrt{3\epsilon'}$ and hence

$$\left| \sum_{k=1}^{n} \delta_k \, \Delta t_k \right| \leqq \sum_{k=1}^{n} \sqrt{3\epsilon'} \, \Delta t_k = \sqrt{3\epsilon'}\,(b - a) < \epsilon \tag{7.264}$$

provided ϵ' is so chosen that the last inequality holds. This proves (7.261) and hence (7.26).

In order to introduce coordinates on curves, we suppose that x, y, and z are functions having continuous derivatives over an open interval $a < t < b$ and that C is the curve traversed by the point $P(t)$ having coordinates $(x(t), y(t), z(t))$ as t increases. To avoid difficulties, we suppose that the curve is *simple;* this means that $P(t_1) \neq P(t_2)$ when $t_1 \neq t_2$ so that $P(t)$ cannot be in the same place at two different times. Let t_0 be fixed such that $a < t_0 < b$. Then, as in Figure 7.27, we can assign coordinates to points on C by letting s be the length of the curve running from $P(t_0)$ to $P(t)$ when $t_0 \leqq t < b$ and letting $-s$ be the length of the curve running from $P(t)$ to $P(t_0)$ when $a < t \leqq t_0$. Then, whenever $a < t < b$, the coordinate $s(t)$ of P at time t is

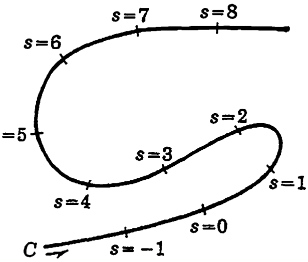

Figure 7.27

$$s(t) = \int_0^t \sqrt{[x'(\tau)]^2 + [y'(\tau)]^2 + [z'(\tau)]^2}\, d\tau. \tag{7.28}$$

In this formula τ (tau, the Greek t) is used as a dummy variable of integration. Since our hypothesis implies that the integrand is continuous, Theorem 4.35 enables us to differentiate with respect to t to obtain the formula

$$s'(t) = \sqrt{[x'(t)]^2 + [y'(t)]^2 + [z'(t)]^2}, \tag{7.281}$$

which is often written in the form

$$\frac{ds}{dt} = \sqrt{\left(\frac{dx}{dt}\right)^2 + \left(\frac{dy}{dt}\right)^2 + \left(\frac{dz}{dt}\right)^2}. \tag{7.282}$$

This is related to the formulas we get when we set

$$\mathbf{r} = x(t)\mathbf{i} + y(t)\mathbf{j} + z(t)\mathbf{k} \tag{7.283}$$

and calculate the velocity $\mathbf{v}$ and the speed $|\mathbf{v}|$ from the formulas

$$\mathbf{v} = x'(t)\mathbf{i} + y'(t)\mathbf{j} + z'(t)\mathbf{k} \tag{7.284}$$

and

$$|\mathbf{v}| = \sqrt{[x'(t)]^2 + [y'(t)]^2 + [z'(t)]^2}. \tag{7.285}$$

Since the right members of (7.282) and (7.285) are the same, this shows that, in appropriate circumstances, the speed determined so quickly by taking the absolute value of the velocity is the same as the "speed of the particle in its path" determined by use of coordinates on the path.

Problems 7.29

1 Find the length of the part of the helix

$$x = a\cos t, \qquad y = a\sin t, \qquad z = kt$$

traversed by a particle at $P(x,y,z)$ as t increases from 0 to 2π.

2 Using the first standard equation in

$$\frac{x^2}{a^2} + \frac{y^2}{b^2} = 1, \qquad x = a\cos\theta, \qquad y = b\sin\theta,$$

where $0 < b < a$, set up an integral for the length of the part of the ellipse lying in the first quadrant. Then use the parametric equations to set up another integral for the same length

Ans.:
$$\int_0^a \sqrt{\frac{a^2 - k^2x^2}{a^2 - x^2}}\,dx, \qquad a\int_0^{\pi/2} \sqrt{1 - k^2\cos^2\theta}\,d\theta,$$

where $k^2 = (a^2 - b^2)/a^2$. These are *elliptic integrals*, and others more or less like them are also called elliptic integrals. There is no easy way to obtain their exact numerical values.

3 Set up an integral for the length L of the curve traced by the point P having coordinates

$$x = a\theta - b\sin\theta, \qquad y = a - b\cos\theta$$

as θ increases from 0 to 2π, and show that the result can be put in the form

$$L = (a + b)\int_0^{2\pi} \sqrt{1 - \frac{4ab}{(a + b)^2}\cos^2\frac{\theta}{2}}\,d\theta.$$

When $b \neq a$, this is an elliptic integral. When $b = a$, the graph is, as Problem 16 of Section 6.5 shows, an ordinary cycloid. Sketch a figure and explain a simple geometric argument which shows that, when $b = a$ and the approximations $\pi = 3$ and $\pi^2 = 10$ are used, $\sqrt{52}\,a < L < 10a$. Finally, show that $L = 8a$.

4 Find the length of the part of the curve having the equations

$$x = 2t^3, \qquad y = \frac{t^2 - 3}{2}, \qquad z = \frac{2 - t^2}{2}$$

which lies between the points $(0, -\frac{3}{2}, 1)$ and $(2, -1, \frac{1}{2})$. *Ans.:* $L = \frac{\sqrt{2}}{54}[19^{3/2} - 1]$.

5 When $0 < b < a$ and a circle (or cog wheel) of radius b rolls without slipping inside a circle of radius a as in Figure 7.291, the path traced by a point on the small rolling circle is a hypocycloid (inside-cycloid) that appeared in one of Problems 6.59 and that even small dictionaries describe. It can be shown that when the center of the small circle has passed over an angle θ (that could be ωt), the point initially at $(a,0)$ has coordinates

$$x = (a - b)\cos\theta + b\cos\frac{a-b}{b}\theta$$

$$y = (a - b)\sin\theta - b\sin\frac{a-b}{b}\theta.$$

With the aid of Figure 7.291 find the amount by which θ must increase as P traverses one arch of the cycloid from the big circle back to the big circle. Then find the length of one arch of the cycloid. *Ans.:* $8b(a - b)/a$.

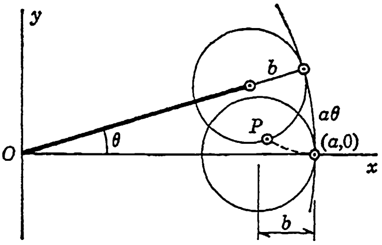

Figure 7.291

6 It is a remarkable fact that when $b = a/4$, so that the hypocycloid of the preceding problem has four cusps, the equations can be put in the form

$$x = \frac{a}{4}(3\cos\theta + \cos 3\theta) = a\cos^3\theta$$

$$y = \frac{a}{4}(3\sin\theta - \sin 3\theta) = a\sin^3\theta$$

so that

$$x^{2/3} + y^{2/3} = a^{2/3}.$$

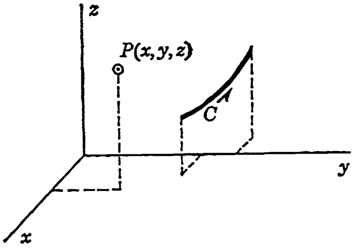
Using this formula, find the length of the part of the hypocycloid in the first quadrant. *Ans.:* $3a/2$.

7 Let f and g have continuous derivatives over $a \leqq u \leqq b$. Let C be the curve which the point $P(f(u), g(u))$ traverses in an xy plane as u increases from a to b. Let C be regarded as a wire having linear density δ so that a piece of C of length L has mass δL. Let p be a nonnegative integer and let x_0 be a constant. Set up an integral for the pth moment of the wire about the line having the equation $x = x_0$.

8 With or without assistance from the preceding problem, set up an integral for the pth moment about a diameter of a circular wire having linear density δ.

9 Centroids of triangles, rectangles, and regular polygons coincide with the centroids of the regions that they bound. Draw some polygons for which there is violent departure from coincidence.

Figure 7.292



10 Figure 7.292 is intended to steer our thoughts toward a wire or cord concentrated on a curve C and to make us realize that we have not yet calculated the gravitational force $\mathbf{F}$ upon a particle P^* of mass m at $P(x,y,z)$ that is produced by the wire. Set up an integral for $\mathbf{F}$. *Outline of solution:* Since x, y, z have been preempted, we take the curve C to be the ordered set of points $P(t) = P(u,v,w)$ for which u, v, w are functions of t having continuous derivatives and

$$\overrightarrow{OP} = u(t)\mathbf{i} + v(t)\mathbf{j} + w(t)\mathbf{k} \qquad (a \leqq t \leqq b), \tag{1}$$

and suppose that the linear density (mass per unit length) of C at $P(t)$ is $\delta(t)$, where δ is a continuous function of t. Letting Q be a partition of the interval $a \leqq t \leqq b$ with partition points t_k and supposing that $t_{k-1} \leqq t_k^* \leqq t_k$, we take the number $\delta(t_k^*)\ |\overrightarrow{P_{k-1}P_k}|$ as an approximation to the mass of an element of the wire. The force $\Delta\mathbf{F}_k$ which this element produces upon the particle P^* of mass m at $P(x,y,z)$ should have approximate magnitude

$$\frac{Gm\delta(t_k^*)|\overrightarrow{P_{k-1}P_k}|}{|\overrightarrow{PP}(t_k^*)|^2}. \tag{2}$$

Introducing vectors and coordinates gives the approximation

$$\Delta\mathbf{F}_k = Gm\delta(t_k^*)\sqrt{\left(\frac{\Delta u_k}{\Delta t}\right)^2 + \left(\frac{\Delta v_k}{\Delta t}\right)^2 + \left(\frac{\Delta w_k}{\Delta t}\right)^2} \\ \frac{[u(t_k^*) - x]\mathbf{i} + [v(t_k^*) - y]\mathbf{j} + [w(t_k^*) - z)]\mathbf{k}}{\{[u(t_k^*) - x]^2 + [v(t_k^*) - y]^2 + [w(t_k^*) - z]^2\}^{3/2}}\Delta t. \tag{3}$$

The limit of the sum of these things should be $\mathbf{F}$, and we are led to the definition

$$\mathbf{F} = Gm\int_a^b \delta(t)\ \sqrt{[u'(t)]^2 + [v'(t)]^2 + [w'(t)]^2} \\ \frac{[u(t) - x]\mathbf{i} + [v(t) - y]\mathbf{j} + [w(t) - z]\mathbf{k}}{\{[u(t) - x]^2 + [v(t) - y]^2 + [w(t) - z]^2\}^{3/2}}\,dt. \tag{4}$$

This is our result. In case the wire coincides with a circle of radius a in the yz plane having its center at the origin, we can set $u(t) = 0$, $v(t) = a\cos t$, $w(t) = a\sin t$ and put (4) in the form

$$\mathbf{F} = Gma\int_0^{2\pi} \delta(t)\,\frac{-x\mathbf{i} + [a\cos t - y]\mathbf{j} + [a\sin t - z]\mathbf{k}}{\{x^2 + [a\cos t - y]^2 + [a\sin t - z]^2\}^{3/2}}\,dt. \tag{5}$$

In case P^* is on the axis of the wire so that $y = z = 0$, this takes the much simpler form

$$\mathbf{F} = Gma\int_0^{2\pi} \delta(t)\,\frac{-x\mathbf{i} + a\cos t\mathbf{j} + a\sin t\mathbf{k}}{(x^2 + a^2)^{3/2}}\,dt. \tag{6}$$

In case the wire is a uniform wire so that, for some constant δ_0 we have $\delta(t) = \delta_0$ for each t, the coefficients of $\mathbf{j}$ and $\mathbf{k}$ are zero because

$$\int_0^{2\pi} \cos t\,dt = \int_0^{2\pi} \sin t\,dt = 0 \tag{7}$$

(or, as is usually said, "because of symmetry") and (6) reduces to

$$\mathbf{F} = -\frac{GmMx}{(x^2 + a^2)^{3/2}}\mathbf{i}, \tag{8}$$

where $M = 2\pi a\delta_0$, the total mass of the wire. *Remark:* With slight differences in notation, (8) was used extensively in some of the Problems 4.79.

11 Let units of measurement be so employed that the potential at $P_0(x_0,y_0,z_0)$ due to a particle of mass m concentrated at a point $P(x,y,z)$ is $m/|\overline{P_0P}|^2$. Let x, y, z have continuous derivatives over $a \leqq u \leqq b$, and let $P(x,y,z)$ traverse a curve C as u increases from a to b. Let C have linear density δ. Let $P_0(x_0,y_0,z_0)$ be a point not on C. Remembering that potentials are scalars, and remembering or learning quickly that the potential due to a collection of particles is equal to the sum of the potentials due to the individual particles, set up an integral which is equal to the potential at P_0 due to C.

12 Set up an integral equal to the moment of inertia (second moment) about the z axis of the curve C of the preceding problem.

13 When a particle has fallen (or slid without friction) from height $G(b)$ to a lower height $G(u)$, its speed is $\sqrt{2g[G(b) - G(u)]}$, where g is the acceleration of gravity. We all know that if we travel a short distance with a constant speed, we get the time required for the trip by dividing the distance by the speed. With this basic information, we are prepared to attack a problem. Let F and G be functions having positive continuous derivatives over $0 \leqq u \leqq b$ and let the point $P(F(u), G(u))$ traverse a curve C from the origin to a point B in the first quadrant of an xy plane as u increases from 0 to b. Sketch a schematic figure showing the curve C. Set up an integral which gives the time T required for a particle starting from rest at B to slide without friction down the curve C to the origin.

14 The reflecting surface of a headlight is a part of a paraboloid, of depth 4 inches and diameter 12 inches, obtained by rotating a part of a parabola about its axis. Find its area. *Solution:* This is not an easy problem, since a basic difficulty lurks in the fact that areas of such surfaces have not been defined. We start by so determining k that the parabola having the equation $y = kx^2$ contains (or passes through) the point (6,4). This gives $y = \frac{1}{9}x^2$ for the equation of the generating parabola. With the possibility of setting $a = 0$, $b = 6$, and $f(x) = \frac{1}{9}x^2$, we suppose that f has a continuous derivative over an interval $a \leqq x \leqq b$. Let S be the surface generated by rotating, about the y axis, the part of the graph G of $y = f(x)$ for which $a \leqq x \leqq b$. Expecting to use some intuitive ideas about areas, we make a partition P of the interval $a \leqq x \leqq b$ and consider one particular subinterval $x_{k-1} \leqq x \leqq x_k$. As an approximation to the length L_k of the segment G_k of the graph G containing points x for which $x_{k-1} \leqq x \leqq x_k$, we may use the number

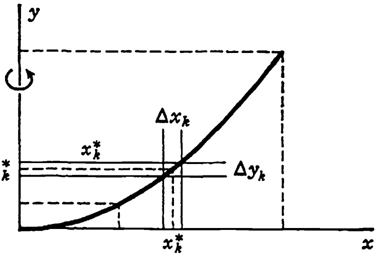


Figure 7.293

$$(1) \qquad \sqrt{\Delta x_k^2 + \Delta y_k^2} = \sqrt{1 + \left(\frac{\Delta y_k}{\Delta x_k}\right)^2}\,\Delta x_k = \sqrt{1 + [f'(x_k^*)]^2}\,\Delta x_k,$$

where $\Delta x_k = x_k - x_{k-1}$, $\Delta y_k = f(x_k) - f(x_{k-1})$, and x_k^* is a number for which $x_{k-1} < x_k^* < x_k$. Figure 7.293 is helpful. Even though areas are not yet defined. we can have a feeling that when the segment G_k is rotated about the y axis, its points all travel approximately the same distance $2\pi x_k$ and that the segment generates a surface essentially like a ribbon having width L_k and length $2\pi x_k$. This leads us to the intuitive idea that one term in the sum

$$|S| = \lim \Sigma 2\pi \sqrt{1 + [f'(x_k)]^2}\, x_k\, \Delta x_k \tag{2}$$

should, when the norm $|P|$ of P is small, be a good approximation to the area of the part of S generated by one segment of the graph G. The next step is to adopt the tentative intuitive conclusion that the sum is a good approximation to the total area $|S|$ of S when the norm of P is small or, in other words, that (2) should be valid. Our theory of Riemann sums and integrals assures us that if (2) is true, then

$$|S| = 2\pi \int_a^b \sqrt{1 + [f'(x)]^2}\, x\, dx. \tag{3}$$

If we have sufficient confidence in our calculations (it would, of course, be fatal to use an incorrect formula for the circumference of a circle of radius x_k) and in our intuitive ideas, we can install the formula (3) as one (not *the*) definition of area of surfaces of revolution. It does not make sense to claim that this definition is "correct," but experience shows that it is useful and this is all that we can expect from definitions. For the case in which $f(x) = kx^2$, $a = 0$, and $b = r$, (3) reduces to

$$|S| = 2\pi \int_0^r (1 + 4k^2x^2)^{1/2} x\, dx = \frac{\pi}{6k^2}[(1 + 4k^2r^2)^{3/2} - 1].$$

When $k = \frac{1}{8}$ and $r = 6$, this reduces to $|S| = 49\pi$.

15 We invest a little time to look at some *curve integrals* that are called *line integrals* by those who adhere to the notion that curves are lines. Let functions $x(t)$, $y(t)$, $z(t)$, the point $P(t)$, the vector $\mathbf{r}(t)$, the curve C, the partition P of $a \leqq t \leqq b$, and the numbers Δt_k, Δx_k, Δy_k, Δz_k be defined as in the part of this section preceding (7.231). Let a vector function $\mathbf{F}$ having scalar components f_1, f_2, f_3 be defined and continuous over a part of E_3 that contains the curve C. We consider $\mathbf{F}$ to be a force which operates upon a particle at $P(t)$ as the particle moves from $P(a)$ to $P(b)$. The schematic Figure 7.294 may be helpful. With the idea that the work done by $\mathbf{F}$ as the particle moves from $P(t_{k-1})$ to $P(t_k)$ is closely approximated by

Figure 7.294

$$\mathbf{F}(x_k,y_k,z_k)\cdot\Delta\mathbf{r}_k \tag{1}$$

when the norm of the partition P is small, we can define the total work W done by $\mathbf{F}$ by the formula

$$W = \lim \Sigma \mathbf{F}(x_k,y_k,z_k)\cdot\Delta\mathbf{r}_k. \tag{2}$$

The right member of (2) is an example of a *curve integral*, and it is denoted by the symbol in

$$W = \int_C \mathbf{F}(\mathbf{r})\cdot d\mathbf{r}, \tag{3}$$

where $\mathbf{F}(\mathbf{r})$ is the vector function of the vector $\mathbf{r}$ defined by

$$\mathbf{F}(\mathbf{r}) = \mathbf{F}(x,y,z) \tag{4}$$

in which x, y, z are the numbers for which $\mathbf{r} = x\mathbf{i} + y\mathbf{j} + z\mathbf{k}$. The right member of (3) is read "the integral over C of $\mathbf{F}(\mathbf{r})$ dot $d\mathbf{r}$," the fundamental idea being that it is the curve C that is partitioned to produce the approximating sums. To learn something about this curve integral, we can use the formulas

$$\mathbf{F}(x,y,z) = f_1(x,y,z)\mathbf{i} + f_2(x,y,z)\mathbf{j} + f_3(x,y,z)\mathbf{k} \tag{5}$$

$$\Delta\mathbf{r}_k = \Delta x_k\mathbf{i} + \Delta y_k\mathbf{j} + \Delta z_k\mathbf{k} \tag{6}$$

to put (2) in the form

$$W = \lim \sum \left[f_1(x(t_k),\, y(t_k),\, z(t_k))\,\frac{\Delta x_k}{\Delta t_k} + f_2(x(t_k),\, y(t_k),\, z(t_k))\,\frac{\Delta y_k}{\Delta t_k} + f_3(x(t_k),\, y(t_k),\, z(t_k))\,\frac{\Delta z_k}{\Delta t_k}\right]\Delta t_k. \tag{7}$$

A proof very similar to the one centering around (7.255) enables us to show that

$$W = \int_a^b f_1(x(t),\, y(t),\, z(t))x'(t)\, dt + \int_a^b f_2(x(t),\, y(t),\, z(t))y'(t)\, dt + \int_a^b f_3(x(t),\, y(t),\, z(t))z'(t)\, dt. \tag{8}$$

This is a formula from which W can be calculated or approximated. Since we are not electronic computers, we do not (at least at the present time) make calculations, but we do point out that the integrals in (8) are abbreviated to those in the formula

$$W = \int_C [f_1(x,y,z)\, dx + f_2(x,y,z)\, dy + f_3(x,y,z)\, dz]. \tag{9}$$

The integrals in (9) are scalar curve integrals. Whenever we want to know what these things mean and how they can be evaluated, we should have the wits to check back to see what they abbreviate. While it may be possible to overemphasize the importance of the matter, we can observe that if we set

$$\mathbf{F}(\mathbf{r}) = f_1(x,y,z)\mathbf{i} + f_2(x,y,z)\mathbf{j} + f_3(x,y,z)\mathbf{k} \tag{10}$$

and make the pretense that $d\mathbf{r}$ is a vector for which

$$d\mathbf{r} = dx\,\mathbf{i} + dy\,\mathbf{j} + dz\,\mathbf{k} \tag{11}$$

and

$$\mathbf{F}(\mathbf{r})\cdot d\mathbf{r} = f_1(x,y,z)\, dx + f_2(x,y,z)\, dy + f_3(x,y,z)\, dz, \tag{12}$$

then we can substitute (12) into (3) to obtain (9). Of course, it should be thoroughly understood that we have done nothing but explain symbols. This would be a stupid waste of time if it were not for the fact the symbols are useful. They appear even in quite elementary physics and engineering, and mathematicians have a responsibility to tell what they mean.

7.3 *Center and radius of curvature* Courses and textbooks in "differential geometry" provide information about matters relating to curvature of curves that lie in E_3. In this section, we give most of our attention to curves that lie in an xy plane. Our approach to the subject sacrifices brevity to place emphasis upon elementary geometric ideas that can be of interest to everyone and are needed by engineers and others who study the bending of beams.

Let x and y, or $x(t)$ and $y(t)$, have continuous second derivatives over some open interval $a < t < b$ in which t and $t + \Delta t$ are always supposed to lie. Let $P(t)$ denote the point with coordinates $(x(t), y(t))$ and let $\mathbf{r}(t)$ be the vector running from the origin to $P(t)$ so that

$$\begin{aligned} &(7.311) & \mathbf{r}(t) &= x(t)\mathbf{i} + y(t)\mathbf{j} \\ &(7.312) & \mathbf{v}(t) &= x'(t)\mathbf{i} + y'(t)\mathbf{j} \\ &(7.313) & \mathbf{a}(t) &= x''(t)\mathbf{i} + y''(t)\mathbf{j}. \end{aligned}$$

Let C be the curve traversed by $P(t)$ and the tip of $\mathbf{r}(t)$ as t increases, so that $\mathbf{v}(t)$ is tangent to C at $P(t)$ when $\mathbf{v}(t) \neq 0$. Henceforth we consider only values of t for which

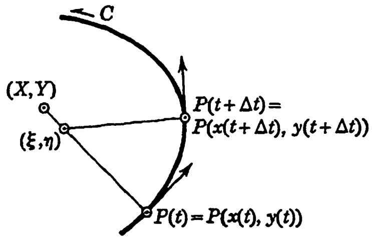
$$(7.32)\quad \mathbf{v}(t) \times \mathbf{a}(t) = \begin{vmatrix} \mathbf{i} & \mathbf{j} & \mathbf{k} \\ x'(t) & y'(t) & 0 \\ x''(t) & y''(t) & 0 \end{vmatrix} = [x'(t)y''(t) - x''(t)y'(t)]\mathbf{k} \neq 0.$$

Since $|\mathbf{v} \times \mathbf{a}| = |\mathbf{v}|\,|\mathbf{a}|\,|\sin\theta|$, this means that $\mathbf{v}$ and $\mathbf{a}$ are nonzero vectors which do not lie on parallel lines. This and the first of the formulas

$$(7.321)\quad \lim_{\Delta t \to 0} \frac{\mathbf{v}(t + \Delta t) - \mathbf{v}(t)}{\Delta t} = \mathbf{a}(t), \qquad \mathbf{v}(t) \times \frac{\mathbf{v}(t + \Delta t) - \mathbf{v}(t)}{\Delta t} \neq 0$$

implies existence of a $\delta > 0$ such that the second holds when $0 < |\Delta t| < \delta$. Since $\mathbf{v}(t) \times \mathbf{v}(t) = 0$, we conclude that $\mathbf{v}(t) \times \mathbf{v}(t + \Delta t) \neq 0$ and hence that the tangents $\mathbf{v}(t)$ and $\mathbf{v}(t + \Delta t)$ do not lie on parallel lines when $0 < |\Delta t| < \delta$.

Figure 7.33



Supposing that $0 < |\Delta t| < \delta$, we construct Figure 7.33 and look at it. Since the tangents $\mathbf{v}(t)$ and $\mathbf{v}(t + \Delta t)$ to C at $P(t)$ and $P(t + \Delta t)$ do not lie on parallel lines, the normals to C at these points must intersect at a point (ξ,η) having coordinates ξ (xi) and η (eta). If C is a circle, then the most elementary of elementary geometry tells us that the points (ξ,η) obtained for different values of Δt would all lie at the center (X,Y) of the circle. This is no time to be devoid of ideas. We can have at least a vague feeling that, even when our curve C is not a circle, a small section of C in a neighborhood of $P(t)$ should be so much like a circle that there should be a point (X,Y) such that (ξ,η) is near (X,Y) whenever Δt is small. If all this happens, we should give the point (X,Y) a name and find formulas for X and Y. All this does happen. The point is called the *center of curvature* of C at $P(t)$. We shall find formu'as for X and Y and for the distance from (X,Y) to $P(t)$. This distance is called the *radius of curvature* ρ (rho) of C at $P(t)$. The circle with center at (X,Y) and radius ρ is called the *circle of curvature* of C at $P(t)$.

The coordinates ξ and η are determined by the system of equations

$$\begin{aligned}[]
[\xi - x(t)]x'(t) \quad &+ \quad [\eta - y(t)]y'(t) = 0\\
[\xi - x(t+\Delta t)]x'(t+\Delta t) &+ [\eta - y(t+\Delta t)]y'(t+\Delta t) = 0.
\end{aligned}$$

The left member of the first equation is the scalar product of the vector $\mathbf{v}(t)$ tangent to C at $P(t)$ and the vector running from $P(t)$ to (ξ,η), and the equation expresses the fact that the two vectors are orthogonal. Similarly, the second equation expresses the fact that (ξ,η) lies on the normal to C at $P(t + \Delta t)$. Replacing the quantities in brackets in the second equation by

$$[\xi - x(t) - x(t+\Delta t) + x(t)] \qquad \text{and} \qquad [\eta - y(t) - y(t+\Delta t) + y(t)]$$

and transposing a part of the result enables us to put the two equations in the form

$$[\xi - x(t)]x'(t) + [\eta - y(t)]y'(t) = 0 \tag{7.341}$$

$$[\xi - x(t)]x'(t+\Delta t) + [\eta - y(t)]y'(t+\Delta t) = Q, \tag{7.342}$$

where we have simplified matters by letting Q denote the quantity

$$Q = [x(t+\Delta t) - x(t)]x'(t+\Delta t) + [y(t+\Delta t) - y(t)]y'(t+\Delta t). \tag{7.343}$$

To eliminate η from the two equations (7.341) and (7.342), we multiply the first by $y'(t+\Delta t)$ and the second by $-y'(t)$ and add to obtain the first of the formulas

$$D[\xi - x(t)] = -Qy'(t), \qquad D[\eta - y(t)] = Qx'(t), \tag{7.35}$$

where D is the determinant

$$D = x'(t)y'(t+\Delta t) - x'(t+\Delta t)y'(t)$$

which can be put in the form

$$D = x'(t)[y'(t+\Delta t) - y'(t)] - [x'(t+\Delta t) - x'(t)]y'(t). \tag{7.351}$$

A similar procedure, in which the multipliers $-x'(t+\Delta t)$ and $x'(t)$ are used, gives the second of the formulas (7.35). Formulas for ξ and η are now obtained from (7.35) by dividing and transposing. As we shall see, formulas for X and Y are obtained by dividing (7.35) by Δt and taking limits as $\Delta t \to 0$. Since (7.343) and (7.351) show that

$$\lim_{\Delta t\to 0} \frac{Q}{\Delta t} = [x'(t)]^2 + [y'(t)]^2$$

$$\lim_{\Delta t\to 0} \frac{D}{\Delta t} = x'(t)y''(t) - x''(t)y'(t),$$

we find from (7.35) that

$$(7.361) \quad X - x(t) = \lim_{\Delta t\to 0} [\xi - x(t)] = -\frac{[x'(t)]^2 + [y'(t)]^2}{x'(t)y''(t) - x''(t)y'(t)}\, y'(t)$$

$$(7.362) \quad Y - y(t) = \lim_{\Delta t\to 0} [\eta - y(t)] = \frac{[x'(t)]^2 + [y'(t)]^2}{x'(t)y''(t) - x''(t)y'(t)}\, x'(t).$$

Transposing the terms $x(t)$ and $y(t)$ gives formulas

$$(7.363) \qquad X = x(t) - \frac{[x'(t)]^2 + [y'(t)]^2}{x'(t)y''(t) - x''(t)y'(t)}\, y'(t)$$

$$(7.364) \qquad Y = y(t) + \frac{[x'(t)]^2 + [y'(t)]^2}{x'(t)y''(t) - x''(t)y'(t)}\, x'(t)$$

for the coordinates (X,Y) of the center of curvature of C at the point $(x(t), y(t))$, but these new formulas are sometimes less useful than their parents. The definition of radius of curvature ρ implies that

$$\rho = \sqrt{[X - x(t)]^2 + [Y - y(t)]^2}$$

and hence

$$(7.37) \qquad \rho = \frac{\{[x'(t)]^2 + [y'(t)]^2\}^{3/2}}{|x'(t)y''(t) - x''(t)y'(t)|}.$$

In case $x(t) = t$ so $x'(t) = 1$ and $x''(t) = 0$, it is customary to replace t by x and write

$$(7.371) \qquad \rho = \frac{\{1 + [y'(x)]^2\}^{3/2}}{|y''(x)|} = \frac{\left[1 + \left(\frac{dy}{dx}\right)^2\right]^{3/2}}{\left|\frac{d^2y}{dx^2}\right|}.$$

To steer our thoughts toward another problem involving curvature, we consider the rate of change of direction of an automobile which traverses a level road that winds around swamps and between mountains. At each time t the rate depends upon the speed of the automobile and upon another number which is called the curvature of the road at the position of the automobile. To be more precise about this matter, let

x and y be functions of t having two derivatives each over some interval and let C be the curve traversed by the point $P(t)$, having coordinates $x(t)$, $y(t)$, as t increases over the interval. We suppose that there is no t for which $x'(t)$ and $y'(t)$ are both 0. Our results will be obtained with the aid of the three familiar vectors

$$\mathbf{r}(t) = x(t)\mathbf{i} + y(t)\mathbf{j} \tag{7.381}$$
$$\mathbf{v}(t) = x'(t)\mathbf{i} + y'(t)\mathbf{j} \tag{7.382}$$
$$\mathbf{a}(t) = x''(t)\mathbf{i} + y''(t)\mathbf{j}. \tag{7.383}$$

The vector $\mathbf{v}(t)$ having its tail at $P(t)$ is the forward tangent to C at $P(t)$. With each t we wish to associate an angle $\phi(t)$ that determines the direction of $\mathbf{v}(t)$, and this is a matter that must not be treated carelessly. To restrict $\phi(t)$ to an interval like $-\pi < \phi \leqq \pi$, so that ϕ would be discontinuous when the vector rotates from northwest to southwest, would defeat our purpose. To formulate general principles by which $\phi(t)$ can be calculated may be beyond our capabilities. Let us then avoid possible unforeseen topological difficulties by restricting attention to curves C for which it is clearly possible to determine $\phi(t)$ by the following procedure. Let t_0 be a particular t in the interval considered and let $\phi(t_0)$ be the angle for which $-\pi < \phi(t_0) \leqq \pi$ and $\phi(t_0)$ is the ordinary trigonometric angle having its initial side on the positive x axis and its terminal side on the vector through the origin parallel to $\mathbf{v}(t_0)$. Then, as t increases (or decreases) from t_0, let $\phi(t)$ vary with the vector $\mathbf{v}(t)$ in such a way that ϕ is continuous. Some curves are less complicated than that shown in Figure 7.384, and some are more complicated. Supposing that $\phi(t)$ is satisfactorily determined, we can put the formula (7.382) for $\mathbf{v}(t)$ in the form

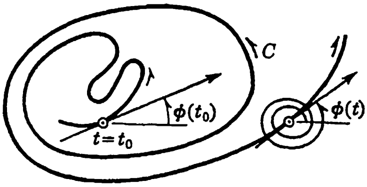


Figure 7.384

$$|\mathbf{v}(t)|[\cos\phi(t)\mathbf{i} + \sin\phi(t)\mathbf{j}] = \mathbf{v}(t), \tag{7.385}$$

where

$$x'(t) = |\mathbf{v}(t)|\cos\phi(t), \qquad y'(t) = |\mathbf{v}(t)|\sin\phi(t) \tag{7.3851}$$

and

$$|\mathbf{v}(t)| = \{[x'(t)]^2 + [y'(t)]^2\}^{1/2} \neq 0. \tag{7.3852}$$

Since we want a formula for $\phi'(t)$, it is reasonable to differentiate (7.385) with respect to t and to try to use the result. We divide by $|\mathbf{v}(t)|$ and then differentiate to obtain

$$[-\sin\phi(t)\mathbf{i} + \cos\phi(t)\mathbf{j}]\phi'(t) = \frac{|\mathbf{v}(t)|\mathbf{a}(t) - \mathbf{v}(t)\dfrac{d}{dt}|\mathbf{v}(t)|}{|\mathbf{v}(t)|^2}. \tag{7.386}$$

The coefficient of $\phi'(t)$ is the unit vector $\mathbf{n}$ for which

$$\mathbf{n} = [-\sin\phi(t)\mathbf{i} + \cos\phi(t)\mathbf{j}] = \frac{-y'(t)\mathbf{i} + x'(t)\mathbf{j}}{|\mathbf{v}(t)|}. \tag{7.3861}$$

Since $\mathbf{n}\cdot\mathbf{v}(t) = 0$, we can equate the scalar products of $\mathbf{n}$ and the members of (7.386) to obtain

$$\phi'(t) = \frac{|\mathbf{v}(t)|\mathbf{a}(t)\cdot\mathbf{n}(t)}{|\mathbf{v}(t)|^2} = \frac{[x''(t)\mathbf{i} + y''(t)\mathbf{j}]\cdot[-y'(t)\mathbf{i} + x'(t)\mathbf{j}]}{|\mathbf{v}(t)|^2}$$

and hence

$$\phi'(t) = \frac{x'(t)y''(t) - x''(t)y'(t)}{[x'(t)]^2 + [y'(t)]^2}. \tag{7.387}$$

For some applications of (7.387), we can set $x(t) = t$ so that $x'(t) = 1$ and $x''(t) = 0$. In such cases, we can replace t by x to obtain

$$\phi'(x) = \frac{y''(x)}{1 + [y\ (x)]^2}. \tag{7.3871}$$

In this, and in any other case in which $x'(t) \neq 0$, we can eliminate practically all of the work of this section by writing

$$\tan\phi = \frac{y'(t)}{x'(t)} \tag{7.3872}$$

with or without the aid of (7.3851) and then differentiating with respect to t to obtain (7.387).

Returning to (7.387), we note that $\phi'(t)$, which might be measured in radians per minute, gives the time rate of change of ϕ with respect to t. In case the point $P(t)$ traverses C with unit speed, which might be 1 kilometer per minute, $\phi'(t)$ becomes also a number of radians per unit distance measured along C, and this is called the *curvature* K or $K(t)$ of C at $P(t)$. To give curvature an additional leg upon which to stand, we introduce upon C a coordinate system like that in Figure 7.27 with the stipulation that the coordinate s of $P(t)$ increases as t increases. The curvature of C at $P(t)$ can then be defined by the formula

$$K = K(t) = \frac{d\phi}{ds}. \tag{7.388}$$

Since $d\phi/ds = \phi'(t)/s'(t) = \phi'(t)/|v(t)|$, the formulas (7.387) and (7.3852) yield the formula

$$K = \frac{x'(t)y''(t) - x''(t)y'(t)}{\{[x'(t)]^2 + [y'(t)]^2\}^{3/2}} \tag{7.389}$$

from which the curvature of C at $P(t)$ can be calculated without reference to other formulas. Perhaps we should take notice of the fact that a curve C is an ordered set of points, and that we can misunderstand (7.389) when we forget this fact. In particular, the sign in (7.389) will be wrong if we put the coordinate system on C backwards so that s decreases as t increases.

We conclude with a fundamental observation. As formulas (7.37) and (7.389) show, *the radius of curvature ρ and the absolute value $|K|$ of the curvature K* are reciprocals wherever we have defined both of them.

Problems 7.39

1 By use of the equations

$$x = a \cos t, \qquad y = a \sin t,$$

show that the curvature of the curve C consisting of a circle of radius a traced in the *positive* direction is identically $1/a$. Then by use of the equations

$$x = a \cos t, \qquad y = -a \sin t,$$

show that the curvature of the curve Γ (capital gamma) consisting of a circle of radius a traced in the *negative* direction is identically $-1/a$.

2 Hindsight can be very good. Look at (7.388). Then run with constant speed and in the positive direction around a circle of radius a and observe that ϕ increases at a constant rate. Then reverse the direction of the run and observe that ϕ decreases at the same constant rate.

3 Determine the radius of curvature of (that is, at points of) the parabola having the equation $y = kx^2$. Find the minimum radius of curvature. Sketch a graph for the case in which $k = 1$ and determine whether the answer seems to be correct.

4 Show that the normals to the graph of $y = x^2$ at the points (0,0) and (0.01, 0.0001) intersect at the point (0, 0.5001). Show that this intersection is at distance 0.0001 from the center of curvature of the graph at the point (0,0).

5 A glance at the graph of $y = \log x$ suggests that the absolute value of the curvature is greatest and that the radius of curvature is least when x is somewhere between $\frac{1}{2}$ and 2. Find the x for which the radius of curvature attains its minimum value. *Ans.:* $\sqrt{2}/2 = 0.707$.

6 When a point $P(x,y)$ moves along an arc or curve C having equations $x = x(t)$, $y = y(t)$ that satisfy appropriate conditions, the center (X,Y) of curvature moves along an arc that is called the *evolute* of C. The formulas (7.363) and (7.364), which we should be able to use but need not remember, show how X

and Y depend upon t. Supposing P moves along the graph of $y = kx^2$ in such a way that $x = t$ and $y = kt^2$, show that the equations of the evolute are

$$X = -4k^2t^3, \qquad Y = \frac{1}{2k} + 3kt^2.$$

7 This problem involves a little story. A string is wound in a clockwise direction around a circular spool of radius a with an end at the point $(a,0)$. When the string is unwound, being kept stretched during the process, the end of the string traces the spiral curve C shown in Figure 7.391. When $a\theta$ units of string have been unwound, this part of the string is tangent to the spool at the point $Q(X,Y)$ for which

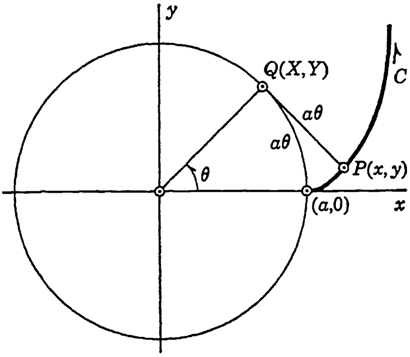

Figure 7.391

$$X = a\cos\theta, \qquad Y = a\sin\theta$$

and the end of the string is at the point $P(x,y)$ for which

$$\begin{aligned} x &= x(\theta) = a\cos\theta + a\theta\sin\theta \\ y &= y(\theta) = a\sin\theta - a\theta\cos\theta. \end{aligned}$$

It can be observed that Q moves around the circle just as rapidly as the distance from Q to P increases. It is not unreasonable to guess (or at least to consider the possibility) that the center and radius of curvature of C at P are Q and $a\theta$. On the other hand, a skeptic can be uncertain whether QP is perpendicular to the tangent to C at P. The situation demands clarification. Start with the equations of C and find the center and radius of curvature of C at P. *Ans.:* (X,Y) and $a\theta$. *Remark:* The curve C is called the *involute* of the spool. The spool is the evolute of its involute.

8 Determine the radius of curvature of the "standard ellipse"

$$\frac{x^2}{a^2} + \frac{y^2}{b^2} = 1 \qquad \text{or} \qquad x = a\cos\theta, \qquad y = b\sin\theta$$

by use of the first "standard equation" and then by use of the latter parametric equations.

9 Using the parametric equations of Problem 8, find the evolute of the standard ellipse.

10 As an alternative to (or in addition to) Problem 8, find the radius of curvature of the "standard hyperbola."

11 A glance at the hypocycloid having the equations

$$x = a\cos^3 t, \qquad y = a\sin^3 t$$

indicates that the radius of curvature ρ should be a maximum at points (x,y) for which $|x| = |y|$ and a minimum at points for which $xy = 0$. Can we believe our eyes? *Ans.:* No, because ρ has no minimum. When $t \neq n\pi/2$, calculations give $\rho = \frac{3a}{2}|\sin 2t|$. Thus ρ is a maximum when $2t = \left(n + \frac{1}{2}\right)\pi$ or $t = \left(\frac{n}{2} + \frac{1}{4}\right)\pi$ and hence when $|\sin t| = |\cos t|$ or $|x| = |y|$. We see that $\rho \to 0$ as $t \to 0$, but the curvature at the cusps is undefined.

12 When a flexible cord or chain (the Latin word for chain is *catena*) is suspended from its ends in a parallel force field, it hangs in a curve (or point set) called a *catenary*. Differential equations textbooks show that a rectangular coordinate system can be chosen in such a way that the equation of the catenary is

$$y = \frac{a}{2}(e^{x/a} + e^{-x/a}).$$

Find the radius of curvature of this catenary at the point (x,y). *Ans.:* y^2/a.

13 Find the radius of curvature of the cycloid having the equation

$$x = a(\theta - \cos\theta), \qquad y = a(1 - \cos\theta).$$

14 Find the evolute of the cycloid of Problem 13.

15 Persons who picnic beside lakes several miles long can wonder whether poor visibility instead of curvature of the earth is responsible for invisibility of distant boats and shores. This problem involving curvature can be solved very simply. Figure 7.392 shows the center of a spherical earth at C on the positive y axis, the x axis being tangent to the surface of the earth at O. The line from C to $Q(x,0)$ intersects the surface of the earth at P. The number $|\overrightarrow{PQ}|$ is the height h of an object which is visible from the point O on the earth x miles away. The simple calculation

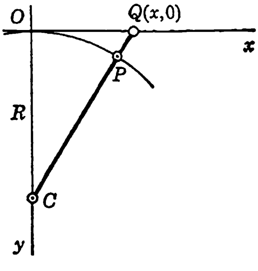

Figure 7.392

$$h = \sqrt{R^2 + x^2} - R = \frac{x^2}{\sqrt{R^2 + x^2} + R} \tag{1}$$

shows that the approximate formula

$$(2) \qquad h = \frac{x^2}{2R}$$

gives good results when x is small in comparison to R. It is a quite remarkable fact that if h and R are measured in miles and if the height H of the object is measured in feet so that $H = 5280h$, then we can put $R = 3960$ in (2) and multiply by 5280 to obtain

$$H = \tfrac{2}{3}x^2.$$

Putting $H = 6$ shows that only the hair on the top of the head of a man 6 feet tall is visible from a point on the earth 3 miles away. Putting $x = 30$ gives $H = 600$ and shows that less than the top half of the Empire State Building can be seen by persons on a ship 30 miles away.

16 It is sometimes useful to have formulas obtainable from (7.361) and (7.362). Letting $\mathbf{N}$ [where the N can make us think of a normal to C at $P(t)$] be the vector running from $P(t)$ to the center (X,Y) of curvature, we see that

$$(1) \qquad \mathbf{N} = \frac{[x'(t)]^2 + [y'(t)]^2}{x'(t)y''(t) - x''(t)y'(t)}\,[-y'(t)\mathbf{i} + x'(t)\mathbf{j}].$$

Let $\mathbf{b}$ (where the b can make us think of binormal or "second normal") be the unit vector in the direction of $\mathbf{v}(t) \times \mathbf{a}(t)$ so that, as (7.32) shows, $\mathbf{b}$ is the coordinate vector $\mathbf{k}$ in our work. Then, with the aid of (7.32) and the fact that $\mathbf{b}\cdot\mathbf{b} = 1$, we can put (1) in the intrinsic form

$$(2) \qquad \mathbf{N} = \frac{\mathbf{v}(t)\cdot\mathbf{v}(t)}{[\mathbf{v}(t) \times \mathbf{a}(t)]\cdot\mathbf{b}(t)}\,\mathbf{b}(t) \times \mathbf{v}(t)$$

in which coordinates do not appear. The formula (2) is valid when C is a curve in E_3 for which x,y,z are functions having continuous second derivatives and

$$\begin{aligned}
\mathbf{r}(t) &= x(t)\mathbf{i} + y(t)\mathbf{j} + z(t)\mathbf{k}\\
\mathbf{v}(t) &= x'(t)\mathbf{i} + y'(t)\mathbf{j} + z'(t)\mathbf{k}\\
\mathbf{a}(t) &= x''(t)\mathbf{i} + y''(t)\mathbf{j} + z''(t)\mathbf{k}
\end{aligned}$$

whenever t is such that $\mathbf{v}(t) \times \mathbf{a}(t) \neq 0$. We shall not prove this, but remark that the point (ξ,η,ζ) analogous to the point (ξ,η) of Figure 7.33 is the intersection of three planes and that (X,Y,Z) is the limit as $\Delta t \to 0$ of (ξ,η,ζ).

17 It is possible to obtain very informative formulas by considering the motion of a particle which moves along a plane curve C, endowed with coordinates as in Figure 7.27, in such a way that s increases as t increases. We assume existence and continuity of all the derivatives we want to use, and we assume that $dx/dt > 0$. Let $\mathbf{t}$ be the unit forward tangent vector to C at time t so that

$$(1) \qquad \mathbf{t} = \cos\phi\mathbf{i} + \sin\phi\mathbf{j},$$

where ϕ is, as in the discussion of Figure 7.384, an angle giving the direction of $\mathbf{t}$ at time t. Show that differentiating (1) gives

$$(2) \qquad \frac{d\mathbf{t}}{dt} = [-\sin\phi\mathbf{i} + \cos\phi\mathbf{j}]\frac{d\phi}{dt} = \mathbf{n}\frac{d\phi}{ds}\frac{ds}{dt} = \frac{ds}{dt}K\mathbf{n},$$

where $\mathbf{n}$ is the unit normal obtained by rotating $\mathbf{t}$ clockwise through the angle $\pi/2$, ds/dt is the speed of the particle, and K is the curvature $d\phi/ds$ of C. Show that writing the formula $\mathbf{v} = |\mathbf{v}|\mathbf{t}$ in the form

$$\mathbf{v} = \frac{ds}{dt}\mathbf{t} \tag{3}$$

and differentiating give

$$\mathbf{a} = \frac{d\mathbf{v}}{dt} = \frac{d^2s}{dt^2}\mathbf{t} + \frac{ds}{dt}\frac{d\mathbf{t}}{dt} \tag{4}$$

and that use of (2) then gives

$$\mathbf{a} = \frac{d^2s}{dt^2}\mathbf{t} + \left(\frac{ds}{dt}\right)^2 K\mathbf{n}. \tag{5}$$

Remark: This elegant formula gives the normal (or transverse) and tangential scalar components of the acceleration in terms of the speed and rate of change of the speed of the particle. The simplest applications involve the case in which the particle moves along the curve with constant speed σ so that $ds/dt = \sigma$ and $d^2s/dt^2 = 0$ at each time. In this case, (5) reduces to the simple but important formula

$$\mathbf{a} = \sigma^2 K\mathbf{n}. \tag{6}$$

If $K = 0$, then $\mathbf{a} = 0$. If $K \neq 0$, then $\mathbf{a}$ has magnitude $\sigma^2|K|$ or σ^2/ρ (where ρ is the radius of curvature) and is directed toward the center of curvature. Use ot (6) and the formula $\mathbf{F} = m\mathbf{a}$ gives the force required to propel a particle of mass m along a curve C with constant speed σ.

18 Let C be a simple closed convex curve which could, for example, be a famous "triangular roller" composed of the three vertices of an equilateral triangle together with three circular arcs of which each has its center at one vertex and contains the other two vertices. Let R be a rod (or line segment) whose length L is small enough to permit the rod to be "slid around" C in such a way that its two ends both remain on C. It is easy to presume, as has sometimes been done in "proofs" of the "Holditch theorem," that each point P on R must traverse a simple closed convex curve C_P as R slides around C. Persons having a compass, a straightedge like the edge of a sheet of paper upon which marks can be placed, and some spare time at their disposal can sketch interesting figures. Surprises await those who let C be a triangular roller, let the length L of the rod R be equal to or only a bit less than the distance between two vertices of the equilateral triangle, and let P be the mid-point of L.

8

Trigonometric functions

8.1 Trigonometric functions and their derivatives We are studying and perhaps even learning mathematics, and it may be amusing and perhaps even useful to see how an unscientific but highly critical Justice of a Supreme Court might be introduced to angles and trigonometry. We would teach him enough about numbers, E_2, continuous functions, and curves to make him realize that if we start with positive numbers a and h for which $0 < h < a$, then the ordered set of points $(x, \sqrt{a^2 - x^2})$ for which $h \leqq x \leqq a$, the point for which $x = x_2$ preceding the point for which $x = x_1$ when $a \leqq x_1 < x_2 \leqq h$, is a curve. Our curve lies on the circle with center at the origin and radius a, and we simplify (or complicate) matters by calling our curve "the arc, of the circle with center at the origin and radius a, which runs in the positive direction from the point $(a,0)$ to the point Q having coordinates $(h, \sqrt{a^2 - h^2})$" or, for temporary purposes, simply "the arc." To help us remember the meanings of our symbols, we can start constructing Figure 8.11 and amplify it as we proceed. Next we must teach our pupil a theory of length and prove to him that the arc has a length which we may denote by s. Knowing that our quantities depend upon h and a, we can define a number θ by the formula

$$(8.12) \quad \theta = \frac{s}{a} = \frac{\text{length of arc}}{\text{radius}}.$$

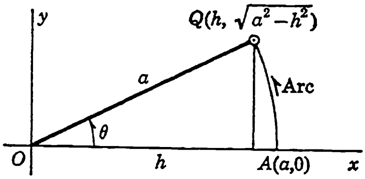

Figure 8.11

If we multiply each of a and h by the same positive constant λ (lambda), we get a new radius and a new arc, but the ratio s/a remains the same. To prove this, we must prove that the length of the new arc is the product of λ and the length of the original arc. Our theory of length enables us to do this because, by drawing radial lines from the origin, we can see that each polygon inscribed in the new arc determines (and is determined) by a polygon inscribed in the original arc and that the lengths of the straight segments of the polygons all differ by the same factor λ. All this shows that we get the same θ when we take another pair of values of a and h for which the point $(h, \sqrt{a^2 - h^2})$ lies on the same half-line extending from O through Q. Now we can again simplify (or complicate) matters by considering the number θ to be "a measure of the amount of rotation required to bring a line from the position OA to the position OQ" or "a measure of the opening between the lines OA and OQ." Perhaps to remind us where the number θ came from, or perhaps to indicate something of which θ is to be considered a measure, we complete Figure 8.11 by inserting the θ together with the curved arrow which shows the direction of our arc. It is the fashion to call θ an angle, but it should be permanently remembered that θ, like 5, is a number. The facts that we sometimes use θ to measure an amount of rotation and use 5 to measure a number of fingers do not imply that θ *is* a rotation and that 5 *is* a fistful of fingers, but we can nevertheless understand and even use the more or less convenient terminologies involving "angles" that have become a part of nonscientific as well as scientific attempts to convey information. If all this indicates that trigonometry is a subject much too difficult for inclusion in trigonometry textbooks, we do have one consolation. The hard work is done and the rest is easy.

Our theory of curves is sufficiently general to allow us to extend the above account of positive (that is, counterclockwise) arcs and angles to cover situations in which the arc is longer and Q lies in the second or third or fourth quadrant. Moreover, the arc can be so long that we must encircle the origin more than once to traverse it, and the number (or angle) θ is still defined by the same formula (8.12). In case the arc starts at A and is oriented in the negative (or clockwise) direction, everything is the same except that the directions of the arrows are reversed, a negative sign is prefixed to the middle and last members of

(8.12), and the number θ is negative. Even though we could pretend to be appalled by the idea that numbers have sides, we bow to conventions and agree that the way to find the six fundamental trigonometric functions of a given angle θ is to construct "the terminal side of θ" as in Figure 8.13, pick a point $P(x,y)$ on this terminal side, let r be the distance (positive, of course) from O to P, and use the numbers x, y, r in the usual way.

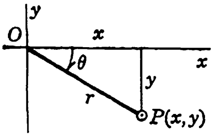

Figure 8.13

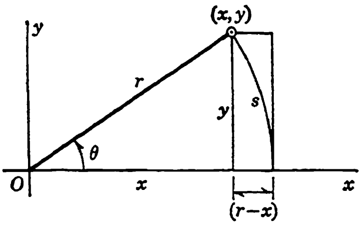
It is our purpose to present formulas for derivatives of trigonometric functions with derivations to which no logical objections can be raised. We could undertake to use the formula $A = \frac{1}{2}\theta r^2$ for the area of a circular sector of radius r which has central angle θ, but it would be immediately recognized that this formula has not been proved. Even if it be conceded that we know that the area of a whole circular disk of radius r is πr^2, it is only the docile acceptance of a crafty fraud that would allow us to "see at once" that the sector "obviously" has area $\frac{1}{2}\theta r^2$ because the area of the sector divided by the area of the circle is "obviously" $\theta/2\pi$. Nothing is obvious. Even a hazy understanding of the theory of area is enough to show that nothing can be proved without making substantial use of precise definitions and completeness of the real-number system or, what amounts to the same thing, consequences of these things. Since we do not now wish to be responsible for furnishing a complete treatment of areas of sectors, we shall base our work on the inequality (7.12). This inequality, the truth of which should seem thoroughly reasonable to a person at B who has the choice of walking two paths to D, has a virtue. It has been proved.

It was indicated in Problem 12 at the end of Section 3.2 that we will be able to derive the formulas for derivatives of trigonometric functions when we have proved the two formulas

$$(8.14)\qquad \lim_{\theta\to 0}\frac{\sin\theta}{\theta} = 1, \qquad \lim_{\theta\to 0}\frac{1-\cos\theta}{\theta} = 0.$$

Like a man who has drilled a hole and filled it with blasting powder to split a rock, we are ready to produce results. Figure 7.11 can be put into a coordinate system as in Figure 8.141, and we suppose that $0 < \theta < \pi/2$. In terms of the notation of this figure, the inequality (7.12) becomes

Figure 8.141



$$y \leqq s \leqq y + (r - x).$$

Dividing by r gives

$$(8.142)\qquad \sin\theta \leqq \theta \leqq \sin\theta + (1 - \cos\theta).$$

Since $1 - \cos\theta > 0$ and $1 + \cos\theta > 1$ and $\sin\theta < \theta$, the last term can be overestimated by the inequality

$$(8.143)\quad 0 < (1 - \cos\theta) < (1 - \cos\theta)(1 + \cos\theta) \\ = 1 - \cos^2\theta = \sin^2\theta < \theta\sin\theta.$$

Hence we can replace the last term in (8.142) by $\theta\sin\theta$ and divide by $\sin\theta$ to obtain the first and hence the second of the significant inequalities

$$(8.144)\qquad 1 \leqq \frac{\theta}{\sin\theta} < 1 + \theta, \qquad \frac{1}{1+\theta} < \frac{\sin\theta}{\theta} \leqq 1.$$

Dividing (8.143) by θ and using (8.142) gives

$$(8.145)\qquad 0 < \frac{1 - \cos\theta}{\theta} < \sin\theta < \theta.$$

The above inequalities have been proved to hold when $0 < \theta < \pi/2$. Since $|\theta| = \theta$ when $\theta > 0$, (8.144) and (8.145) imply that the inequalities

$$(8.146)\qquad \frac{1}{1+|\theta|} < \frac{\sin\theta}{\theta} \leqq 1, \qquad 0 < \frac{1-\cos\theta}{|\theta|} < |\theta|$$

hold when $0 < \theta < \pi/2$. Since the members of these inequalities are not changed when we replace θ by $-\theta$, we conclude that they hold when $|\theta| < \pi/2$ and $\theta \neq 0$. The desired formulas (8.14) follow from this and the sandwich theorem.

To derive the formulas for derivatives of sines and cosines, we use the formulas

$$\sin(x + \Delta x) = \sin x\cos\Delta x + \cos x\sin\Delta x$$
$$\cos(x + \Delta x) = \cos x\cos\Delta x - \sin x\sin\Delta x$$

to obtain

$$\sin(x + \Delta x) - \sin x = -\sin x(1 - \cos\Delta x) + \cos x\sin\Delta x$$
$$\cos(x + \Delta x) - \cos x = -\cos x\,(1 - \cos\Delta x) - \sin x\sin\Delta x.$$

After dividing by Δx, taking limits as $\Delta x \to 0$ of the resulting difference quotients gives, with the aid of (8.14), the fundamental formulas

$$(8.15)\qquad \frac{d}{dx}\sin x = \cos x, \qquad \frac{d}{dx}\cos x = -\sin x.$$

These formulas, which we have used many times, have at long last been proved. For values of x for which the functions are defined, we obtain

$$(8.151)\quad \frac{d}{dx}\tan x = \frac{d}{dx}\frac{\sin x}{\cos x} = \frac{\cos^2 x + \sin^2 x}{\cos^2 x} = \sec^2 x$$

$$(8.152)\quad \frac{d}{dx}\cot x = \frac{d}{dx}\frac{\cos x}{\sin x} = \frac{-\cos^2 x - \sin^2 x}{\sin^2 x} = -\csc^2 x$$

$$(8.153)\quad \frac{d}{dx}\sec x = \frac{d}{dx}\frac{1}{\cos x} = \frac{\sin x}{\cos^2 x} = \sec x \tan x$$

$$(8.154)\quad \frac{d}{dx}\csc x = \frac{d}{dx}\frac{1}{\sin x} = \frac{-\cos x}{\sin^2 x} = -\csc x \cot x.$$

The graphs of $\sin x$ and $\cos x$ are so important that we reproduce Figure 1.58 in Figure 8.16 and give further attention to the procedure by which reasonably accurate graphs are quickly sketched with or without use of graph paper. The trick is to sketch guide lines 1 unit above and 1 unit below the x axis, to hop 3 units and a bit more to the right of the origin to mark π, to make another such hop to mark 2π, and then sketch reasonably good copies of the figure. Each graph has slope 1 or -1 where it crosses an axis, and noticeable contradictions of this fact should not appear. In the problems at the end of the next section, we shall obtain formulas from which $\sin\theta$ and $\cos\theta$ can, for a given θ, be calculated as accurately as we wish. Meanwhile, we can be interested in Figure 8.17, which enables us to obtain reasonable estimates of $\sin\theta$ and $\cos\theta$ when $0 < \theta < \pi/2$. The circle has radius 1, and the radial lines make angles 0.1, 0.2, $\cdots$, 1.5 with the positive x axis. For example, the rough approximations

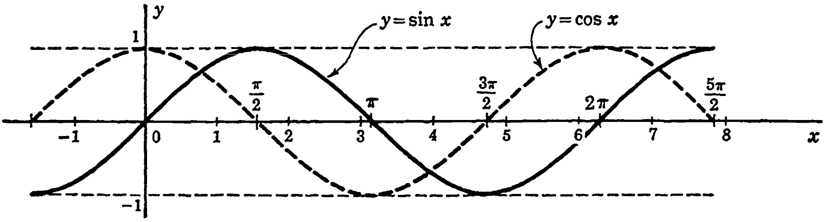


Figure 8.16

$$\sin 0.35 = \frac{0.34}{1} = 0.34, \qquad \cos 0.35 = \frac{0.94}{1} = 0.94,$$

$$\tan 0.35 = \frac{0.34}{0.94} = 0.36$$

can be read from the figure.

With the aid of information about derivatives, it is easy to see that the graph of the function t for which $t(x) = \tan x$ has the form shown in

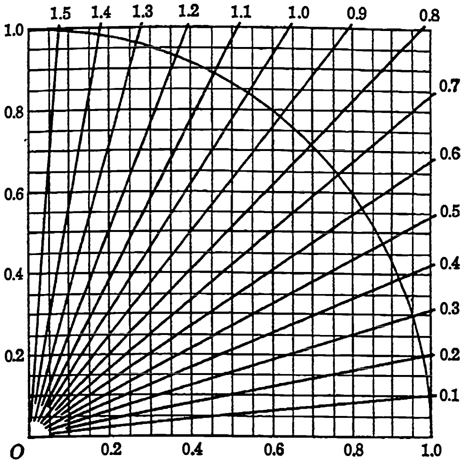

Figure 8.17

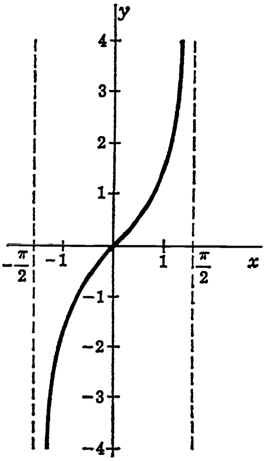

Figure 8.171

Figure 8.171. For each integer n, the interval $|x - n\pi| < \pi/2$ contains an exact copy of the graph in the interval $|x| < \pi/2$. The lines

$$x = n\pi \pm \frac{\pi}{2}$$

are all vertical asymptotes of the graph, and $\tan(n\pi \pm \pi/2)$ is undefined.

We should now be quite familiar with the fact that each formula for a derivative has a chain extension. The following list contains the chain extensions of formulas for derivatives of the six trigonometric functions and three additional formulas. All of these must be learned.

$$\frac{d}{dx}\sin u = \cos u\,\frac{du}{dx} \qquad \frac{d}{dx}\cot u = -\csc^2 u\,\frac{du}{dx}$$

$$\frac{d}{dx}\cos u = -\sin u\,\frac{du}{dx} \qquad \frac{d}{dx}\sec u = \sec u\tan u\,\frac{du}{dx}$$

$$\frac{d}{dx}\tan u = \sec^2 u\,\frac{du}{dx} \qquad \frac{d}{dx}\csc u = -\csc u\cot u\,\frac{du}{dx}$$

$$\frac{d}{dx}u^n = nu^{n-1}\frac{du}{dx}, \qquad \frac{d}{dx}e^u = e^u\frac{du}{dx}, \qquad \frac{d}{dx}\log u = \frac{1}{u}\frac{du}{dx}$$

Problems 8.19

1 With all graphs and tables out of sight, make the pretense that it has been forgotten whether the derivative with respect to x of $\sin x$ is $\sin x$ or $-\sin x$ or $\cos x$ or $-\cos x$. Sketch graphs of $\sin x$ and $\cos x$ and make these graphs give the correct answer.

2 Explain how you should modify the procedure for sketching the graph of

$y = \sin x$ to obtain a procedure for sketching the graph of $y = 3 \sin x$, and sketch the graph.

3 Equate the derivatives of the two members of the identity in the left column and show that obvious simplifications give the identity in the right column when

(*a*) $\sin 2x = 2 \sin x \cos x$	$\cos 2x = \cos^2 x - \sin^2 x$
(*b*) $\cos 2x = \cos^2 x - \sin^2 x$	$\sin 2x = 2 \sin x \cos x$
(*c*) $\sin^2 x + \cos^2 x = 1$	$0 = 0$
(*d*) $\sin (x + \phi)$ $= \sin x \cos \phi + \cos x \sin \phi$	$\cos (x + \phi)$ $= \cos x \cos \phi - \sin x \sin \phi$
(*e*) $\cos (x + \phi)$ $= \cos x \cos \phi - \sin x \sin \phi$	$\sin (x + \phi)$ $= \sin x \cos \phi + \cos x \sin \phi$
(*f*) $\cos^2 x = \dfrac{1 + \cos 2x}{2}$	$2 \sin x \cos x = \sin 2x$
(*g*) $\sin^2 x = \dfrac{1 - \cos 2x}{2}$	$2 \sin x \cos x = \sin 2x$
(*h*) $\sin \left(x + \dfrac{\pi}{2}\right) = \cos x$	$\cos \left(x + \dfrac{\pi}{2}\right) = -\sin x$
(*i*) $e^x e^x = e^{2x}$	$e^x e^x = e^{2x}$
(*j*) $\log x^2 = 2 \log x$	$\dfrac{2x}{x^2} = \dfrac{2}{x}$

4 Supposing that $0 \leqq x < \pi/2$, let $f(x) = \tan x$ and show that

$$\begin{aligned} f'(x) &= \sec^2 x \\ f''(x) &= 2 \sec^2 x \tan x \\ f'''(x) &= 2 \sec^4 x + 4 \sec^2 x \tan^2 x, \end{aligned}$$

and obtain the next derivative. Show that each derivative of higher order will also be a sum of terms of the form $A \sec^p x \tan^q x$, where A, p, q are nonnegative integers, and hence that $f^{(n)}(x) \geqq 0$ for each n and x.

5 Supposing that $0 < x < \pi/2$, calculate the first three derivatives of $\sec x$. Show that these and all derivatives of higher order are nonnegative.

6 Again supposing that $0 < x < \pi/2$, calculate some derivatives of $\sqrt{\tan x}$ and try to decide whether they are all nonnegative.

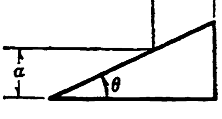
7 Prove the formula

$$\int \frac{\sin \theta}{1 + \sin \theta}\, d\theta = \sec \theta - \tan \theta + \theta + c$$

by differentiating the right side.

8 The length L of the longest beam that can be taken in a horizontal position around the corner of Figure 8.191 is the length L of the shortest line segment placed like the one in the figure. Find L. *Ans.:* $L = (a^{2/3} + b^{2/3})^{3/2}$. *Remark:* Putting the equation in the form $a^{2/3} + b^{2/3} = L^{2/3}$ can make us wonder why (a,b) should, for a fixed L, be a point on a hypocycloid.

Figure 8.191



9 Find the length L of the shortest ladder that can reach from level ground to a high wall when it must go over a fence which is a feet high and b feet from the wall. *Ans.:* $L = (a^{2/3} + b^{2/3})^{3/2}$.

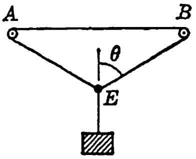


Figure 8.192

10 A heavy body is suspended from a rope, as in Figure 8.192, that runs up from the body to a pulley at E and thence (a wonderful word) over two stationary pulleys at A and B on the same horizontal level and back to E, where the pulley is tied to the other end of the rope. How should old man gravity select the θ of the figure in order to gratify his desire to bring the heavy body to its lowest possible position? *Ans.:* $\cos\theta = \frac{1}{2}$ and $\theta = \pi/3$ or $\theta = 60°$.

11 If $|P_n|$ is the length of a regular polygon of n sides which is inscribed in a circle of radius a, prove that $|P_n| = 2an \sin(\pi/n)$ and hence that $\lim\limits_{n\to\infty} |P_n| = 2\pi a$.

12 Supposing that A and B are constants not both 0 and that

$$y(x) = A \sin x + B \cos x,$$

calculate $y'(x) = y''(x)$ and show that

$$y''(x) = -y(x).$$

In terms of the graph of $y(x)$, tell precisely what it means to say that $y''(x) < 0$ when $y(x) > 0$ and $y''(x) > 0$ when $y(x) < 0$. Sketch graphs and verify your conclusion when $A = 0$ and when $B = 0$. It is now required that we learn a little trick that happens to be very important. Plot the point having coordinates (A,B) and, as in Figure 8.193, let ϕ be an angle having its terminal side on the line running from the origin to the point. Let $C = \sqrt{A^2 + B^2}$ and observe that

$$A = C \cos\phi \qquad \text{and} \qquad B = C \sin\phi$$

so

$$y(x) = C(\sin x \cos\phi + \cos x \sin\phi)$$

and hence

$$y(x) = C \sin(x + \phi).$$

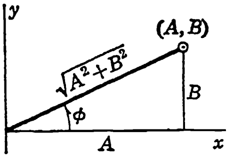

Figure 8.193

Finally, it is required that we learn some technical terminology by which this result can be remembered. Functions of the form $E \sin(\omega t + \phi)$ and $E \cos(\omega t + \phi)$ are called *sinusoids* (things like sines) of *angular frequency* ω. Since x can be ωt, we have proved that *the sum of two sinusoids having the same frequency ω is also a sinusoid having frequency ω.*

13 It is very easy to show that if k, A, B are constants for which $k > 0$ and if

$$y = A \sin kt + B \cos kt \tag{1}$$

then

$$\frac{d^2y}{dt^2} + k^2y = 0. \tag{2}$$

All we need to do is differentiate (1) twice and look at the result. The theory of differential equations contains theorems which imply that *if y is a function* *for which* (2) *holds, then there must be constants* A *and* B *for which* (1) *holds.* The latter and more difficult result is often needed by students who have not yet made reliable contacts with differential equations. Our solution of the more difficult problem will be postponed until we have solved the easy problem by a new method which involves only reversible steps. Starting with the formulas

$$(3)\qquad \begin{cases} y = A \sin kt + B \cos kt \\ \dfrac{dy}{dt} = Ak \cos kt - Bk \sin kt, \end{cases}$$

we eliminate B, and then eliminate A, from these equations to obtain

$$(4)\qquad \begin{cases} \cos kt \dfrac{dy}{dt} + (k \sin kt)y = Ak \\ \sin kt \dfrac{dy}{dt} - (k \cos kt)y = -Bk. \end{cases}$$

Therefore,

$$(5)\qquad \begin{cases} \dfrac{d}{dt}\left[\cos kt \dfrac{dy}{dt} + (k \sin kt)y\right] = 0 \\ \dfrac{d}{dt}\left[\sin kt \dfrac{dy}{dt} - (k \cos kt)y\right] = 0 \end{cases}$$

or

$$(6)\qquad \begin{cases} \cos kt \dfrac{d^2y}{dt^2} - k \sin kt \dfrac{dy}{dt} + k \sin kt \dfrac{dy}{dt} + (k^2 \cos kt)y = 0 \\ \sin kt \dfrac{d^2y}{dt^2} + k \cos kt \dfrac{dy}{dt} - k \cos kt \dfrac{dy}{dt} + (k^2 \sin kt)y = 0 \end{cases}$$

or

$$(7)\qquad \begin{cases} \cos kt \left[\dfrac{d^2y}{dt^2} + k^2y\right] = 0 \\ \sin kt \left[\dfrac{d^2y}{dt^2} + k^2y\right] = 0. \end{cases}$$

Since there is no t for which $\cos kt$ and $\sin kt$ are both 0, we conclude that

$$(8)\qquad \frac{d^2y}{dt^2} + k^2y = 0.$$

We are now ready to prove the more difficult result. Suppose that y is a given function for which (8) holds. Then we can multiply by $\cos kt$ and $\sin kt$ to obtain (7) and hence (6) and hence (5). Since the derivatives of the quantities in brackets are zero, these quantities must be constants which we can call Ak and $-Bk$ to obtain (4). Solving the equations (4) for y and dy/dt gives (3) and our problem is solved.

14 It is very easy to show that if k, A, B are constants for which $k > 0$ and if

$$(1)\qquad y = Ae^{kx} + Be^{-kx},$$

then

$$(2)\qquad \frac{d^2y}{dt^2} - k^2y = 0.$$

Do this. Then adapt the method of the preceding problem to show that if y is a function for which (2) holds, then there must be constants A and B for which (1) holds.

15 Prove that if y and u are functions of t having second derivatives and if

$$y = e^{-ht}u,$$

then

$$\frac{d^2y}{dt^2} + 2h\frac{dy}{dt} + k^2y = e^{-ht}\left[\frac{d^2u}{dt^2} + (k^2 - h^2)u\right].$$

16 A right circular cylinder (like a tomato can from which the top and bottom have been removed) has height h and base radius a. We examine the idea that good approximations to the area of this surface are obtained by triangulating it and calculating the sum of the areas of the triangles. The surface is partitioned into m strips each having height h/m like the one shown in Figure 8.194. On the top and bottom circular boundaries of each strip, we place the vertices of $2n$ isosceles triangles congruent to the triangle ABC of the figure. The side AB of the triangle subtends the angle $2\pi/n$ at the center O of the top circle. Of the $2n$ triangles in the top strip, n have two vertices on the top circle and the other n have two vertices on the lower circle. The total number of triangles congruent to the triangle ABC is $2mn$. The first factor in the product

$$(1)\qquad \left(a \sin\frac{\pi}{n}\right)\sqrt{\left(\frac{h}{m}\right)^2 + \left(a - a\cos\frac{\pi}{n}\right)^2}$$

is half the length of the base AB of the triangle. The last factor is the altitude, being the length of the hypotenuse of a triangle one leg of which runs from C to the right angle on the upper circle and the other leg of which runs (in the direction of O) from the right angle to the base AB. The sum S_{mn} of the areas of all of the triangles is the product of (1) and $2mn$. Therefore,

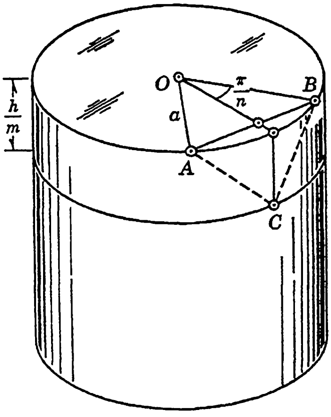

Figure 8.194

$$(2)\qquad S_{mn} = 2\pi ah\frac{\sin\frac{\pi}{n}}{\frac{\pi}{n}}\sqrt{1 + \left(\frac{\pi^2a}{2h}\right)^2\left(\frac{\sin\frac{\pi}{2n}}{\frac{\pi}{2n}}\right)^4\left(\frac{m}{n^2}\right)^2}.$$

When m and n are both large, the quotients having $\sin(\pi/n)$ in their numerators are near 1 and we have the approximation

$$(3)\qquad S_{mn} \sim 2\pi ah\sqrt{1 + \left(\frac{2\pi^2a}{h}\right)^2\left(\frac{m}{n^2}\right)^2}.$$

In case $m = n$, and in other cases where

$$\lim_{m,n\to\infty} \frac{m}{n^2} = 0, \tag{4}$$

we have

$$\lim_{m,n\to\infty} S_{mn} = 2\pi ah, \tag{5}$$

the right member being the number usually considered to be the correct area of the cylinder. In case $m = n^2$, we obtain

$$\lim_{m,n\to\infty} S_{mn} = 2\pi ah\sqrt{1 + \left(\frac{2\pi^2 a}{h}\right)^2}, \tag{6}$$

the right member being a number which is not usually considered to be the correct area of the cylinder. Other remarks can be made. The above calculations were made by a German mathematician Schwarz, and they constitute the *Schwarz paradox*. The paradox shows that the triangulation idea provides a precarious basis for definitions of area of curved surfaces. The theory of these areas is extremely complicated.

17 It is sometimes useful as well as interesting to have information about the things we see. A *polynomial* P in x and y is the sum of a finite set of terms of the form cx^jy^k, where c is a constant and j and k are nonnegative integers. The polynomial has *degree* n if $j + k = n$ for at least one term in the sum having a nonzero coefficient and $j + k \leqq n$ for each term in the sum having a nonzero coefficient. A polynomial in which the coefficients are all zero is said to be *trivial;* it does not have a degree. Thus the polynomials having values

$$x^4 + xy + y^4 - 34, \qquad (x^2 - y^2 - 1)(x^2 + y^2 - 4) \tag{1}$$

both have degree 4. A nontrivial polynomial is *irreducible* if it is not the product of two polynomials of lower degree. An *algebraic equation* of degree n is an equation of the form $P(x,y) = 0$, where P is a nontrivial polynomial of degree n in x and y. The graph of an algebraic equation is an *algebraic graph.* A function f of one variable x is said to be an *algebraic function* if there is a nontrivial polynomial $P(x,y)$ such that

$$P(x, f(x)) = 0 \tag{2}$$

for each x in the domain of f. Since each nontrivial polynomial in x and y can be put in the form

$$Q_0(x) + Q_1(x)y + Q_2(x)y^2 + \cdots + Q_n(x)y^n, \tag{3}$$

where $Q_0, Q_1, \cdots, Q_n$ are polynomials in x at least one of which is nontrivial, it follows that a function f is an algebraic function if and only if there exist polynomials $Q_0, Q_1, \cdots, Q_n$ in x such that Q_n is nontrivial and

$$Q_0(x) + Q_1(x)f(x) + Q_2(x)[f(x)]^2 + \cdots + Q_n(x)[f(x)]^n = 0 \tag{4}$$

for each x in the domain of f. Functions that are not algebraic functions are said to be *transcendental functions*, the old idea being that polynomials lie at the foundation of human experience and that things not closely related to polynomials are more ethereal. This matter can be of interest to us now because, even in quite elementary mathematics, the trigonometric functions are called transcendental functions. For example, the assertion that $\sin x$ is transcendental means that there do not exist polynomials $Q_0, Q_1, \cdots, Q_n$ in x such that Q_n is nontrivial and (4) is true for each x when $f(x) = \sin x$. Let us now think briefly about real numbers. A number x is said to be an *algebraic number* if there exist integers $k_0, k_1, k_2, \cdots, k_n$ not all zero such that

$$k_0 + k_1x + k_2x^2 + \cdots + k_nx^n = 0.$$

Thus a number x is algebraic if it is a zero of a nontrivial polynomial in x having integer coefficients. A number x which is not an algebraic number is said to be a *transcendental number*. The numbers π and e are transcendental. Nobody can prove these things unless he devotes very much time and energy to the operation, but nobody requires us to be so busy digging ditches that we never look at the stars. We can know that there exist theories of algebraic functions and algebraic numbers and that these theories invite the attention of persons who have completed studies of analytic geometry and calculus.

8.2 *Trigonometric integrands* Before introducing chain extensions and other modifications of the formulas, we systematically work out formulas for integrals of the six trigonometric functions. Even though the last three or four have minor importance, we must learn about them to be respectable. The first two are

$$\int \sin x\,dx = -\cos x + c, \qquad \int \cos x\,dx = \sin x + c. \tag{8.21}$$

They are immediate consequences of the formulas for derivatives of sines and cosines, since the formula

$$\int f(x)\,dx = F(x) + c$$

is valid over an interval if and only if $F'(x) = f(x)$ over the interval. It is necessary to keep negative signs in their places when we differentiate and integrate sines and cosines, and it happens that a foolish little trick enables us to permanently remember how the signs go. We can mentally write

$$\left\{\begin{array}{ll} \text{derivative} & \text{integral} \\ \text{sine} & \text{cosine} \end{array}\right. \tag{8.22}$$

in their natural orders and remember that "like things give plus," so differentiating sines and integrating cosines give plus signs, but that "unlike things give minus," so differentiating cosines and integrating sines give minus signs.

If an interval contains one of the points $n\pi \pm \pi/2$, there can be no F such that $\int \tan x\,dx = F(x) + c$ over that interval. When x is confined to an interval containing none of these points, we can use the fundamental formula

$$\int [u(x)]^{-1}u'(x)\,dx = \log|u(x)| + c$$

to obtain

$$(8.23)\qquad \int \tan x\,dx = -\int \frac{1}{\cos x}(-\sin x)\,dx = -\log|\cos x| + c$$
$$= \log|\sec x| + c.$$

In most applications of this formula, $|x| < \pi/2$, so $\cos x > 0$ and the absolute-value signs can be omitted. For $\cot x$, a miniature graph of which appears in Figure 8.232, we suppose that x is confined to an interval containing none of the points $x = n\pi$ and obtain

$$(8.231)\qquad \int \cot x\,dx = \int \frac{1}{\sin x}\cos x\,dx = \log|\sin x| + c.$$

In most applications of this formula, $0 < x < \pi$, so $\sin x > 0$ and the absolute-value signs can be omitted.

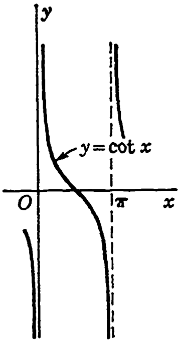

Figure 8.232

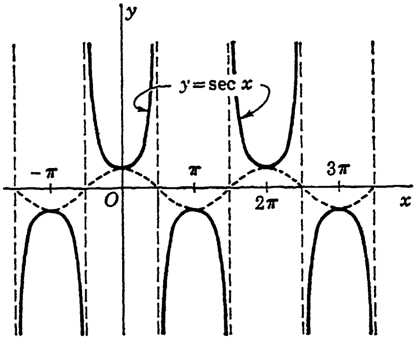

Figure 8.233

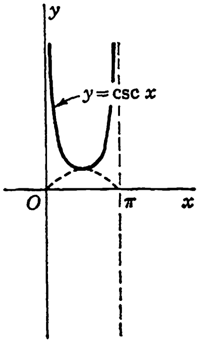

Figure 8.234

A sketch of the graph of $y = \sec x$ is most easily obtained by sketching a graph of $y = \cos x$ and estimating reciprocals. As the graph in Figure 8.233 indicates, $\sec x$ is undefined when x is an odd integer multiple of $\pi/2$. When we integrate $\sec x$ over an interval, we must suppose that the interval contains none of these points. We can then obtain the formula

$$(8.235)\qquad \int \frac{\sec x}{1}\,dx = \int \frac{1}{\sec x + \tan x}(\sec^2 x + \sec x \tan x)\,dx$$
$$= \log|\sec x + \tan x| + c$$

provided we happen to know that the result is obtained by multiplying the numerator and denominator of (sec x)/1 by the implausible factor sec x + tan x. We dispose of csc x as rapidly as possible by writing

$$(8.236)\quad \int \frac{\csc x}{1}\,dx = -\int \frac{1}{\csc x + \cot x}(-\csc^2 x - \csc x \cot x)\,dx = -\log|\csc x + \cot x| + c.$$

When $0 < x < \pi$ as in Figure 8.234, we can omit the absolute-value signs. The chain extensions of the six formulas are placed in a table at the end of this section where they are most available for reference. The formulas

$$(8.24)\quad \int \sin ax\,dx = \frac{1}{a}\int \sin ax\; a\,dx = -\frac{1}{a}\cos ax + c$$

$$(8.241)\quad \int \cos ax\,dx = \frac{1}{a}\int \cos ax\; a\,dx = \frac{1}{a}\sin ax + c,$$

which hold when $a \neq 0$, are by far the most important applications of the chain extensions.

We now consider some of the more or less important integrals that can be evaluated in terms of elementary functions. Adding and subtracting the two elementary formulas

$$(8.25)\quad \cos^2\theta + \sin^2\theta = 1$$

$$(8.251)\quad \cos^2\theta - \sin^2\theta = \cos 2\theta$$

gives the two formulas

$$(8.252)\quad \cos^2\theta = \frac{1+\cos 2\theta}{2}, \qquad \sin^2\theta = \frac{1-\cos 2\theta}{2}$$

that are so useful that we should either learn them or be able to work them out very quickly. Moreover, these formulas should come to mind when we are asked to evaluate the first integrals in the formulas

$$(8.253)\quad \int \cos^2 ax\,dx = \int \frac{1+\cos 2ax}{2}\,dx = \frac{1}{2}\left[x + \frac{1}{2a}\int \cos 2ax(2a)\,dx\right] = \frac{1}{2}\left[x + \frac{1}{2a}\sin 2ax\right] + c$$

and

$$(8.254)\quad \int \sin^2 ax\,dx = \int \frac{1-\cos 2ax}{2}\,dx = \frac{1}{2}\left[x - \frac{1}{2a}\int \cos 2ax(2a)\,dx\right] = \frac{1}{2}\left[x - \frac{1}{2a}\sin 2ax\right] + c.$$

Students are frequently called upon to realize that the formula

$$\cos^4 x = (\cos^2 x)^2 = \left(\frac{1 + \cos 2x}{2}\right)^2 = \frac{1 + 2 \cos 2x + \cos^2 2x}{4}$$

is useful when the left member must be integrated, and to know what to do to complete the problem.

The integral in

$$I = \int \sin mx \cos nx \, dx \tag{8.26}$$

looks forbidding until it is discovered or remembered that a useful formula for the integrand can be obtained by adding the formulas

$$\begin{aligned} \sin(\theta + \phi) &= \sin\theta \cos\phi + \cos\theta \sin\phi \\ \sin(\theta - \phi) &= \sin\theta \cos\phi - \cos\theta \sin\phi. \end{aligned}$$

Thus

$$\tfrac{1}{2}[\sin(mx + nx) + \sin(mx - nx)] = \sin mx \cos nx$$

and

$$\begin{aligned} I &= \frac{1}{2(m+n)} \int [\sin(m+n)x](m+n)\,dx \\ &\qquad + \frac{1}{2(m-n)} \int [\sin(m-n)x](m-n)\,dx \\ &= \frac{1}{2(m+n)} \cos(m+n)x - \frac{1}{2(m-n)} \cos(m-n)x + c \end{aligned} \tag{8.261}$$

except when $m = n$ or $m = -n$. Similarly, the integrals

$$\int \sin mx \sin nx \, dx, \qquad \int \cos mx \cos nx \, dx \tag{8.262}$$

can be evaluated by use of formulas obtained by adding and subtracting the formulas

$$\begin{aligned} \cos(\theta - \phi) &= \cos\theta \cos\phi + \sin\theta \sin\phi \\ \cos(\theta + \phi) &= \cos\theta \cos\phi - \sin\theta \sin\phi. \end{aligned}$$

Sometimes integrals can be evaluated by making quite direct use of the power formula and other integration formulas. For example,

(8.~~2~~63)

$$\begin{aligned} &\int \sin^p ax\ \cancel{\cos ax \, dx} \\ &\qquad = \frac{1}{a} \int (\sin ax)^p (a \cos ax)\,dx = \frac{1}{a}\frac{\sin^{p+1} ax}{p+1} + c \end{aligned}$$

when $a \neq 0$ and $p \neq -1$. Sometimes we need some ingenuity. For example, the integral

$$\int \sin^2 x \cos^3 x \, dx \tag{8.264}$$

is rendered manageable by replacing the factor $\cos^3 x$ by the last member of the formula

$$\cos^3 x = \cos^2 x \cos x = (1 - \sin^2 x) \cos x.$$

The integral in

$$(8.265) \qquad \int e^{\cos x} \sin x \, dx = -\int e^{\cos x}(-\sin x)\, dx = -e^{\cos x} + c$$

is evaluated by making the adjustment and compensation necessary to put it in the form $\int e^{u(x)}u'(x)\, dx$, and opportunities to make such adjustments and compensations should always be observed.

There are reasons why some of the integrals we have evaluated may be said to be so important that everyone should know how to evaluate them. There is an old and perhaps honorable tradition that requires students of the calculus to spend huge amounts of time cultivating "the technique" of "formal integration." The fact that we live in an age of electronic computers makes it much more important to learn fundamental theory than to acquire skill in formal integration. For this reason, the author requests that teachers join him in avoiding all but the simplest formal integration problems that are not likely to be encountered by undergraduates in courses other than calculus courses. "The student" who has not read dozens of calculus books and does not know what we are talking about is invited to look at the shiny example

$$(8.27) \qquad I = \int \sqrt{\sin x \tan x(1 + \sqrt{\cos x})}\, dx$$

of an integral that we shall not expect him to evaluate quickly. A person who has constructed this problem can easily feel very sure that the only sensible attack upon the problem lies in setting

$$(8.271) \qquad u(x) = 1 + (\cos x)^{1/2};$$

so, when $0 < x < \pi/2$,

$$(8.272) \qquad \begin{aligned} u'(x) &= \tfrac{1}{2}(\cos x)^{-1/2}(-\sin x) \\ &= -\tfrac{1}{2}\sqrt{\frac{\sin^2 x}{\cos x}} = -\tfrac{1}{2}\sqrt{\sin x \tan x} \end{aligned}$$

and hence

$$(8.273) \qquad \begin{aligned} I &= -2 \int [u(x)]^{1/2}[u'(x)]\, dx \\ &= -2 \cdot \frac{[u(x)]^{3/2}}{\frac{3}{2}} + c = -\tfrac{4}{3}[1 + \sqrt{\cos x}]^{3/2} + c. \end{aligned}$$

Instead of inviting attention to problems of this nature, we present problems more likely to promote scientific competence.

Table 8.28

$$\int \sin u \frac{du}{dx}\,dx = -\cos u + c \qquad \int \cos u \frac{du}{dx}\,dx = \sin u + c$$

$$\int \tan u \frac{du}{dx}\,dx = \log|\sec u| + c \qquad \int \cot u \frac{du}{dx}\,dx = \log|\sin u| + c$$

$$\int \sec u \frac{du}{dx}\,dx = \log|\sec u + \tan u| + c \qquad \int \csc u \frac{du}{dx}\,dx = \log|\csc u - \cot u| + c$$

$$\int u^n \frac{du}{dx}\,dx = \frac{u^{n+1}}{n+1} + c, \int \frac{1}{u}\frac{du}{dx}\,dx = |\log u| + c, \int e^u \frac{du}{dx}\,dx = e^u + c.$$

Problems 8.29

1 Make all of the calculations necessary to show that

(*a*) $\int_0^\pi \sin x\,dx = 2$ (*b*) $\int_0^{\pi/2} \cos x\,dx = 1$

(*c*) $\lim_{\omega\to\infty} \int_a^b \sin \omega x\,dx = 0$ (*d*) $\lim_{\omega\to\infty} \int_a^b \cos \omega x\,dx = 0$

(*e*) $\lim_{x\to\infty} \frac{1}{x}\int_0^x \sin^2 \omega t\,dt = \frac{1}{2}$ (*f*) $\lim_{x\to\infty} \frac{1}{x}\int_0^x \cos^2 \omega t\,dt = \frac{1}{2}$

(*g*) $\int_0^{\pi/4} \tan x\,dx = \frac{1}{2}\log 2$ (*h*) $\int_0^{\pi/2} \tan x\,dx = \infty$

2 Recall that, when u is a differentiable function of x and $u \neq 0$,

$$\frac{d}{dx}\log|u| = \frac{1}{u}\frac{du}{dx}; \tag{1}$$

the absolute-value signs, which are superfluous when $u > 0$, need not bother us. Supposing that x is not an odd multiple of $\pi/2$ and that

$$f(x) = \log|\sec x + \tan x|, \qquad g(x) = \log\left|\tan\left(\frac{x}{2} + \frac{\pi}{4}\right)\right|, \tag{2}$$

show that $f'(x) = \sec x$ and $g'(x) = \sec x$.

Remark: This proves that the two formulas

$$\int \sec x\,dx = \log|\sec x + \tan x| + c_1 \tag{3}$$

$$\int \sec x\,dx = \log\left|\tan\left(\frac{x}{2} + \frac{\pi}{4}\right)\right| + c_2 \tag{4}$$

are both correct. Some integral tables contain both of them. These things imply that, over each interval containing no odd multiple of $\pi/2$, $f(x) - g(x)$

must be a constant, but they do not imply that this constant must be zero. The identity

$$\tan\left(\frac{x}{2}+\frac{\pi}{4}\right)=\frac{1+\tan\frac{x}{2}}{1-\tan\frac{x}{2}}=\frac{\cos\frac{x}{2}+\sin\frac{x}{2}}{\cos\frac{x}{2}-\sin\frac{x}{2}}\,\frac{\cos\frac{x}{2}+\sin\frac{x}{2}}{\cos\frac{x}{2}+\sin\frac{x}{2}}$$

$$=\frac{1+2\sin\frac{x}{2}\cos\frac{x}{2}}{\cos^2\frac{x}{2}-\sin^2\frac{x}{2}}=\frac{1+\sin x}{\cos x}=\sec x+\tan x$$

clarifies the matter.

3 Prove that if x is not an even multiple of $\pi/2$ and

$$f(x)=\log|\csc x-\cot x|,\qquad g(x)=\log\left|\tan\frac{x}{2}\right|,$$

then $f'(x)=\csc x$ and $g'(x)=\csc x$. *Remark:* This proves that the two formulas

$$\int\csc x\,dx=\log|\csc x-\cot x|+c,\qquad \int\csc x\,dx=\log\left|\tan\frac{x}{2}\right|+c$$

are both correct.

4 When a steady (or constant) current I (measured in amperes) flows through a wire (or resistor) having resistance R (measured in ohms), the quantity Q (measured in watthours, or thousandths of kilowatthours) of energy converted into heat in Δt hours is calculated from the formula

$$Q=I^2R\,\Delta t. \tag{1}$$

With this basic information, show that if $I(t)$ is integrable (Riemann) over the time interval $t_1\leqq t\leqq t_2$, then the quantity $Q(t_1,t_2)$ of energy converged into heat between times t_1 and t_2 is (or should be)

$$Q(t_1,t_2)=R\int_{t_1}^{t_2}[I(t)]^2\,dt. \tag{2}$$

Suppose now that $I(t)$ is the sinusoidal (or alternating) current determined by

$$I(t)=I_0\sin(\omega t+\phi), \tag{3}$$

where I_0 is a constant "maximum current," ω is a constant "angular frequency," and ϕ is a "phase angle." Show that, in this case,

$$Q(t_1,t_2)=\frac{t_2-t_1}{2}I_0^2R-\frac{I_0^2R}{4\omega}[\sin(2\omega t_2+2\phi)-\sin(2\omega t_1+2\phi)]. \tag{4}$$

The last term is 0 whenever $2\omega t_2-2\omega t_1$ is an integer multiple of 2π, and in every case the absolute value of the last term cannot exceed $RI_0^2/2\omega$. In all ordinary applications of this formula, t_2-t_1 is so large in comparison to $1/\omega$ that the last term in (4) is insignificant. In such cases, (4) is always replaced by

$$Q(t_1,t_2)=\tfrac{1}{2}I_0^2R(t_2-t_1). \tag{5}$$

Putting (5) in the form

$$Q(t_1,t_2) = \left(\frac{I_0}{\sqrt{2}}\right)^2 R(t_2 - t_1) \tag{6}$$

shows that a sinusoidal current having maximum value I_0 produces heat (or dissipates energy) just as rapidly as a steady current of magnitude $I_0/\sqrt{2}$. For this reason, the number $I_0/\sqrt{2}$ is called the *effective value* of the sinusoidal current. For ordinary house current having "effective voltage" 120 volts, the maximum (or peak) voltage is not 120 volts but is 120 $\sqrt{2}$ volts.

5 Let, when L is a positive number and $n = 1, 2, 3, \cdots$,

$$\phi_n(x) = \sqrt{\frac{2}{L}} \sin \frac{n\pi x}{L}, \qquad \psi_0(x) = \frac{1}{\sqrt{L}}, \qquad \psi_n(x) = \sqrt{\frac{2}{L}} \cos \frac{n\pi x}{L}.$$

Show that the first of the formulas

$$\int_0^L \phi_m(x)\phi_n(x)\,dx = 0, \qquad \int_0^L [\phi_n(x)]^2\,dx = 1$$

holds when m and n are different positive integers and that the second holds when $n = 1, 2, 3, \cdots$. Show that the first of the formulas

$$\int_0^L \psi_m(x)\psi_n(x)\,dx = 0, \qquad \int_0^L [\psi_n(x)]^2\,dx = 1$$

holds when m and n are different nonnegative integers and that the second holds when $n = 0, 1, 2, \cdots$. Show that

$$\int_0^L \psi_0(x)\phi_n(x)\,dx = \sqrt{2}\,\frac{1 - \cos n\pi}{n\pi} \qquad (n = 1, 2, 3, \cdots).$$

Show that, when $m, n = 1, 2, 3, \cdots$,

$$\int_0^L \psi_m(x)\phi_n(x)\,dx = \frac{1 - \cos (m + n)\pi}{(m + n)\pi} + \frac{1 - \cos (m - n)\pi}{(m - n)\pi},$$

where the last term is to be omitted when $m = n$. *Remark:* While students in calculus courses have not yet heard about the matter, the above formulas are of great interest in the theory of orthonormal sets and Fourier series of the trigonometric variety. Our calculations and a little theory produce the interesting formulas

$$\frac{\pi}{4} = \sin \frac{\pi x}{L} + \frac{1}{3} \sin \frac{3\pi x}{L} + \frac{1}{5} \sin \frac{5\pi x}{L} + \cdots \qquad (0 < x < L)$$

$$\frac{\pi^2}{8} = 1 + \frac{1}{3^2} + \frac{1}{5^2} + \frac{1}{7^2} + \cdots, \qquad \frac{\pi^2}{6} = 1 + \frac{1}{2^2} + \frac{1}{3^2} + \frac{1}{4^2} + \cdots$$

and many others.

6 A problem in Section 8.4 will tell us about the formula

$$\int_0^{\pi/2} \sin^p \theta \cos^q \theta\,d\theta = \frac{\frac{p-1}{2}!\,\frac{q-1}{2}!}{2\,\frac{p+q}{2}!}$$

which is correct whenever $p > -1$ and $q > -1$. As usual, $0! = 1$, $1! = 1$, $2! = 1\cdot 2$, $3! = 1\cdot 2\cdot 3$, $4! = 1\cdot 2\cdot 3\cdot 4$, etcetera. The values of $x!$ when x is not an integer are more esoteric, but $x! > 0$ when $x > -1$. Put $p = q = 0$ and discover that $(-\frac{1}{2})! = \sqrt{\pi}$. Show that the formula is correct when $p = q = 1$. Put $p = q = 2$ and discover that $(\frac{1}{2})! = \sqrt{\pi}/2$. Put $p = 2x - 1$ and $q = 1$ and use the result to prove that $x!$ is the product of x and $(x - 1)!$.

7 With an assist from (8.144), which shows that

$$\int_0^1 \frac{1}{(1+\theta)^2}\,d\theta \leqq \int_0^1 \left(\frac{\sin\theta}{\theta}\right)^2 d\theta \leqq \int_0^1 1\,d\theta,$$

the middle integral being a Riemann-Cauchy integral because the integrand is undefined when $\theta = 0$, show that

$$\tfrac{1}{2} \leqq \int_0^1 \left(\frac{\sin\theta}{\theta}\right)^2 d\theta \leqq 1.$$

Then prove the first of the inequalities

$$0 \leqq \int_1^\infty \left(\frac{\sin\theta}{\theta}\right)^2 d\theta \leqq 1, \qquad \tfrac{1}{2} \leqq \int_0^\infty \left(\frac{\sin\theta}{\theta}\right)^2 d\theta \leqq 2$$

and use it to obtain the second.

8 Let a and b be constants for which $a = 0$ and $b = 1$ or $a = 1$ and $b = 0$ and let $x > 0$. Show that

$$-1 \leqq a\cos x + b\sin x \leqq 1.$$

Replace x by t and integrate over the interval $0 \leqq t \leqq x$ to obtain

$$-x \leqq a\sin x - b(\cos x - 1) \leqq x.$$

Replace x by t and integrate over the interval $0 \leqq t \leqq x$ to obtain

$$-\frac{x^2}{2} \leqq -a(\cos x - 1) - b(\sin x - x) \leqq \frac{x^2}{2}.$$

Repeat the process to obtain

$$-\frac{x^3}{3!} \leqq -a(\sin x - x) + b\left(\cos x - 1 + \frac{x^2}{2}\right) \leqq \frac{x^3}{3!}$$
$$-\frac{x^4}{4!} \leqq a\left(\cos x - 1 + \frac{x^2}{2!}\right) + b\left(\sin x - x + \frac{x^3}{3!}\right) \leqq \frac{x^4}{4!}$$
$$-\frac{x^5}{5!} \leqq a\left(\sin x - x + \frac{x^3}{3!}\right) - b\left(\cos x - 1 + \frac{x^2}{2!} - \frac{x^4}{4!}\right) \leqq \frac{x^5}{5!}.$$

Repeat the process two more times. With or without more attention to details, jump to the conclusion that

$$\left|\sin x - \left(x - \frac{x^3}{3!} + \frac{x^5}{5!} - \frac{x^7}{7!} + \cdots \pm \frac{x^{2n+1}}{(2n+1)!}\right)\right| \leqq \frac{|x|^{2n+3}}{(2n+3)!}$$
$$\left|\cos x - \left(1 - \frac{x^2}{2!} + \frac{x^4}{4!} - \frac{x^6}{6!} + \cdots \pm \frac{x^{2n}}{(2n)!}\right)\right| \leqq \frac{|x|^{2n+2}}{(2n+2)!}$$

for each $n = 1, 2, 3, \cdots$. It is true (and is easy to surmise) that, for each x, $|x|^n/n! \to 0$ as $n \to \infty$. Therefore,

$$\sin x = x - \frac{x^3}{3!} + \frac{x^5}{5!} - \frac{x^7}{7!} + \cdots$$
$$\cos x = 1 - \frac{x^2}{2!} + \frac{x^4}{4!} - \frac{x^6}{6!} + \cdots.$$

9 The formulas at the end of the preceding problem have been proved to be correct when $x > 0$. Use this fact to prove that the formulas are also correct when $x \leqq 0$. *Hint:* Look first at the case in which $x = 0$. Then use the facts that $\sin(-x) = -\sin x$ and $\cos(-x) = \cos x$.

10 Have a good look at the formulas at the end of Problem 8 and start learning them by obtaining some of the following results correct to four or more decimal places.

$$\begin{array}{ll} \sin 0.01 = 0.00999\,9833 & \cos 0.01 = 0.99995\,0000 \\ \sin 0.02 = 0.01999\,8667 & \cos 0.02 = 0.99980\,0007 \\ \sin 0.10 = 0.09983\,3417 & \cos 0.10 = 0.99500\,4165 \\ \sin 0.20 = 0.19866\,9331 & \cos 0.20 = 0.98006\,6587 \\ \sin 1.00 = 0.84147\,0985 & \cos 1.00 = 0.54030\,2306 \\ \sin 1.10 = 0.89120\,7360 & \cos 1.10 = 0.45359\,6121 \end{array}$$

11 Digest the following idea. We have a desk calculator and National Bureau of Standards Tables giving the values

$$\sin 0.2345 = 0.23235\,6699$$
$$\cos 0.2345 = 0.97263\,0641$$

If we want to find sin 0.23456 789 correct to eight decimal places, we can use the identity

$$\sin(x + 0.2345) = \sin x \cos 0.2345 + \cos x \sin 0.2345,$$

where $x = 0.00006789$. The values of $\sin x$ and $\cos x$ can easily be found correct to 10 decimal places from the formulas at the end of Problem 8.

8.3 Inverse trigonometric functions Before coming to the announced subject of this section, we think about a general situation applications of which appear in many branches of mathematics. Suppose we have an operator or transformer or mapper or function f that carries or transforms or maps each element x of a set D (the domain of f) into an element y of a set R (the range of f). In some cases the transformer transforms two or more different elements of D into the same element of R. For example, if f is one of the six trigonometric functions and $f(x)$ exists, then $f(x + 2\pi) = f(x)$ and hence more than one element of the domain is carried into the same element $f(x)$ of the range. When problems involving domains and ranges are involved, it is very often possible to eliminate confusion by singling out for special attention a subset D_1 of D such that to each y in R there corresponds exactly one x

in D_1 for which $f(x) = y$. Then we can introduce a function f_1, which is different from f because it has a different domain, for which $f_1(x) = f(x)$ when x is in D_1 and for which $f_1(x)$ is undefined when x is not in D_1. This function f_1 is called *the restriction of f to D_1*. We now have a general situation that may be easier to visualize than its applications to trigonometric functions. The schematic Figure 8.31 shows the domain and range of f_1, and the upper arc from x to y can make us think of a path along which f_1 might carry x to the y which is $f_1(x)$. The function f_1 sets up a one-to-one (or *schlicht*) correspondence between D_1 and R, that is, to each x in D_1 corresponds exactly one y in R for which $f(x) = y$ and to each y in R corresponds exactly one x in D_1 for which $f(x) = y$. The function with domain R and range D_1 which carries each y in R into the x in D_1 for which $f_1(x) = y$ is called the *inverse* of f_1 and is denoted by f_1^{-1}. As indicated by the figure, f_1^{-1} undoes what f_1 does. If $f_1(x) = y$, then $x = f_1^{-1}(y)$. Moreover, $f_1^{-1}(f_1(x)) = x$ when x is in D and

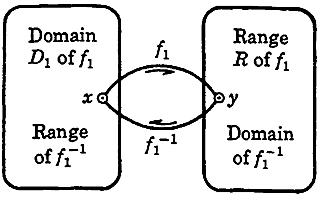

Figure 8.31

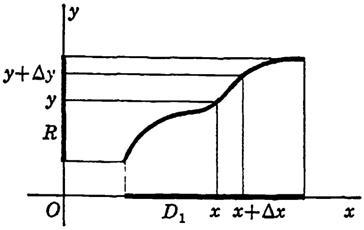

Figure 8.32

$$f_1(f_1^{-1}(y)) = y$$

when y is in R.

Figure 8.32 shows the graph of a particular function f to which the following theorem applies.

Theorem 8.33 *If f is continuous over an interval D_1 in E_1 and if f has a derivative for which $f'(x) > 0$ at each inner point x of D_1 [or $f'(x) < 0$ at each inner point x of D_1] then the restriction f_1 of f to D_1 has a range R which is an interval and has also an inverse f_1^{-1} which is differentiable at each inner point y of R. Moreover, the first of the formulas*

$$f_1^{-1\prime}(y) = \frac{1}{f_1'(f_1^{-1}(y))}, \qquad \frac{dx}{dy} = \frac{1}{\dfrac{dy}{dx}} \tag{8.331}$$

is valid when y is an inner point of R.

It seems to be possible to put the first formula of (8.331) in the second form without sacrifice of meaning. To prove the theorem, we use the hypotheses to conclude that f_1 is increasing (or decreasing) over D_1 and that (because of the intermediate-value theorem) R is an interval. Hence

f_1 has an inverse defined over R. Since we must *prove* that f_1^{-1} is differentiable, we introduce difference quotients for f_1^{-1}. Supposing that y and $y + \Delta y$ belong to the domain R of f_1^{-1}, we define x and $x + \Delta x$ by the formulas $x = f_1^{-1}(y)$ and $x + \Delta x = f_1^{-1}(y + \Delta y)$ and obtain $y = f_1(x)$, $y + \Delta y = f_1(x + \Delta x)$. Since f_1 has a positive (or negative) derivative, we conclude that $\Delta x \neq 0$ when $\Delta y \neq 0$ and that $\Delta x \to 0$ as $\Delta y \to 0$. Therefore,

$$\text{(8.332)} \quad \lim_{\Delta y \to 0} \frac{f_1^{-1}(y + \Delta y) - f_1^{-1}(y)}{\Delta y} = \lim_{\Delta y \to 0} \frac{\Delta x}{f_1(x + \Delta x) - f_1(x)}$$
$$= \lim_{\Delta y \to 0} \frac{1}{\dfrac{f_1(x_1 + \Delta x) - f_1(x)}{\Delta x}} = \frac{1}{f_1'(x)} = \frac{1}{f_1'(f_1^{-1}(y))}.$$

This proves Theorem 8.33. Of course it is possible to abbreviate the calculations by writing

$$\text{(8.333)} \qquad \frac{dx}{dy} = \lim_{\Delta y \to 0} \frac{\Delta x}{\Delta y} = \frac{1}{\lim\limits_{\Delta x \to 0} \dfrac{\Delta y}{\Delta x}} = \frac{1}{\dfrac{dy}{dx}},$$

but this one line is not, by itself, the equivalent of a theorem and proof which present conditions under which the formula is correct.

Our general discussion of inverse functions and Theorem 8.33 will now be used to guide us to six functions that are called inverse trigonometric functions even though they are in fact inverses of restrictions of trigonometric functions. It will turn out that the six functions will all have values between 0 and $\pi/2$, and that all of the information implied by Figures 8.341, 8.342, and 8.343 will be correct, provided $0 < x < 1$ in Figure 8.341, $x > 0$ in Figure 8.342, and $x > 1$ in Figure 8.343. The first figure shows, for example, that

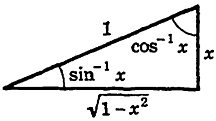

Figure 8.341

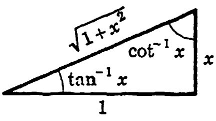

Figure 8.342

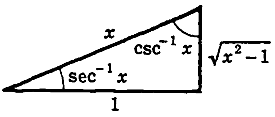

Figure 8.343

$$\sin(\sin^{-1} x) = x, \qquad \tan(\sin^{-1} x) = \frac{x}{\sqrt{1 - x^2}}$$

when $0 < x < 1$. These triangles can sometimes provide helpful information even when the functions appear in problems involving the misfortunes of gamblers who bet on horse races.

To begin, let f be the trigonometric function for which $f(x) = \sin x$, the domain D being the infinite interval $-\infty < x < \infty$ and the range

R being the closed interval $-1 \leqq y \leqq 1$. When we are called upon to select a domain D_1 to which we can apply Theorem 8.33, the graph of $y = \sin x$ can remind us of known properties of its derivative which show us that if we are going to be able to apply Theorem 8.33, we must let D_1 be the interval $-\pi/2 < x < \pi/2$ or some other interval lying $n\pi$ (n an integer) units to the right or left of it. Making the simplest choice, we let f_1 be the function, defined only when $-\pi/2 \leqq x \leqq \pi/2$, for which $f_1(x) = \sin x$. The inverse of f_1 is called the inverse sine. If $y = f_1(x)$, so that $y = \sin x$ and $-\pi/2 \leqq x \leqq \pi/2$ and $-1 \leqq y \leqq 1$, we write $x = \sin^{-1} y$. The graph of $x = \sin^{-1} y$ coincides with the part of the graph of $y = \sin x$ for which $-\pi/2 \leqq x \leqq \pi/2$, and the graph is shown in Figure 8.351. When we interchange x and y, which amounts to replacing each point (x,y) by its "image" (y,x) in the line $y = x$, we find that the graph of the equation $y = \sin^{-1} x$ is the same as the part of the graph of $x = \sin y$ for which $-\pi/2 \leqq y \leqq \pi/2$ and that the graph is shown in Figure 8.352. When $-1 < x < 1$ and $y = \sin^{-1} x$, we have $\sin y = x$, $-\pi/2 < y < \pi/2$, and $\cos y > 0$. Since Theorem 8.33, with x and y interchanged, implies that dy/dx exists, we can use the chain rule to obtain $\cos y(dy/dx) = 1$ and hence

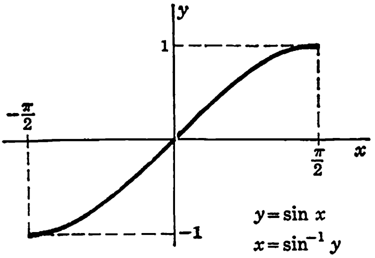

Figure 8.351

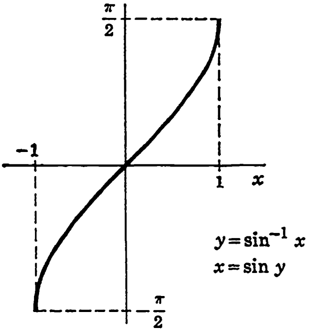

Figure 8.352

$$(8.353)\quad \frac{d}{dx}\sin^{-1} x = \frac{dy}{dx} = \frac{1}{\cos y} = \frac{1}{\sqrt{1-\sin^2 y}} = \frac{1}{\sqrt{1-x^2}}.$$

While we could not be expected to guess the result in this formula, we can look at Figure 8.352 and see that it seems to be a very reasonable answer. One who feels that inverse sines and their derivatives could never be useful should be informed at once that (8.353) gives the formula

$$(8.354)\qquad \int \frac{1}{\sqrt{1-x^2}}\,dx = \sin^{-1} x + c \qquad (|x| < 1)$$

which is useful because the integral appears in important problems.

The inverse cosine is the inverse of the function f_1, with domain $0 \leqq x \leqq \pi$ and range $-1 \leqq x \leqq 1$, for which $f_1(x) = \cos x$. Graphs of $x = \cos^{-1} y$, of $y = \cos^{-1} x$, and of the relevant parts of $y = \cos x$ and $x = \cos y$ appear in Figures 8.355 and 8.356. When $-1 < x < 1$ and $y = \cos^{-1} x$, then $\cos y = x$, $0 < y < \pi$, and $\sin y > 0$. Again Theorem 8.33 implies that dy/dx exists, so $(-\sin y)\,(dy/dx) = 1$ and

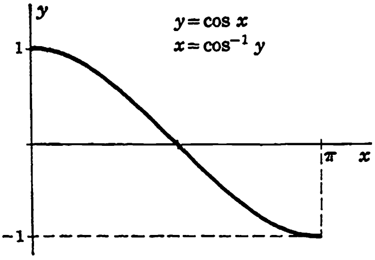

Figure 8.355

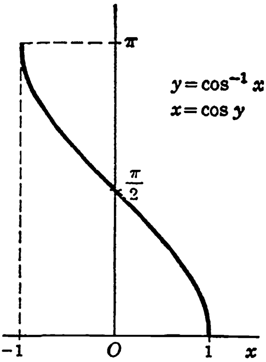

Figure 8.356

$$(8.357)\quad \frac{d}{dx}\cos^{-1} x = \frac{dy}{dx} = \frac{-1}{\sin y} = \frac{-1}{\sqrt{1-\cos^2 y}} = \frac{-1}{\sqrt{1-x^2}}.$$

This gives the integration formula

$$(8.358)\qquad \int \frac{1}{\sqrt{1-x^2}}\,dx = -\cos^{-1} x + c \qquad (|x| < 1)$$

which, because $\sin^{-1} x + \cos^{-1} x = \pi/2$, does not contradict (8.354).

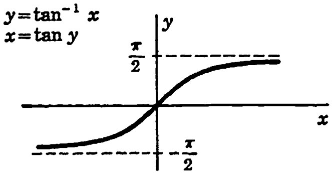

Figure 8.36

As Figure 8.171 may suggest, the inverse tangent is the inverse of the function f_1, with domain $-\pi/2 < x < \pi/2$ and range $-\infty < x < \infty$, for which $f_1(x) = \tan x$. The graph of $y = \tan^{-1} x$, which is the same as a part (sometimes called the principal part) of the graph of $x = \tan y$, is shown in Figure 8.36. The domain of the inverse tangent is the entire set of numbers, and if $y = \tan^{-1} x$, then $\tan y = x$ and $\sec^2 y(dy/dx) = 1$, so

$$(8.361)\quad \frac{d}{dx}\tan^{-1} x = \frac{dy}{dx} = \frac{1}{\sec^2 y} = \frac{1}{1+\tan^2 y} = \frac{1}{1+x^2}.$$

This gives the important formula

$$(8.362)\qquad \int \frac{1}{1+x^2}\,dx = \tan^{-1} x + c.$$

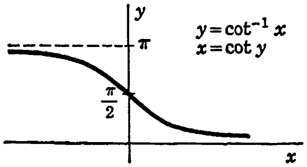

Figure 8.37

The inverse cotangent is the inverse of the function f_1, with domain $0 < x < \pi$ and range $-\infty < y < \infty$. A graph of $y = \cot^{-1} x$ is shown in Figure 8.37. The domain of the inverse cotangent is the entire set of real numbers and if $y = \cot^{-1} x$, then $\cot y = x$ and $-\csc^2 y(dy/dx) = 1$, so

$$(8.371) \qquad \frac{d}{dx}\cot^{-1} x = \frac{dy}{dx} = \frac{-1}{\csc^2 y} = \frac{-1}{1 + \cot^2 y} = \frac{-1}{1 + x^2}.$$

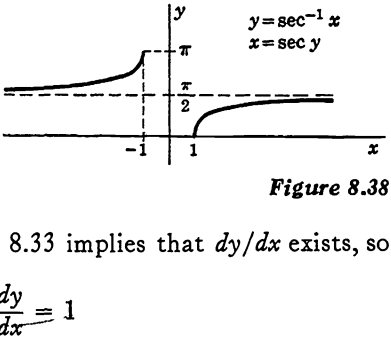

Figure 8.38

As Figure 8.233 indicates, the graph of $y = \sec x$ presents a difficulty that has not previously appeared. It is impossible to select an interval D_1 of values of x such that $\sec x$ is defined and continuous over D_1 and each y in the range of $\sec x$ is attained for some x in D_1. The best we can do is let D_1 be the interval $0 \leqq x \leqq \pi$ with the center point $x = \pi/2$ omitted. The inverse secant is then the inverse of the function f_1 with domain D_1 for which $f_1(x) = \sec x$. The graph of $y = \sec^{-1} x$, which coincides with a part of the graph of $x = \sec y$, is shown in Figure 8.38. If $x > 1$ or $x < -1$ and $y = \sec^{-1} x$, then $\sec y = x$, $0 < y < \pi$, $y \neq \pi/2$, and $\sec y \tan y > 0$. Again Theorem 8.33 implies that dy/dx exists, so

$$\sec y \tan y \frac{dy}{dx} = 1$$

and

$$(8.381) \qquad \frac{d}{dx}\sec^{-1} x = \frac{dy}{dx} = \frac{1}{\sec y \tan y} = \frac{1}{|\sec y|\,|\tan y|}$$
$$= \frac{1}{|\sec y|\sqrt{\sec^2 y - 1}} = \frac{1}{|x|\sqrt{x^2 - 1}}.$$

This gives the formula

$$(8.382) \qquad \int \frac{1}{|x|\sqrt{x^2 - 1}}\,dx = \sec^{-1} x + c,$$

which is valid when $x > 1$ and also when $x < -1$.

The graph of $y = \csc x$ presents the same difficulty that the graph of $y = \sec x$ presented. The best we can do is let D_1 be the interval $-\pi/2 \leqq x \leqq \pi/2$ with the center point $x = 0$ omitted. The inverse cosecant is then the inverse of the function f_1 with domain D_1 for which $f_1(x) = \csc x$. The graph of $y = \csc^{-1} x$, which coincides with a part of the graph of $x = \csc y$, is shown in Figure 8.383. If $x > 1$ or $x < -1$ and $y = \csc^{-1} x$, then $\csc y = x$, $-\pi/2 < y < \pi/2$, $y \neq 0$, and hence $\csc y \cot y > 0$. Again Theorem 8.33 implies that dy/dx exists, so

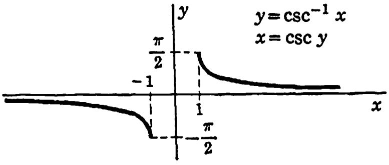

Figure 8.383

$$-\csc y \cot y \frac{dy}{dx} = 1$$

and

$$(8.384) \quad \frac{d}{dx} \csc^{-1} x = \frac{dy}{dx} = \frac{-1}{\csc y \cot y} = \frac{-1}{|\csc y|\,|\cot y|}$$
$$= \frac{-1}{|\csc y| \sqrt{\csc^2 y - 1}} = \frac{-1}{|x| \sqrt{x^2 - 1}}.$$

Problems 8.39

1 Supposing that $a > 0$ and $b^2 < 4ac$, show how the first of the formulas

$$(1) \quad \int \frac{1}{1 + u^2}\, du = \tan^{-1} u + c, \qquad \int \frac{1}{a^2 + u^2}\, du = \frac{1}{a} \tan^{-1} \frac{u}{a} + c$$

$$(2) \quad \int \frac{1}{ax^2 + bx + c}\, dx = \frac{2}{\sqrt{4ac - b^2}} \tan^{-1} \frac{2ax + b}{\sqrt{4ac - b^2}} + c$$

can be used to obtain the other two. *Remark:* Everyone should know how the last of these formulas and many similar ones are presented in standard integral tables. Let $a > 0$ and let

$$X = ax^2 + bx + c, \qquad q = b^2 - 4ac.$$

Then (2) takes the form

$$(3) \quad \int \frac{1}{X}\, dx = \frac{2}{\sqrt{-q}} \tan^{-1} \frac{2ax + b}{\sqrt{-q}} + c$$

when $q < 0$ and hence $-q > 0$. The derivation of (3) is based upon the identity

$$(4) \quad X = a\left[x^2 + \frac{b}{a}x + \frac{c}{a}\right] = a\left[\left(x^2 + \frac{b}{a}x + \frac{b^2}{4a^2}\right) + \left(\frac{c}{a} - \frac{b^2}{4a^2}\right)\right]$$
$$= a\left[\left(x + \frac{b}{2a}\right)^2 + \left(\frac{\sqrt{4ac - b^2}}{2a}\right)^2\right] = a\left[\left(x + \frac{b}{2a}\right)^2 + \left(\frac{\sqrt{-q}}{2a}\right)^2\right]$$

which involves completing a square. It may be time to renew the idea that normal persons who have forgotten (or never remembered) needed integral formulas either work them out to satisfy their vanities and preserve their mathematical powers or stoop to hunting them in a book containing a table of integrals.

2 Show that

$$\int_0^y \frac{1}{y^2 + x^2}\,dx = \frac{\pi}{4y}$$

when $y > 0$ and that

$$\int_1^a \left\{\int_0^y \frac{1}{y^2 + x^2}\,dx\right\} dy = \frac{\pi \log a}{4}$$

when $a > 0$.

3 Supposing that $-1 < x < 1$ and

$$T_n(x) = 2^{1-n} \cos (n \cos^{-1} x), \tag{1}$$

find formulas for $T_n'(x)$ and $T_n''(x)$. Then multiply $T_n(x)$ by n^2, multiply $T_n'(x)$ by $-x$, multiply $T_n''(x)$ by $(1 - x^2)$, and add the results to discover that

$$(1 - x^2)\frac{d^2y}{dx^2} - x\frac{dy}{dx} + n^2y = 0 \tag{2}$$

when $y = T_n(x)$. *Remark:* This problem involves much more than meets the eye. When n is a positive integer, T_n is the Tchebycheff polynomial of degree n and (2) is the Tchebycheff differential equation of order n. One who wishes a simple and brief discussion of these astonishing things can find it in the author's textbook "Differential Equations," 2d ed , McGraw-Hill Book Company, Inc., New York, 1960.

4 Supposing that $-1 < x < 1$ and $u = (\sin^{-1} x)^2$, calculate the first two derivatives of u and show that

$$(1 - x^2)\frac{d^2u}{dx^2} - x\frac{du}{dx} = 2.$$

5 The eye of a man is at a point E that is, as in Figure 8.391, x feet from a vertical wall bearing a picture the bottom and top of which are a and b feet above eye level. The angle θ which the picture subtends at the eye is surely small when x is small and when x is large. Derive the formulas

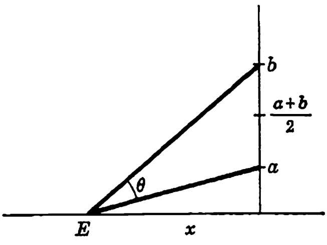

Figure 8.391

$$\theta = \tan^{-1}\frac{b}{x} - \tan^{-1}\frac{a}{x}, \qquad \frac{d\theta}{dx} = \frac{(b - a)(ab - x^2)}{(a^2 + x^2)(b^2 + x^2)}$$

and show that θ is a maximum when $x = \sqrt{ab}$. *Remark:* Addicts of elementary plane geometry can be pleased to see that the x which maximizes θ can be found in another way. As in Figure 8.392 let C be a circle which passes through the top and bottom of the picture and intersects the eye-level line L at two points E_1 and E_2. The angles which the picture subtends at E_1 and E_2 are equal. Of all such circles C that intersect L, the smallest one that produces the greatest θ is the circle C_0 for which E_1 and E_2 coincide, so C_0 is tangent to L. The radius of C_0 is $(b + a)/2$, and use of an appropriate right triangle shows that the distance from the wall to the center and to the critical point of tangency of C_0 is

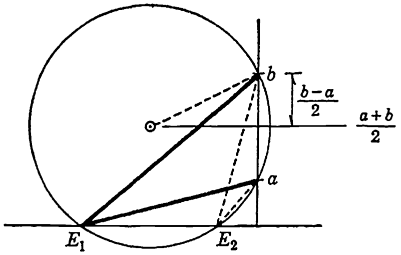

Figure 8.392

$$\sqrt{\left(\frac{b+a}{2}\right)^2 - \left(\frac{b-a}{2}\right)^2} \quad \text{or} \quad \sqrt{ab}.$$

6 Supposing that $a > 0$ and $|ax| < 1$, prove the formula

$$\tan^{-1} x + \tan^{-1} a = \tan^{-1} \frac{a+x}{1-ax}$$

by showing that the two members of the equation are equal when $x = 0$ and have equal derivatives when $|ax| < 1$.

7 With or without undertaking to prove the fundamental fact that $\cot^{-1} x = \tan^{-1} (1/x)$ when $x > 0$, suppose that $x \neq 0$ and fill in the omitted steps in the calculation

$$\frac{d}{dx} \cot^{-1} x = \frac{d}{dx} \tan^{-1} \frac{1}{x} = \cdots = \frac{-1}{1+x^2}.$$

8 With or without undertaking to prove the fundamental fact that $\sec^{-1} x = \cos^{-1} (1/x)$ when $|x| \geqq 1$, suppose that $|x| > 1$ and fill in the omitted steps in the calculation

$$\frac{d}{dx} \sec^{-1} x = \frac{d}{dx} \cos^{-1} \frac{1}{x} = \cdots = \frac{1}{|x| \sqrt{x^2 - 1}}.$$

Hint: Do not forget the chain rule and the fact that $x^2 = |x|\,|x|$.

9 With the aid of Figure 8.343 we can see that the formula

$$\sec^{-1} x = \sin^{-1} \frac{\sqrt{x^2-1}}{x} \tag{1}$$

is valid at least when $x > 1$. Differentiate the two members of (1) and determine the set of numbers x for which the derivatives are equal.

10 Letting N be a positive integer (which we shall not call "arbitrary"), manufacture and solve N problems of the nature of the preceding one.

11 Prove that

$$\int_0^1 \frac{1}{1+x^2}\,dx = \frac{\pi}{4}, \qquad \int_0^\infty \frac{1}{1+x^2}\,dx = \frac{\pi}{2}.$$

12 *Remark:* We should not be so busy that we never have time to look at our formulas and see that we can learn things from them. Supposing for simplicity that $x > 0$, we can look at the formula

$$\tan^{-1} x = \int_0^x \frac{1}{1+t^2}\,dt \tag{1}$$

and realize that each member is equal to the area of the shaded region in Figure 8.393. Any information we can obtain about $\tan^{-1} x$ or the area or the integral therefore provides information about all three. While there are much more complicated ways of getting the information, we can quickly learn some significant facts by starting with the formula

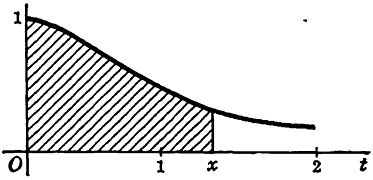

Figure 8.393

$$\frac{1}{1+t^2} = 1 - t^2 + t^4 - t^6 + \cdots + t^{4n} - \frac{t^{4n+2}}{1+t^2} \tag{2}$$

which can be obtained by long division and can be checked by multiplication by $(1 + t^2)$. Integrating this over the interval $0 \leqq t \leqq x$ gives the formula

$$\tan^{-1} x = x - \frac{x^3}{3} + \frac{x^5}{5} - \frac{x^7}{7} + \cdots + \frac{x^{4n+1}}{4n+1} - R_n(x), \tag{3}$$

where

$$R_n(x) = \int_0^x \frac{t^{4n+2}}{1+t^2}\,dt. \tag{4}$$

Suppose now that $0 \leqq x \leqq 1$. Then $1 \leqq 1 + t^2 \leqq 2$ and therefore

$$\int_0^x \frac{t^{4n+2}}{2}\,dt \leqq R_n(x) \leqq \int_0^x t^{4n+2}\,dt \tag{5}$$

so

$$\frac{x^{4n+3}}{2(4n+3)} \leqq R_n(x) \leqq \frac{x^{4n+3}}{4n+3}. \tag{6}$$

This gives us an excellent estimate of $R_n(x)$ which implies the more crude estimate

$$0 \leqq R_n(x) \leqq \frac{1}{4n+3}. \tag{7}$$

This and the sandwich theorem imply that $R_n(x) \to 0$ as $n \to \infty$, and the definition involving (5.622) shows that

$$\tan^{-1} x = x - \frac{x^3}{3} + \frac{x^5}{5} - \frac{x^7}{7} + \frac{x^9}{9} - \frac{x^{11}}{11} + \cdots \tag{8}$$

when $0 < x \leqq 1$. Changing the sign of x changes the signs of both sides and shows that the formula is correct when $-1 \leqq x \leqq 1$. Putting $x = 1$ gives the famous Leibniz formula

$$\frac{\pi}{4} = 1 - \frac{1}{3} + \frac{1}{5} - \frac{1}{7} + \frac{1}{9} - \frac{1}{11} + \cdots, \tag{9}$$

which is of particular interest to those who have not previously seen a formula from which π could be calculated. Putting $x = 1$ in (6) shows that we must take many terms of the series (8) to obtain a sum agreeing with $\pi/4$ to three or four decimal places, and we say that the series "converges slowly." The series in (8) converges more rapidly when x is nearer 0. We are not now in the computing business, but it is easy to verify that

$$\frac{\pi}{4} = \tan^{-1}\frac{1}{2} + \tan^{-1}\frac{1}{3}, \tag{10}$$

by taking tangents of both sides, and to use (8) to show that π is roughly 3.14. The formula of Machin (1680–1751)

$$\frac{\pi}{4} = 4\tan^{-1}\frac{1}{5} - \tan^{-1}\frac{1}{239}, \tag{11}$$

which is not so easily proved, is used by professional computers.

13 Find whether the function f for which $f(x) = x + \sin x$ has an inverse and, if so, whether the inverse is differentiable.

14 Let E be an interval of values of x; it could be the interval $x > 0$, and it could be the interval $-1 \leqq x \leqq 1$. Let D be the operator or transformer or differentiator which, when applied to a function f which is defined and differentiable over E, produces the function ϕ for which $\phi(x) = f'(x)$ when x is in E. The domain Δ of D is then the set of functions f that are defined and differentiable over E, and the range R of D is the set of functions ϕ that are defined over E and are derivatives of functions differentiable over E. Show that D does not possess an inverse.

15 Let E be the interval $-1 < x < 1$. Let D_1 be the restriction of the operator D of the preceding problem to the domain Δ_1 consisting of functions f defined over E for which $f(0) = 0$ and f' exists and is continuous over E. Show that D_1 has an inverse.

16 Let E be the interval $-1 < x < 1$. Let I_1 be the operator or transformer or integrator which, when applied to a function g which is continuous over E, produces the function G for which

$$G(x) = \int_0^x g(t)\,dt$$

when x is in E. Describe the domain and range of I_1 and show that I_1 has an inverse.

17 Try to understand and even prove the statement that each of the operators D_1 and I_1 (of the two preceding problems) is the inverse of the other.

8.4 Integration by trigonometric and other substitutions

We begin with a statement of the fact that there is an elementary function F whose derivative with respect to x is $\sqrt{a^2 - x^2}$. Letting F denote one such function, we try to learn about F by writing

$$F(x) = \int \sqrt{a^2 - x^2}\, dx \tag{8.41}$$

and searching for an idea. Once upon a time somebody discovered that if we substitute $x = a \sin \theta$, then the integrand will become $\sqrt{a^2 - a^2 \sin^2 \theta}$ or $\sqrt{a^2 \cos^2 \theta}$, and this is $a \cos \theta$ if $a \cos \theta > 0$. Thus a trigonometric substitution removes the radical and leaves $\pm a \cos \theta$, but we can still be unsure of the meaning of $\int \cos \theta\, dx$. Hence we must pause to make an observation.

The chain rule of Theorem 3.65 tells us that if

$$F'(x) = f(x) \tag{8.42}$$

and if u is a differentiable function whose range lies in the domain of F, then

$$\begin{aligned} \frac{d}{dt} F(u(t)) &= F'(u(t))u'(t) \\ &= f(u(t))u'(t). \end{aligned} \tag{8.421}$$

This gives the following important substitution theorem which shows how to replace x by $u(t)$ in integrals.

Theorem 8.43 *If*

$$F(x) = \int f(x)\, dx \tag{8.431}$$

and if u is a differentiable function whose range lies in the domain of f, then

$$F(u(t)) = \int f(u(t))u'(t)\, dt. \tag{8.432}$$

This theorem is used so often that it is worthwhile to be able to get from the right side of (8.431) to the right side of (8.432) in a purely formal way without thinking about the way in which the theorem was proved and the meanings of the formulas. We replace the old integrand $f(x)$ by the new integrand $f(u(t))u'(t)$ and the old dx by the new dt. This seems like a simple ritual, but the factor $u'(t)$ might be forgotten when problems are being solved. It seems to be safer and easier to think of $f(x)$ being replaced by $f(u(t))$ and dx being replaced by $u'(t)\, dt$. If we follow historical precedents, we become carried away by our own enthusiasm and try to eliminate all possibility of overlooking the factor $u'(t)$ by creating the fiction that dx is a number (a bunch of bananas would serve the same purpose) and $u'(t)\, dt$ is the same thing. There is a sense in which this whole business is utterly silly, but it really is a convenience to imagine that dx, $u'(t)$, and dt are three numbers for which $dx = u'(t)\,dt$. When $x = u(t)$, we can differentiate to get $\frac{dx}{dt} = u'(t)$, and the pretense that $\frac{dx}{dt}$ is the quotient of two numbers then enables us to multiply by dt to get the formula $dx = u'(t)\,dt$ that tells us to replace dx by $u'(t)\,dt$. It is possible to try to say more about these matters but, for present purposes, the important thing is that we do not forget the factor $u'(t)$.

Since it is not always convenient to introduce a new symbol, such as u, for the function which carries t into x, we restate the theorem in the following form which can be ignored by those who prefer the first version.

Theorem 8.433 *If*

$$F(x) = \int f(x)\,dx \tag{8.434}$$

and if x is a differentiable function whose range lies in the domain of f, then

$$F(x(t)) = \int f(x(t))x'(t)\,dt \tag{8.435}$$

or

$$F(x(t)) = \int f(x(t))\,\frac{dx}{dt}\,dt \tag{8.436}$$

or

$$F(x) = \int f(x)\,dx. \tag{8.437}$$

We give further attention to changes of variables in integrals by proving the following very useful variant of Theorem 8.433 which involves Riemann integrals.

Theorem 8.44 *If f is continuous over the interval $a \leqq x \leqq b$ and if u is a function which has a continuous derivative and is such that $u(t)$ increases from a to b as t increases (or decreases) from α to β, then*

$$\int_a^b f(x)\,dx = \int_\alpha^\beta f(u(t))u'(t)\,dt. \tag{8.441}$$

To prove this theorem, let F be a function whose derivative is f so that $\int f(x)\,dx = F(x) + c$ and

$$\int_a^b f(x)\,dx = F(x)\Big]_a^b = F(b) - F(a). \tag{8.442}$$

The chain formula for derivatives then implies that

$$\int_\alpha^\beta f(u(t))u'(t)\,dt = F(u(t))\Big]_\alpha^\beta = F(u(\beta)) - F(u(\alpha)). \tag{8.443}$$

The required conclusion (8.441) then follows from the fact that α and β are chosen such that $u(\alpha) = a$ and $u(\beta) = b$. Careful attention must be given to the manner in which the new limits of integration are determined. When we set $x = u(t)$, we must determine α such that x is a when t is α and we must determine β such that x is b when $t = \beta$.

We are now ready to attack (8.41) and, since this is the first time we have made a substitution (or changed the variable) in an integral, we proceed with great caution. Supposing that $a > 0$ and that $-a \leqq x \leqq a$, we set

$$F(x) = \int \sqrt{a^2 - x^2}\, dx \tag{8.45}$$

and let $x = a \sin \theta$, where $-\pi/2 \leqq \theta \leqq \pi/2$. Figure 8.451 always helps

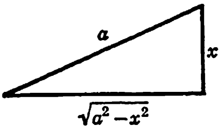

Figure 8.451

us to see what we are doing on occasions like this. Since $dx/d\theta = a \cos \theta$, we obtain

$$F(a \sin \theta) = \int \sqrt{a^2 \cos^2 \theta}\, a \cos \theta\, d\theta. \tag{8.452}$$

But $\cos \theta \geqq 0$ when $-\pi/2 \leqq \theta \leqq \pi/2$, so

$$\begin{aligned} F(a \sin \theta) &= a^2 \int \cos^2 \theta\, d\theta = \frac{a^2}{2} \int (1 + \cos 2\theta)\, d\theta \\ &= \frac{a^2}{2} [\theta + \tfrac{1}{2} \sin 2\theta] + c \\ &= \tfrac{1}{2}[a^2\theta + a^2 \sin \theta \cos \theta] + c. \end{aligned} \tag{8.453}$$

Since each x in the range $-1 \leqq x \leqq 1$ is obtained for a θ in the interval $-\pi/2 < \theta < \pi/2$, we can use Figure 8.451 and the fact that $\cos \theta \geqq 0$ to return to the original variable x so that

$$F(x) = \tfrac{1}{2}\left[a^2 \sin^{-1} \frac{x}{a} + x \sqrt{a^2 - x^2}\right] + c. \tag{8.454}$$

This gives the formula

$$\int \sqrt{a^2 - x^2}\, dx = \tfrac{1}{2}\left[a^2 \sin^{-1} \frac{x}{a} + x \sqrt{a^2 - x^2}\right] + c. \tag{8.455}$$

We are not always so careful about all of the details, and we do not always get correct answers either. There is a reason why we can sometimes be careless about quadrants in which angles lie. There is a "theory of analytic functions" that guarantees that, in many situations, a formula which is correct when angles lie in the first quadrant will be correct wherever we want to use it.

When we wish to make a substitution to evaluate the integral in

$$I = \int \frac{1}{\sqrt{a^2 - x^2}}\, dx, \tag{8.46}$$

we can clarify our work and save writing the integral by denoting it by I, or by I_1 or J if we wish to distinguish it from other integrals. We can then put $x = a \sin \theta$ and allow the variables to shift for themselves while we write

$$\begin{aligned} I &= \int \frac{1}{\sqrt{a^2 \cos^2 \theta}}\, a \cos \theta\, d\theta = \int 1\, d\theta \\ &= \theta + c = \sin^{-1} \frac{x}{a} + c. \end{aligned} \tag{8.461}$$

We have evaluated an integral that previously appeared in (8.354).

The identity $1 - \cos^2 \theta = \sin^2 \theta$ provides the reason why the substitution $x = a \sin \theta$ eliminated the square roots from the integrands of the above integrals. The identities

$$\sec^2 \theta - 1 = \tan^2 \theta, \qquad \tan^2 \theta + 1 = \sec^2 \theta, \tag{8.47}$$

which are obtainable from the one involving sines and cosines by dividing by $\cos^2 \theta$, are less familiar but are nevertheless important when we want to use them. Their uses are illustrated below.

To evaluate the integral in

$$J = \int \frac{1}{(x^2 + a^2)^{3/2}}\, dx, \tag{8.471}$$

we look at it and generate the idea that we should try setting $x = a \tan \theta$. Then $x' = a \sec^2 \theta$, so

$$\begin{aligned} J &= \int \frac{1}{(a^2 \sec^2 \theta)^{3/2}}\, a \sec^2 \theta\, d\theta = \frac{1}{a^2} \int \frac{1}{\sec \theta}\, d\theta \\ &= \frac{1}{a^2} \int \cos \theta\, d\theta = \frac{1}{a^2} \sin \theta + c = \frac{x}{a^2 \sqrt{x^2 + a^2}} + c, \end{aligned} \tag{8.472}$$

the last step being assisted by a figure showing θ, a, and x in the right way.

To evaluate the integral in

$$J_1 = \int \frac{1}{(x^2 - a^2)^{3/2}}\, dx, \tag{8.473}$$

we look at it and generate the idea that we should try setting $x = a \sec \theta$. Then $x' = a \sec \theta \tan \theta$, so

$$\begin{aligned} J_1 &= \int \frac{1}{(a^2 \tan^2 \theta)^{3/2}} a \sec \theta \tan \theta \, d\theta \\ &= \frac{1}{a^2} \int \frac{\sec \theta}{\tan^2 \theta} d\theta = \frac{1}{a^2} \int \frac{\cos \theta}{\sin^2 \theta} d\theta \\ &= \frac{1}{a^2} \int (\sin \theta)^{-2} \cos \theta \, d\theta = \frac{1}{a^2} \frac{(\sin \theta)^{-1}}{-1} + c \\ &= -\frac{1}{a^2} \frac{x}{\sqrt{x^2 - a^2}} + c. \end{aligned} \tag{8.474}$$

It is not implied that we know in advance that the integrand should be written in terms of sines and cosines, but trying this possibility and seeing that the power formula can be applied is all a part of the game.

Our last problem has a lengthy solution. We can bravely start to evaluate the integral in

$$J_2 = \int \sqrt{x^2 - a^2} \, dx \tag{8.48}$$

by setting $x = a \sec \theta$. Then $x' = a \sec \theta \tan \theta$ and

$$J_2 = \int \sqrt{a^2 \tan^2 \theta} \, a \sec \theta \tan \theta \, d\theta$$

so

$$J_2 = a^2 \int \tan^2 \theta \sec \theta \, d\theta. \tag{8.481}$$

It happens that this integral is an elementary function, but there is no simple direct way of discovering the facts. Authors and teachers, as well as students, can work for hours on this problem unless they remember how to solve it or (and this much better) have a guiding principle. The principle is the following. If we want to learn something about an integral and other methods fail to be helpful, we try integration by parts. By this we mean that we try to determine two functions u and v of the variable of integration in such a way that the integral we are studying will be the left member of the formula

$$\int u(\theta) v'(\theta) \, d\theta = u(\theta) v(\theta) - \int v(\theta) u'(\theta) \, d\theta \tag{8.482}$$

and, moreover, the "parts" on the right side enable us to make progress with our problem. Assuming that u and v have continuous derivatives over intervals where we use the formula, differentiation shows that the formula is correct. The trick is to use it effectively. Naturally, we want the functions u, v, u', v' to be as simple as possible, and it is quite easy to discover that the best way to convert J_2 into the left member of (8.482) is to set

$$\left\{ \begin{aligned} u(\theta) &= a^2 \tan \theta, & v'(\theta) &= \sec \theta \tan \theta \\ u'(\theta) &= a^2 \sec^2 \theta, & v(\theta) &= \sec \theta. \end{aligned} \right. \tag{8.483}$$

It is always a good idea to display u and v' in one line and u' and v in a lower line and to know that the formula (8.482) for integration by parts says that the integral of the product of the top two is equal to the product of u and v minus the integral of the product of the bottom two.[†] Thus

$$J_2 = a^2 \sec\theta \tan\theta - a^2\int \sec^3\theta\, d\theta. \tag{8.484}$$

The last integral seems to be quite as recalcitrant as J_2, and this really is true because

$$\begin{aligned} a^2\int \sec^3\theta\, d\theta &= a^2\int \sec^2\theta \sec\theta\, d\theta = a^2\int[1 + \tan^2\theta] \sec\theta\, d\theta \\ &= a^2\int \sec\theta\, d\theta + a^2\int \tan^2\theta \sec\theta\, d\theta \\ &= a^2 \log(\sec\theta + \tan\theta) + c + J_2. \end{aligned}$$

Instead of developing faint hearts by throwing everything into a wastebasket, we substitute our last result into (8.484) and get

$$J_2 = a^2 \sec\theta \tan\theta - a^2 \log(\sec\theta + \tan\theta) - c - J_2. \tag{8.485}$$

If we can now suddenly remember that we are trying to find J_2, we can transpose the term $-J_2$ (or add J_2 to both sides of our equation if transposing is onerous) and divide by 2 to obtain

$$J_2 = \tfrac{1}{2}a^2 \sec\theta \tan\theta - \tfrac{1}{2}a^2 \log(\sec\theta + \tan\theta) + c, \tag{8.486}$$

where the new constant c, like the old $-c/2$, can be any constant. With the aid of a figure showing how θ, a, and x are related, we obtain

$$\begin{aligned} J_2 = \int \sqrt{x^2 - a^2}\, dx &= \tfrac{1}{2}x\sqrt{x^2 - a^2} \\ &\quad - \tfrac{1}{2}a^2 \log \frac{x + \sqrt{x^2 - a^2}}{a} + c. \end{aligned} \tag{8.487}$$

If we wish, we can write the logarithm of the quotient as a difference of logarithms and combine the constant part with the c to obtain the formula

$$\begin{aligned} J_2 = \int \sqrt{x^2 - a^2}\, dx &= \tfrac{1}{2}x\sqrt{x^2 - a^2} \\ &\quad - \tfrac{1}{2}a^2 \log(x + \sqrt{x^2 - a^2}) + c, \end{aligned} \tag{8.488}$$

in which c has another value. The answers in (8.487) and (8.488) look different, but they are both correct. The last one may seem simpler, but the first one gives $c = 0$ if $J_2 = 0$ when $x = a$.

We should recognize the fact that all or nearly all of the integration formulas in the text and problems of this section appear in books of tables. We should hear more than once that books of tables are often used as labor-saving devices, but that many persons like to derive the formulas they use to preserve and improve their mathematical acumen.

[†] These matters are very important, and it is required that we think about them more than once. Our concentrated attack upon integration by parts appears in Section 9.5.

Problems 8.49

1 By making an appropriate figure and trigonometric substitution, fill in all of the missing details which show that

$$(a)\quad \int \frac{1}{\sqrt{x^2 - a^2}}\,dx = \int \sec\theta\,d\theta = \log\,(x + \sqrt{x^2 - a^2}) + c$$

$$(b)\quad \int \frac{1}{a^2 - x^2}\,dx = \frac{1}{a}\int \sec\theta\,d\theta$$
$$= \frac{1}{a}\log\frac{a + x}{\sqrt{a^2 - x^2}} + c = \frac{1}{2a}\log\frac{a + x}{a - x} + c \qquad (|x| < a)$$

$$(c)\quad \int \frac{1}{x^2 - a^2}\,dx = \frac{1}{a}\int \csc\theta\,d\theta$$
$$= -\frac{1}{a}\log\frac{x + a}{\sqrt{x^2 - a^2}} + c = \frac{1}{2a}\log\frac{x - a}{x + a} + c \qquad (x > a)$$

$$(d)\quad \int (a^2 - x^2)^{3/2}\,dx = a^4\int \cos^4\theta\,d\theta$$

2 When $x > 0$, the identity

$$(1)\qquad \sqrt{1 + \frac{1}{x^2}} = \frac{\sqrt{x^2 + 1}}{x} = \frac{x^2 + 1}{x\sqrt{1 + x^2}}$$

shows that

$$(2)\qquad \int \sqrt{1 + \frac{1}{x^2}}\,dx = \int (1 + x^2)^{-1/2}x\,dx + \int \frac{1}{x\sqrt{1 + x^2}}\,dx.$$

The first integral on the right is easily evaluated, and the second can be simplified by a trigonometric substitution. Use these ideas to derive the formula

$$(3)\qquad \int \sqrt{1 + \frac{1}{x^2}}\,dx = \sqrt{1 + x^2} + \log x - \log\,(1 + \sqrt{1 + x^2}) + c.$$

3 Sketch graphs of $y = e^x$ and $y = \log x$ in a single figure and note that each is the mirror image of the other in the line $y = x$. Observe that the arc C_1 on the graph of $y = e^x$ which joins two points (p_1,q_1) and (p_2,q_2) on the graph of $y = e^x$ is congruent to the arc C_2 on the graph of $y = \log x$ which joins the two points (q_1,p_1) and (q_2,p_2) on the graph of $y = \log x$. Letting L denote the length of C_1 and C_2, show that

$$(1)\qquad L = \int_{p_1}^{p_2} \sqrt{1 + e^{2x}}\,dx = \int_{e^{p_1}}^{e^{p_2}} \sqrt{1 + \frac{1}{x^2}}\,dx.$$

This gives the formula

$$(2)\qquad \int_{p_1}^{p_2} \sqrt{1 + e^{2t}}\,dt = \int_{e^{p_1}}^{e^{p_2}} \sqrt{1 + \frac{1}{x^2}}\,dx.$$

To show that errors and misprints have not led us to an incorrect formula, show that the substitution $t = \log x$ converts the first integral in (2) into the second integral in (2).

4 In Problem 2 of Problems 4.39, we called attention to the important nonelementary beta integral formula

$$(1) \qquad \int_0^1 x^p(1-x)^q\,dx\,\frac{p!q!}{(p+q+1)!}$$

which is correct when the integral is a Riemann integral and p and q are nonnegative; we can now report that it is correct when the integral is a Riemann-Cauchy integral and p and q exceed -1. Show that putting $x = \sin^2\theta$, where $0 \leqq \theta \leqq \pi/2$ when $0 \leqq x \leqq 1$, yields the formula

$$(2) \qquad \int_0^{\pi/2} \sin^{2p+1}\theta\cos^{2q+1}\theta\,d\theta = \frac{1}{2}\frac{p!q!}{(p+q+1)!}.$$

Be sure to observe the fact that the limits of integration are correctly determined; setting $x = 0$ in formulas involving x is equivalent to setting $\theta = 0$ in formulas involving θ, and setting $x = 1$ in formulas involving x is equivalent to setting $\theta = \pi/2$ in formulas involving θ. Finally, replace θ by x and let $2p + 1 = \alpha$, $2q + 1 = \beta$ to obtain the formula

$$(3) \qquad \int_0^{\pi/2} \sin^\alpha x\cos^\beta x\,dx = \tfrac{1}{2}\frac{\left(\dfrac{\alpha-1}{2}\right)!\left(\dfrac{\beta-1}{2}\right)!}{\left(\dfrac{\alpha+\beta}{2}\right)!},$$

which is valid when α and β exceed -1. *Remark:* If we happen to know that $(-\frac{1}{2})! = \sqrt{\pi}$, we can conclude from (3) that

$$(4) \qquad \int_0^{\pi/2} \sin^\alpha x\,dx = \sqrt{\frac{\pi}{2}}\frac{\left(\dfrac{\alpha-1}{2}\right)!}{\left(\dfrac{\alpha}{2}\right)!}.$$

5 Replace x by y^2 in the first formula of the preceding problem and then replace y by x to obtain the formula

$$\int_0^1 x^{2p+1}(1-x^2)^q\,dx = \frac{1}{2}\frac{p!q!}{(p+q+1)!}.$$

Tell why the limits of integration are correct.

6 When we proved the formulas for derivatives of trigonometric functions, we were unwilling to base the proofs upon the formula $A = \frac{1}{2}r^2\theta$ for the area of a sector of a circle having central angle θ and radius r. Supposing that $0 < \theta < \pi/2$, this problem requires that the formula be proved. With the aid of an appropriate figure, show that

$$A = \int_0^r f(x)\,dx$$

where

$$f(x) = x\tan\theta \qquad (0 \leqq x \leqq r\cos\theta)$$
$$f(x) = \sqrt{r^2 - x^2} \qquad (r\cos\theta \leqq x \leqq r).$$

Then find A with the aid of the formula (8.455) which has been proved.

7 It is easy to evaluate the integral

$$K_1 = \int x \sin x \, dx$$

with the aid of the formula

$$\int u(x)v'(x)\,dx = u(x)v(x) - \int v(x)u'(x)\,dx$$

for integration by parts. Do it by filling in the first and then the second row of the formulas

$$\begin{aligned} u(x) &= \qquad & v'(x) &= \\ u'(x) &= \qquad & v(x) &= \end{aligned}$$

in the most useful way. Check the result by differentiation.

8 Do not forget our guiding principle. If you have an idea other than integration by parts for evaluating the integral

$$K_2 = \int x^2 \sin x \, dx,$$

write the author a letter. Otherwise, develop a strong heart by solving the problem by integration by parts.

9 When we get good basic ideas we can understand and sometimes even originate modifications of them. If Mr. Watson asks us to evaluate the integral

$$L = \int \frac{1}{\sqrt{x+1}+1}\,dx,$$

we could eliminate the radical by setting $x = \tan^2 \theta$, but the result is unlovely. We can try to simplify matters by making a substitution $x = u(t)$ so cleverly devised that $\sqrt{x+1} = t$. The denominator will then be simply $t + 1$ and the other details may be of such a nature that we can find L. Show that

$$L = 2\sqrt{x+1} - 2\log(\sqrt{x+1}+1) + c.$$

Hint: The simple identity

$$\frac{t}{t+1} = \frac{t+1-1}{t+1} = 1 - \frac{1}{t+1}$$

enables us to integrate the first member in a hurry.

8.5 Integration by substituting $z = \tan \frac{\theta}{2}$

This section provides useful experience in changing variables by treating a particular substitution which is sometimes useful, but the section can be omitted without damaging understanding of the remainder of the book.

We begin by deriving formulas which enable us to use the substitution (or change of variable) $z = \tan \frac{\theta}{2}$ to convert integrals of quotients of polynomials in $\sin \theta$, $\cos \theta$, $\tan \theta$, $\cot \theta$, $\sec \theta$, and $\csc \theta$ into integrals of quotients of polynomials in z. We suppose that $-\pi < \theta < \pi$, so that $-\pi/2 < \theta/2 < \pi/2$, and define z in terms of θ by the formula

$$z = \tan\frac{\theta}{2}. \tag{8.51}$$

Differentiation gives

$$\frac{dz}{d\theta} = \frac{1}{2}\sec^2\frac{\theta}{2} = \frac{1}{2}\left(1 + \tan^2\frac{\theta}{2}\right) = \frac{1+z^2}{2},$$

and hence

$$d\theta = \frac{2}{1+z^2}\,dz. \tag{8.52}$$

Basic trigonometric identities and (8.51) give

$$\sin\theta = 2\sin\frac{\theta}{2}\cos\frac{\theta}{2} = \frac{2\tan\frac{\theta}{2}}{\sec^2\frac{\theta}{2}} = \frac{2z}{1+z^2}, \tag{8.531}$$

$$\begin{aligned}\cos\theta &= \cos^2\frac{\theta}{2} - \sin^2\frac{\theta}{2} = 2\cos^2\frac{\theta}{2} - 1\\ &= \frac{2}{\sec^2\frac{\theta}{2}} - 1 = \frac{2}{1+z^2} - 1 = \frac{1-z^2}{1+z^2}\end{aligned} \tag{8.532}$$

and, except when θ is $\pi/2$ or $-\pi/2$,

$$\tan\theta = \frac{2\tan\frac{\theta}{2}}{1 - \tan^2\frac{\theta}{2}} = \frac{2z}{1-z^2}. \tag{8.533}$$

In fact, Figures 8.541 and 8.542 enable us to write the six trigonometric functions of $\theta/2$ and θ in terms of z. Thus each of $\sin\theta$, $\cos\theta$, $\tan\theta$, $\cot\theta$, $\sec\theta$, $\csc\theta$, and $d\theta/dz$ is a quotient of polynomials in z. It follows from this that if P and Q are polynomials in the six trigonometric functions of x, then

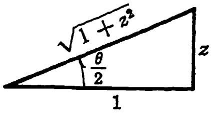

Figure 8.541

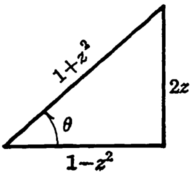

Figure 8.542

$$\int \frac{P}{Q}\,d\theta = \int \frac{P_1}{Q_1}\,dz,$$

where P_1 and Q_1 are polynomials in z. Several examples appear in the problems at the end of this section.

Except in special cases, evaluating integrals of the form

$$\int \frac{a_0 z^m + a_1 z^{m-1} + \cdots + a_{m-1} z + a_m}{b_0 z^n + b_1 z^{n-1} + \cdots + b_{n-1} z + b_n}\, dz$$

is very tedious business. When $n \leqq 2$, and in a few special additional cases, answers can be found in tables of integrals. Some information about the matter will appear in Section 9.4 of this book.

Problems 8.59

1 By use of the substitution $z = \tan \frac{\theta}{2}$, show that

(*a*) $\displaystyle\int \frac{1}{\sin\theta}\, d\theta = \int \frac{1}{z}\, dz = \log |z| + c = \log \left| \tan\frac{\theta}{2} \right| + c$

(*b*) $\displaystyle\int \frac{1}{\cos\theta}\, d\theta = \int \frac{2}{1 - z^2}\, dz = \int \frac{1 - z + 1 + z}{(1 - z)(1 + z)}\, dz$

$$= \int \left(\frac{1}{1 + z} + \frac{1}{1 - z} \right) dz = \log \left| \frac{1 + \tan\frac{\theta}{2}}{1 - \tan\frac{\theta}{2}} \right| + c$$

(*c*) $\displaystyle\int \frac{1}{a + b\sin\theta}\, d\theta = \int \frac{2}{az^2 + 2bz + a}\, dz$

(*d*) $\displaystyle\int \frac{1}{a + b\sin\theta + c\cos\theta}\, d\theta = \int \frac{2}{(a - c)z^2 + 2bz + (a + c)}\, dz$

(*e*) $\displaystyle\int \frac{\sin\theta + \cos\theta}{\tan\theta + \cot\theta}\, d\theta = 4 \int \frac{z(1 - z^2)(1 + 2z - z^2)}{(1 + z^2)^4}\, dz$

(*f*) $\displaystyle\frac{2z}{1 + z^2} + c = \sin\theta + c = \int \cos\theta\, d\theta = 2 \int \frac{1 - z^2}{(1 + z^2)^2}\, dz$

(*g*) $\displaystyle\log \frac{1 + z^2}{1 - z^2} + c = \log \sec\theta + c = \int \tan\theta\, d\theta = 4 \int \frac{z}{1 - z^4}\, dz$

(*h*) $\displaystyle\log \left(a + \frac{2bz}{1 + z^2} \right) + c = \log (a + b\sin\theta) + c$

$$= \int \frac{b\cos\theta}{a + b\sin\theta}\, d\theta$$

$$= 2b \int \frac{1 - z^2}{(az^2 + 2bz + a)(1 + z^2)}\, dz$$

(*i*) $\displaystyle\int \frac{\sin\theta}{1 + \sin\theta}\, d\theta = \int \frac{4z}{(1 + z^2)(1 + z)^2}\, dz$

(*j*) $\displaystyle\int \frac{\cos\theta}{1 + \cos\theta}\, d\theta = \int \frac{1 - z^2}{1 + z^2}\, dz$

$$= \int \frac{2 - 1 - z^2}{1 + z^2}\, dz = 2\tan^{-1}\left(\tan\frac{\theta}{2} \right) - \tan\frac{\theta}{2} + c$$

Chapter 6

Plane isometries and similarities

With this chapter you leave classical geometry, which concentrated on properties of figures constructed from points, lines, planes, circles, and spheres. You enter transformational geometry, whose fundamental objects are points and transformations. A transformation is a function that relates all points to others in a one-to-one way; it induces a correspondence between figures as well. You can use transformations to describe correspondences between various figures of classical geometry, to study positions of figures before and after motions, and to analyze the relationships between corresponding parts of symmetric figures. You can adapt transformational geometry to study aspects of a single figure that may differ when you use different coordinate systems. You'll investigate how figures change under various transformations; and —perhaps more important—you'll study figures and properties that *don't* change.

The transformations you'll study here—isometries and similarities—are closely related to the classical geometric notions of congruence and similarity. Isometries are transformations that preserve distance between points.[1] An isometry can change a triangle's location or its orientation in a plane. By the SSS congruence principle, though, an isometry cannot change a triangle's size or shape. In fact, two triangles are congruent *just in case* they're related by some isometry. This result doesn't lead to much new in the theory of *triangle* congruence, but does provide an easy way to extend the theory to figures of *any* type. You don't have to invent different congruence notions for each type, but can just call figures *congruent* if they're related by some isometry. The connection between the theory of similar figures and the study of similarity transformations, which multiply all distances by a constant ratio, is analogous.

---

[1] The word stems from the Greek words *isos* and *metron* for *equal* and *measure*.

Formulation of a general theory of congruent figures is the first of many uses of transformations in the foundations of geometry. They provide a tool for determining what's common between the geometric theories that result from various alternative axiom systems—for example, from assuming the negation of Euclid's parallel axiom. Those studies lie beyond the scope of this text, but not far![2]

The correspondence between locations of objects before and after a motion is clearly an isometry. This connection is so suggestive that many authors use the term *motion* instead of *isometry*. But isometry doesn't encompass everything involved in motion; it ignores what happens *during* the event. That requires additional apparatus not included in transformational geometry, so *motion* is a misnomer here.

The connection between transformations and symmetry is perhaps not so obvious. We exhibit *bilateral* symmetry because there's a close correspondence between points on our left and right sides. Some features are preserved; we can easily recognize an acquaintance's mirror image. Most familiar animals appear bilaterally symmetric. About a thousand years ago, an artist in the Mimbres region of New Mexico exploited that when she portrayed the dancer in figure 6.0.1, costumed to evoke simultaneously images of a deer, a man, and a bat. But many features of life are not symmetric. For example, it's hard for us to recognize the mirror image of text in figure 6.0.2. In fact, symmetry is defined in terms of isometry: a figure is symmetric if it's unchanged under some isometry. A plane figure is bilaterally symmetric if it's unchanged when you reverse the two sides of some line.

The symmetric frieze ornament in figure 6.0.3, a pottery design from the San Ildefonso Pueblo in New Mexico, is designed to be repeated as required, and remains unchanged as your gaze steps along it. A rotationally symmetric design remains the same if you turn it through a particular angle. For example, the *dharmachakra*, the 24-spoked wheel of right conduct on the flag of India (figure 6.0.4) symbolizes righteousness, truth, and recurrence.[3]

You've tasted transformational geometry if you've studied coordinate transformations in analytic geometry. That application needs a different approach; you're not interested in corresponding points, but rather in corresponding coordinate pairs or triples assigned to a single point by different coordinate systems. This chapter's theory can be adapted to that end. But that's not pursued, because the book's overall emphasis isn't on analytic

---

[2] For an introduction, consult Behnke et al. [1960] 1974, chapters 4 and 5.

[3] According to an official Indian government publication (Sivaramamurti 1966, 8, 14), the *chakra* represents "the Wheel of Law . . . whose message of righteousness was binding even on the greatest monarch. . . . The wheel of life is inexorable . . . . [It] moves on into a cycle of births and deaths, culminating in final liberation . . . . The wheel is thus the symbol of creation."

[4] From Brody, Scott, and LeBlanc 1983, plate 5. Where did the artist intentionally *break* the overall symmetry? Like most surviving Mimbres pottery, this example was recovered from a grave. Mimbres funeral ceremonies evidently included punching a hole in the bottom of each bowl to be buried.

[5] Kenneth M. Chapman 1970, plate 124p. This example originated not far from the Mimbres, but is probably less than a century old.

methods. Coordinate transformation techniques are demonstrated in exercise 6.11.31.

What methods does this chapter use to study transformations? It must depart from the classical methods of earlier chapters. Many practical applications involve computation with coordinates. That's so cumbersome that it's generally avoided in formulating the theory. The computations involve vectors and matrices, so matrix algebra affords some simplification—you can handle matrices as whole entities instead of manipulating their entries. But even greater simplification results from employing the algebra of compositions and inverses of functions. These are the substance of much of modern algebra, particularly group theory. The more deeply you study transformational geometry, particularly its applications to symmetry, the more benefit you gain by using group-theoretic methods. This chapter is an introduction to those techniques. The theory is developed with minimal use of matrix algebra. The matrix computations typical in applications are demonstrated in the exercises that conclude the chapter.

The chapter begins by collecting in section 6.1 the relevant general information about functions, composition, and inverses. Since this material is fundamental to several areas of higher mathematics, you may have encountered much of it already in other courses. Section 6.2 introduces three types of plane isometries—translations, rotations, and reflections—and some of their properties. Sections 6.3 to 6.5 discuss them in greater detail. The chapter's principal result is the structure theorem in 6.6. That enables you to classify every plane isometry as one of several types. You'll see that the earlier introductory treatment omitted one type: glide reflections, which are handled in section 6.7. The connection with matrix algebra is established in section 6.8, and used in 6.9 to refine the classification.

This chapter overview has only once mentioned the other kind of transformation this book studies: similarities. They're introduced in section 6.10. Their study requires only one new technique. Otherwise, methods already introduced for isometries work as well for similarities; there's just more detail.

The chapter concludes with exercises. These pursue further most of the ideas introduced in the previous sections, and will give you much more experience with computation.

For simplicity, chapter 6 is limited to *plane* transformational geometry. But *all* of it extends to three dimensions. In fact, most applications of plane isometries and similarities were originally handled by specialized methods that were less algebraic, more classical, in flavor. The corresponding three-dimensional results are just enough more complicated that a new apparatus was required to handle them. Logically, the three-dimensional material should be integrated into this chapter, because we really live in three-dimensional space, and its complexities make more apparent the need for the new methods. But that would make the chapter too bulky, it wouldn't be so easy for you to discern its simple structure, and the text would become less flexible for instructors and students. So the three-dimensional results are presented together in chapter 7, with a separate set of exercises. Much of the theory in that chapter is identical to the corresponding plane theory, once the definitions are properly formulated. So chapter 7 is even more streamlined, with many details left to you.

Chapter 2 and occasional passages in other previous chapters have offered some details of the history of the material presented there. It's not too hard to find sources for that, because it was often controversial. Researchers reported the background for their ideas, and cited where they agreed or differed with their predecessors. With transformational geometry, the task isn't so simple. Its techniques evolved over a century and a half, beginning in the late 1700s. They were introduced to solve hard applications problems. Mathematicians concentrated on their successes and on new problems. They rarely dwelled on philosophical, organizational, or pedagogical aspects of their work. The order of development of the material from this chapter on was often opposite to its logical order. Many of the complex techniques for applying the theory were introduced early in this period. Leonhard Euler, in 1775, would have found familiar most of the computational exercises in these chapters.[6] Determinants came into use during the early 1800s, and transformation groups and matrices in the mid-1800s. The last part of this material to fall into place is the first part presented; the language and techniques for dealing with functions, their compositions, inverses, and image sets were refined and cast in the form of section 6.1 only in the early 1900s. The history of transformational geometry is thus blurred. When you try to find the origin of a specific concept or result, you often find traces of it in works all the way back to Euler's time, even though it wasn't stated explicitly until much later. You can't readily use history pedagogically, as punctuation for the presentation of the theory. So there are fewer historical references in these later chapters. Don't let their absence give you the impression that the theory was revealed all at once, or that its history is bland! It's involved and intriguing—a challenging field of study.

---

[6] For example, Euler ([1775] 1968) formulated equations for isometries, even though the matrix algebra used for that purpose in theorems 6.8.2 and 7.1.7 wasn't developed until the late 1800s.

6.1 Transformations

Concepts

Functions; domain, value, image, and range
Linear functions
Preserved and invariant properties of figures
Function composition
Associativity and noncommutativity
Surjections, injections, and bijections
Inverse functions
Transformations
Symmetric group, transformation groups
Geometric transformations

This section summarizes elementary material about functions, on which the rest of this chapter is based. Together with appendices A and C, it forms the algebraic foundation for the entire book. You may have met much of this material already in precalculus and calculus courses. But its application to transformational geometry has a flavor so different from those subjects that the fundamentals are presented here for emphasis. You can regard transformational geometry as a very sophisticated development of these few elementary ideas and some others from chapter 3. For that reason it's important that you understand in complete and precise detail these definitions, examples, and first results. The first four exercises in section 6.11 will help you.

As you study this material in other geometry texts or other application areas, you'll encounter conflicting terminology and notation. Its applications spread over all mathematics, and what's convenient and graceful for one area can appear somewhat inappropriate for another. Moreover, this mathematics is younger than most of that in earlier chapters, and its terminology and notation are still evolving. This book's conventions result from many compromises. Several footnotes indicate its differences from other usage, and some of the reasons for the divergence.

This section concludes by mentioning some topics to which this chapter naturally leads, but which lie just beyond its scope.

Functions

The function concept pervades mathematics. In this book, for example, it has appeared among the undefined concepts and axioms:

- The *distance function* assigns to each pair of points X, Y the distance XY.

- A *scale* for a line g assigns to each point P on g a coordinate $c(P)$.
- The *area* function assigns to each polygonal region Σ its area $a\Sigma$.

Functions also occur in later developments, either implicitly or explicitly. For example,

- A function assigns to each pair P, Q of distinct points the *line* $\overleftrightarrow{PQ}$.
- Each *coordinate system* has a function that assigns to each point X a triple $<x_1, x_2, x_3>$ of coordinates.
- An *angular scale* at a point O in a plane ε assigns to each real number a ray in ε with origin O.

Section 3.13 introduced angular scales to help define $\sin x$ and $\cos x$ as real-valued functions of real numbers x. You've met many functions of that type in algebra. The following examples of *exponential*, *power*, *polynomial*, and *linear* functions are considered in detail later in this section:

$$2^x \quad x^3 \quad x^{1/3} \quad x(x^2 - 1) \quad ax + b \text{ for specified constants } a, b.$$

Also, in two or three dimensions, given matrix and vector constants A and B, you've worked with the *linear* function that assigns to each vector X the vector value $AX + B$.[7]

Here's the formal definition that unifies these examples. A *function* f assigns to each element x of a set D a unique *value* $f(x)$ in a set S. This sentence is often abbreviated $f: D \to S$ and read *f maps D into S*.[8] The uniquely determined set D of x to which f applies is called the *domain* of f. But the set S is *not* uniquely determined; if $f: D \to S$, then f also maps D into *any* set that contains S. Often it's more convenient to refer to a formula such as 2^x for the value $f(x)$ than to refer to f by name. In a case like that, you can refer to *the function $x \to 2^x$ that maps x to* 2^x. Since that doesn't mention the set D or S, you must determine them from the context. In this example, D could be the set $\mathbb{R}$ of all real numbers x, and S could be any set that contains all $x > 0$. When there's no doubt which letter is the bound variable, you can use just the formula and refer to *the function* 2^x. Be careful, though—the phrase *function* $ax + b$ is ambiguous unless you know that a and b are constants.[9]

---

[7] Even though they still call $ax + b$ a linear function, most authors of linear algebra texts reserve the term *linear* in higher dimensions to functions of the form AX. They'd call $AX + B$ an *affine* function.

[8] Authors often use the terms *function* and *mapping* interchangeably.

[9] Many older books that apply advanced algebra to geometry use *postfix* functional notation; instead of $f(x)$ they write $(x)f$. Because it clashes with calculus notation, that practice is disappearing. In this text it survives in usages like *the function* $x \to x'$. But here, the symbol $'$ is not a function name, just part of a formula for the function value.

Two functions f and g are regarded as *equal* if they have the same domain D and $f(x) = g(x)$ for every $x \in D$.

If $f : D \to S$, then to each subset $A \subseteq D$ corresponds the *image set* $f[A] = \{f(x) : x \in A\}$. The image $f[D]$ of the domain is called the *range* of f.

Preserved and invariant properties

In many applications, a function maps its domain D into itself. For example, all the trigonometric and algebraic functions mentioned under the previous heading map the domain $D = \mathbb{R}$ into itself. A function $f : D \to D$ is said to *preserve* a property $\mathscr{P}$ of members of D if $f(x)$ has property $\mathscr{P}$ whenever x does. You can use an image set to describe that situation—if $A = \{x \in D : x \text{ has } \mathscr{P}\}$, then f preserves $\mathscr{P}$ just when $f[A] \subseteq A$. For example, $x \to 2^x$ preserves the property of being an integer, but not that of being an odd integer. $\mathscr{P}$ is called *invariant* under f if $f(x)$ has $\mathscr{P}$ *if and only if* x does: $\mathscr{P}$ is invariant under f just when $f[A] = A$. For example, being positive is invariant under $x \to x^3$ but not under $x \to 2^x$.

You can consider properties of pairs, or sequences $<x_1, x_2, \ldots>$ of any number of elements of D the same way. For example, 2^x and x^3 are called *strictly increasing* functions because they leave *order* invariant:

$$x_1 \le x_2 \leftrightarrow 2^{x_1} \le 2^{x_2} \leftrightarrow x_1^3 \le x_2^3 .$$

On the other hand, $\sin x$ doesn't preserve order; you can have $x_1 \le x_2$ but $\sin x_1 > \sin x_2$.

You can consider properties of subsets or sequences of subsets of D the same way. For example, the property *being a bounded open interval* is invariant under $f(x) = 2^x$; if $a < b$, then

$$f[\{x : a < x < b\}] = \{y : 2^a < y < 2^b\}$$

because $a < x < b$ if and only if $2^a < 2^x < 2^b$. But that property isn't preserved by $\sin x$; for example,

$$\sin[\{x : 0° < x < 360°\}] = \{y : -1 \le y \le 1\},$$

which is a bounded *closed* interval, not an open one.

Function composition

If $f : S \to T$ and $g : D \to S$, then the *composition* of f with g is the function $f \circ g : D \to T$ such that $(f \circ g)(x) = f(g(x))$ for all $x \in D$.[10] For example,

---

[10] Many authors used to define composition backward. They called $g \circ f : x \to f(g(x))$ the composition of $g : D \to S$ with $f : S \to T$, letting the left-to-right order emphasize that you perform g first, then f. As you see, that collides with prefix notation for function values. (continued...)

fg *usually* means their composition, and the equation $fg = gf$ is probably false!

Surjections, injections, and bijections

A function $f : D \to S$ is said to map D *onto* S *surjectively* if $S = f[D]$, the range of f.[12] For this phrase to make sense, you *must* specify S. For example, when $D = S = \mathbb{R}$, functions x^3 and $x(x^2 - 1)$ are surjective but 2^x and $\sin x$ are not. Should you change S to $\{x : x > 0\}$ or $\{x : -1 \le x \le 1\}$, then 2^x or $\sin x$, respectively, would become surjective.

f is said to map D into S *injectively* if $f(x_1) \ne f(x_2)$ whenever $x_1 \ne x_2$.[13] Functions 2^x and x^3 are injective but $x(x^2 - 1)$ and $\sin x$ are not. These functions display all four possible combinations of surjectivity and injectivity!

f is said to map D to S *bijectively* if it's both surjective and injective. The function x^3 is bijective; so is the linear function $ax + b$ unless $a = 0$. A bijective function $f : D \to S$ has an *inverse* $f^{-1} : S \to D$, which maps each $y \in S$ to the unique $x \in D$ for which $f(x) = y$. (Surjectivity means there's at *least* one such x; injectivity means there's at *most* one.) For these examples,

$$y = f(x) = x^3 \Rightarrow x = y^{1/3} \Rightarrow f^{-1}(y) = y^{1/3} \Rightarrow f^{-1}(x) = x^{1/3}$$

$$y = g(x) = ax + b \Rightarrow x = a^{-1}y - a^{-1}b$$
$$\Rightarrow f^{-1}(y) = a^{-1}y - a^{-1}b \Rightarrow f^{-1}(x) = a^{-1}x - a^{-1}b.$$

You derive the formula for the inverse function value by solving equation $y = f(x)$ for x in terms of y, then reversing x and y. Notice that *the inverse of a nonconstant linear function is linear*!

You should verify that the inverse of a bijection $f : D \to S$ is a bijection $f^{-1} : S \to D$, and *its* inverse is the original function f.[14]

---

[12] Authors often write merely *f maps D onto S*, omitting the adverb *surjectively*. Then the subtle distinction between *into* and *onto* becomes too important. Moreover, since no convenient adjective or noun matches the preposition *onto*, they must refer awkwardly to *onto* functions or to the property of *onto-ness*. *Surjective* and *surjectivity* are more graceful. The adjectives *surjective*, *injective*, and *bijective* were coined by a pseudonymous group of French mathematicians for use in Bourbaki 1939, the first installment of a multivolume encyclopedia that reformulated advanced mathematics. *Sur* means *on* in French, and the root *-ject-* comes from the past participle of the Latin verb *iacio*, which means *throw*.

[13] Authors often refer to *one-to-one functions*, employing an adverb where an adjective would be appropriate. Moreover, since no convenient noun matches *one-to-one*, they must use the awkward term *one-to-one-ness*. *Injective* and *injectivity* are more graceful.

[14] Many authors use the term *one-to-one correspondence* for *bijection*. The term *correspondence* emphasizes the symmetric nature of such a relation, whereas *bijection* stresses its asymmetric left-to-right nature. The left-to-right convention became predominant in this context after authors found that symmetric terminology obscures the distinction between a bijection and its inverse. For an example of this awkwardness, consult the research papers by

(continued...)

It's also easy to verify the following propositions about compositions:

- If $f: S \to T$ and $g: D \to S$ are both surjective, then so is $fg: D \to T$.
- If $f: S \to T$ and $g: D \to S$ are both injective, then so is $fg: D \to T$.
- If $f: S \to T$ and $g: D \to S$ are both bijective, then so is $fg: D \to T$, and $(fg)^{-1} = g^{-1}f^{-1}: T \to D$.

Be sure you understand the reversed order of the functions in the previous sentence. If $z = f(g(x))$, then $z = f(y)$, where $y = g(x)$, so that $y = f^{-1}(z)$ and $x = g^{-1}(y) = g^{-1}(f^{-1}(z))$. In general, to undo the result of two or more successive operations, you must undo them all *in reverse order*. Think of donning your stockings, shoes, and overshoes, then removing them!

Exercise 6.11.2 provides an interesting sidelight on the previous paragraph, as follows. Suppose $f: S \to T$ and $g: D \to S$. If fg is surjective, then f must be surjective, but not necessarily g. If fg is injective, then g must be injective, but not necessarily f. If fg is bijective, then f is surjective and g injective, but neither is necessarily bijective. To ensure that you understand the concepts under this heading, complete that exercise, proving the positive clauses and finding counterexamples to justify the others.

Suppose $f: D \to D$ bijectively and $\mathcal{P}$ is a property of elements, subsets, or sequences of elements or subsets of D. It's possible for f but not f^{-1} to preserve $\mathcal{P}$. For example, consider $f(x) = x^3$, $f^{-1}(x) = x^{1/3}$ and the property $x > 2$; that inequality implies $x^3 > 2$ but not $x^{1/3} > 2$. But if $\mathcal{P}$ is *invariant* under f, then it's also invariant under f^{-1}. For example, the property $x_1 > x_2$ is invariant under both x^3 and $x^{1/3}$.

Transformations; identity functions

A bijection $f: D \to D$ is called a *transformation* of D.[15] One bijection, in particular, is ubiquitous: the *identity* function $\iota_D : x \to x$. Note that *the identity function for* $D = \mathbb{R}$ *is linear*: $\iota_{\mathbb{R}}(x) = x = 1x + 0$. It's easy to verify the following general propositions about identity functions:

- If $f: D \to S$, then $f\iota_D = f = \iota_S f$. If f is bijective, then $f^{-1}f = \iota_D$ and $ff^{-1} = \iota_S$. If f is a transformation of D, then $f^{-1}f = \iota_D = ff^{-1}$.
- Suppose $f: D \to S$ bijectively and $g: D \to S$ bijectively. If $fg = \iota_D$ or $gf = \iota_S$, then $g = f^{-1}$ and $f = g^{-1}$.
- *Every* property of elements, subsets, or sequences of elements or subsets of D is invariant under ι_D.

---

[14] (...continued)
Hermann Wiener (1890–1893), which introduced the general approach taken in this chapter.

[15] Authors often use the term *permutation* instead of *transformation*, particularly when the domain is finite.

The symmetric group; transformation groups

The family $\mathcal{S}$ of *all* transformations of D is called the *symmetric group* of D. This chapter is concerned with subfamilies $\mathcal{T}$ of $\mathcal{S}$ that satisfy three requirements:

- the identity ι_D must belong to $\mathcal{T}$;
- $\mathcal{T}$ must contain the inverse of each of its members; and
- $\mathcal{T}$ must contain the composition of any two of its members.

If $\mathcal{T}$ satisfies these conditions, it's called a *transformation group on* D. Thus a subfamily of the symmetric group is a transformation group just in case it contains the identity and is *closed* under inversion and composition. D always has at least two transformation groups: the symmetric group itself, and the *trivial* group that has only one member ι_D. Each clearly satisfies the conditions.

If a transformation f belongs to a transformation group $\mathcal{T}$, so do any n-term compositions $f \circ \cdots \circ f$ and $f^{-1} \circ \cdots \circ f^{-1}$; they're called *powers* of f and written f^n and f^{-n}. f^1 and f^0 stand for f and the identity. You can verify that some laws analogous to elementary algebra hold for this concept. For example, $f^{m+n} = f^m f^n$, $f^{mn} = (f^m)^n$, and $(f^n)^{-1} = f^{-n}$.

When one transformation group is a subset of another, it's called a *subgroup*. For example, the trivial group is a subgroup of every transformation group, and every group is a subgroup of itself. A subgroup of a group $\mathcal{G}$ that's different from $\mathcal{G}$ is called a *proper* subgroup.

Transformation groups are often characterized by invariants: If $\mathcal{P}$ is a property of elements, subsets, or sequences of elements or subsets of D, then the family of all permutations of D under which $\mathcal{P}$ is invariant forms a transformation group on D. This family clearly contains the identity and is closed under inversion and composition.

Members of the symmetric group of two- or three-dimensional space $\mathbb{R}^2$ or $\mathbb{R}^3$ are called *geometric transformations.*[16]

Linear transformations

Among the most useful geometric transformations are the two- and three-dimensional linear functions $X \to AX + B$ for specified matrix and vector constants A and B with invertible A. *The identity function is linear*: $X \to X = IX + O$. Just as in the one-dimensional case, *the composition of linear maps is linear*: If $\varphi(X) = AX + B$ and $\chi(X) = CX + D$, then

---

[16] This term is also used more broadly, for analogous concepts in projective, non-Euclidean, and higher-dimensional geometry, and sometimes for permutations of sets of lines or other figures instead of just points.

$$\varphi\chi(X) = A(CX + D) + B = (AC)X + (AD + B)$$

and $(AC)^{-1} = C^{-1}A^{-1}$. Moreover, *the inverse of a linear function is linear*:

$$\varphi^{-1}(X) = A^{-1}X - A^{-1}B$$

and $(A^{-1})^{-1} = A$. Notice how matrix multiplication and inversion correspond to function composition and inversion! The case $B = D = O$ shows that the noncommutativity of matrix multiplication and of linear function composition are two aspects of the same phenomenon.

Invariance of betweenness

Betweenness is invariant under linear transformations. To verify that, consider a transformation $X \to X' = AX + B$ and points P, Q, and R. You must show that P-Q-R if and only if P'-Q'-R'. First, P-Q-R implies that $Q = tP + (1 - t)R$ for some scalar t such that $0 \le t \le 1$, hence

$$\begin{aligned} Q' &= AQ + B = A(tP + (1 - t)R) + B \\ &= t(AP + B) + (1 - t)(AR + B) = tP' + (1 - t)R', \end{aligned}$$

hence P'-Q'-R'. Thus $X \to X'$ preserves betweenness. Its inverse is also linear, hence preserves betweenness, so P'-Q'-R' implies P-Q-R also.

It follows that any property you can define in terms of betweenness is invariant under linear transformations $X \to X'$ (regardless of whether it was originally defined that way). For example, collinearity is invariant: For any points P, Q, and R,

P, Q, and R are collinear
 if and only if P-Q-R or Q-R-P or R-P-Q, hence
  if and only if P'-Q'-R' or Q'-R'-P' or R'-P'-Q', hence
   if and only if P', Q', and R' are collinear.

Similarly, all these properties are definable in terms of betweenness:

coplanarity
convexity

being
  a segment
  a ray
  a line

being
  a half plane
  a plane
  a half space

being
  an angle
  a triangle
  a tetrahedron

being the interior of
  an angle
  a triangle
  a tetrahedron

Therefore, they're all invariant under linear transformations.

The argument in the previous paragraph is more general than its context. It actually shows that if betweenness is invariant under *any* transformation

φ, then all properties definable in terms of betweenness are also invariant under φ.

Are linear transformations the *only* ones under which betweenness is invariant? The answer is *yes*, but its proof requires analysis methods beyond the scope of this book.[17]

Linear transformations don't necessarily preserve distance or even similarity. For example, under the transformation

$$X \to X' = \begin{bmatrix} 1 & 2 \\ 0 & 1 \end{bmatrix} X,$$

the image of ΔOUV is $\Delta O'U'V'$, where

$$\begin{array}{ll} O = <0,0> = O' & V = <0,1> \\ U = <1,0> = U' & V' = <2,1>. \end{array}$$

Notice that $OV \neq O'V'$; and these triangles aren't similar.

The rest of this chapter is a detailed, fairly complete study of those geometric transformations that do preserve distance—called *isometries*—and those that preserve similarity but not necessarily distance—called *similarities*. All isometries and similarities are linear, but not vice-versa. Detailed study of linear transformations that aren't isometries lies beyond the scope of this book.[11]

6.2 Isometries

Concepts

Definition
Physical motions and time are not geometric concepts
Translations
Rotations
Reflections
The isometry group
Noncommutativity
Invariance
Rigidity theorem
Uniqueness theorem

---

[17] Chapter 15 of Martin 1982 is an introduction to that theory in two dimensions. Virtually all the results in *Methods of geometry* about isometries and similarities have both two- and three-dimensional analogues in the theory of general linear transformations. But those are often cast in projective geometric language, and hard to find in the literature. You could start a search with the research paper Ellers 1979 and its references.

This section introduces plane isometries and some related concepts. It presents common examples, but gives few details. Those come later, in sections 6.3 to 6.5 and 6.7, which study in depth four types of isometries. This section and the next are arranged to provide a quick route to the classification theorem, which shows that *every* isometry is one of those four types.

The rest of chapter 6 is concerned with points in a single plane ε. It's always the same plane, so it's never again mentioned explicitly. For example, in the rest of this chapter, *point* means *point in* ε.

A plane isometry $\varphi: P \to P'$ is a transformation of the plane that preserves distance:

(1) to each point P corresponds another, its *image* P';
(2) distinct points $P \neq Q$ have distinct images $P' \neq Q'$;
(3) every point X is the image P' of some point P;
(4) the distance between any points P and Q is the same as that between their images: $PQ = P'Q'$.

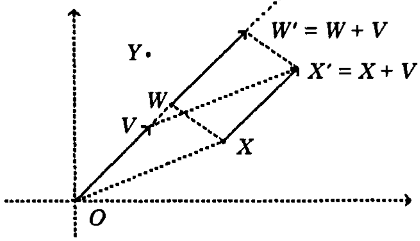
Condition (2) is redundant: If $P \neq Q$, then $PQ \neq 0$, so $P'Q' \neq 0$ by (4), hence $P' \neq Q'$. Nevertheless, the definition is usually phrased this way to emphasize that an isometry (1) is a function, (2) is injective, (3) is surjective, and (4) preserves distance.

Many authors use the term *motion* in place of *isometry*, suggesting physical action. That idea isn't formally incorporated into this text because it involves *time*—the situations before, during, and after the action—and time isn't ordinarily regarded as a geometric concept at this level. Instead, this text emphasizes the bijective correspondence between points P and P'. It alludes to physical motion only occasionally, as an informal guide to your intuition.

Translations

A familiar isometry $\tau: X \to X'$, the *translation* shown in figure 6.2.1, can be described by its effect on a single point O. Once you know $V = O'$, you can define at once the image of any point X not on $g = \overleftrightarrow{OV}$; it's the point X' that makes $OVX'X$ a parallelogram. Determining the image of a point W *on* g takes two parallelograms, as shown, or you can just refer to a scale on g. Phrasing the definition like this is awkward. It's easier just to say

Figure 6.2.1
Translation
$\tau: X \to X' = X + V$



that if you introduce a coordinate system with origin O, then $X' = X + V$ for any X. By the parallelogram law, this gives the same result as the original definition, so it makes no difference which coordinate axes you use. You can regard the identity transformation as the translation τ with $V = O$.

Theorem 1. The translation $\tau : X \rightarrow X + V$ is an isometry.

Proof. It's surjective—any point Y is the image of $Y - V$. Find $Y - V$ in figure 6.2.1! And it preserves distance: $P' - Q' = (P + V) - (Q + V) = P - Q$, so $P'Q' = PQ$ by theorem 3.11.2. ♦

Using the word *translation* for this concept isn't as obscure as it might seem. The Latin prefix *trans-* means *across*, and *latus* is the past participle of the irregular verb *fero*, which means *carry*. So to *translate* X to X', you carry X across the parallelogram, just as you carried O to V.[18]

Rotations

You can conceive of a *rotation*, another kind of isometry, in much the same way. You've an intuition of rotation as a physical action. Hold this book in a vertical plane in front of you, your thumbs pressing on opposite spots on its covers, its spine toward you. Rotate it in that plane through 20° with your fingers, keeping your thumbs stationary. Which direction? Suppose friends on your right and left request the positive, counterclockwise direction. You try to comply, but one or the other always disagrees. Facing each other, they have opposite senses of direction. What one perceives as 20° the other sees as -20°. Perhaps intuition isn't entirely adequate! Your problem is to describe the rotation $X \rightarrow X'$ so that everyone agrees, and so that you can specify its effect on every point in all cases.

One solution is to specify not the center O and angle measure, but a particular angle, designating one ray as *initial* and the other as *terminal*. Actually, it's handier to mention just the rays; that lets you specify opposite rays for 180° and coincident rays for 0° or 360° rotations. To define the rotation $X \rightarrow X'$ about O that carries the initial ray $\overrightarrow{OA}$ to the terminal ray $\overrightarrow{OB}$, use an angular scale at O as in section 3.13. Suppose the rays correspond to angle parameters α and β, and let $\theta = \beta - \alpha$. Set $X' = O$ if $X = O$; otherwise find an angle parameter ξ for ray $\overrightarrow{OX}$, and let X' be the point such that $OX = OX'$ on the ray with angle parameter $\xi + \theta$. Figure 6.2.2 displays an example. This definition doesn't specify α, β, or ξ completely, but any other parameters α_1, β_1, and ξ_1 for the same rays would differ from them by multiples of 360°, so $\xi_1 + (\beta_1 - \alpha_1)$ would correspond to the same ray $\overrightarrow{OX'}$.

---

[18] *Translate* sometimes has this sense in English religious parlance: St. Mark's body was *translated* from Alexandria to Venice in A.D. 828. *Transfer* has the same etymology.

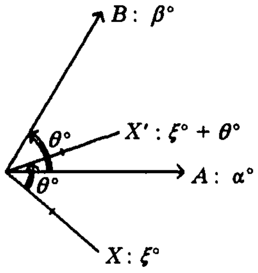


Figure 6.2.2 The rotation ρ_θ about O that maps $\vec{OA}$ to $\vec{OB}$

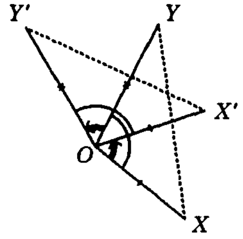

Figure 6.2.3 Rotation preserves distance: $XY = X'Y'$

Because the angle parameter θ figures so directly in the definition, the rotation is often denoted by ρ_θ. Since adding a multiple of 360° has no effect on ray $\vec{OX'}$, nor on the intuitive geometric notion of rotation, you don't have to restrict θ to the interval $0° < \theta < 180°$; it can take any value at all! If $\theta = 0°$, then $X' = X$ and ρ_θ is the identity. If $\theta = 180°$, ρ_θ is called the *half turn* σ_O about O.[19]

Theorem 2. For any θ, the rotation ρ_θ is an isometry.

Proof. Consider points X and Y noncollinear with O, with angle parameters ξ and η, as in figure 6.2.3. Then

$$\mathrm{m}\angle XOY = |(\xi - \eta) \bmod 360°|.$$

The images X' and Y' have angle parameters $\xi' = \xi + \theta$ and $\eta' = \eta + \theta$, so

$$\mathrm{m}\angle XOY = |(\xi' - \eta') \bmod 360°| = \mathrm{m}\angle X'OY'.$$

Triangles ΔXOY and $\Delta X'OY'$ are thus congruent, and $XY = X'Y'$. You should also prove this equation for the remaining case, where X and Y are collinear with O. ♦

Reflections

The reflections constitute a third type of isometry. They're perhaps less familiar, but much easier to describe. The *reflection* $X' = \sigma_g(X)$ of a point X across a line g is X itself if X is on g, else it's the point on the

---

[19] Some authors call σ_O a *point reflection.*

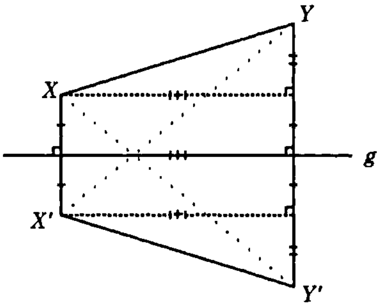

Figure 6.2.4 Reflection across g preserves distance: $XY = X'Y'$.

opposite side of g such that g is the perpendicular bisector of $\overline{XX'}$ —see figure 6.2.4.

Theorem 3. The reflection σ_g across line g is an isometry.

Proof. It's surjective because $X = \sigma_g(X') = \sigma_g(\sigma_g(X))$. Figure 6.2.4 sketches a proof that σ_g preserves the distance between points X and Y when they lie on the same side of g —that is, $XY = X'Y'$. If you show as well that $XY' = X'Y$, then interchange the labels Y and Y', you'll get a proof for X and Y on opposite sides of g. Finally, you can supply the even simpler argument that $XY = X'Y'$ when X and/or Y lies on g. ♦

The isometry group

There are other plane isometries besides the examples already given, but their details are postponed until section 6.7. The rest of this section concentrates on concepts that relate to *all* isometries.

Theorem 4. The isometries form a subgroup of the symmetric group of the plane.

Proof. This means that the identity transformation ι is an isometry, the inverse of an isometry φ is an isometry, and the composition of two isometries φ and χ is an isometry. That is, ι, φ^{-1}, and $\psi = \varphi\chi$ preserve distance. The first is trivial: ι preserves *everything*. To see that φ^{-1} preserves distance, consider two points P and Q. Let $X = \varphi^{-1}(P)$ and $Y = \varphi^{-1}(Q)$. Then $\varphi(X) = P$ and $\varphi(Y) = Q$. Moreover, $XY = \varphi(X)\varphi(Y)$ because φ is an isometry, so

$$\varphi^{-1}(P)\varphi^{-1}(Q) = XY = \varphi(X)\varphi(Y) = PQ.$$

Finally, to verify that $\psi(P)\psi(Q) = PQ$, note first that $\chi(P)\chi(Q) = PQ$ because χ is an isometry. Let $X = \chi(P)$ and $Y = \chi(Q)$. As before, $\varphi(X)\varphi(Y) = XY$, so

$$\psi(P)\psi(Q) = \varphi\chi(P)\varphi\chi(Q) = \varphi(X)\varphi(Y)$$
$$= XY = \chi(P)\chi(Q) = PQ. \blacklozenge$$

Theorem 4 is this book's first result of the form *the elements of a transformation group $\mathcal{T}$ that preserve ... form a subgroup of $\mathcal{T}$.* Here, $\mathcal{T}$ is the group of all transformations of the plane—its symmetric group—and the dots ... represent *distance.* You'll see many theorems that fit this pattern. They're all proved similarly.

Isometries don't necessarily commute. Figure 6.2.5 shows that $\varphi\chi \neq \chi\varphi$ for the reflections $\varphi = \sigma_g$ and $\chi = \sigma_h$ across selected lines g and h. You should investigate various other pairs φ and χ of isometries to get an idea of when their compositions $\varphi\chi$ and $\chi\varphi$ are or are not equal. Under the last heading of this section you'll see that any two *translations* commute. You'll study that question systematically later.

Invariance

A property of sets $\mathcal{X}$ or sequences $<X_1, X_2, \ldots>$ of points is called *invariant* under a transformation $X \rightarrow X'$ if $\mathcal{X}$ or $<X_1, X_2, \ldots>$ has that property when and only when its image $\{X' : X \in \mathcal{X}\}$ or $<X_1', X_2', \ldots>$ does. Distance, viewed as a property of pairs of points, is invariant under isometries by definition. Many other properties are invariant under isometries because you can define them in terms of distance. Theorem 5 presents a basic example.

Theorem 5. Betweenness is invariant under any isometry $X \rightarrow X'$.

Proof. If X_1, X_2, and X_3 are points, then

$$X_1\text{-}X_2\text{-}X_3 \leftrightarrow X_1X_2 + X_2X_3 = X_1X_3$$
$$\leftrightarrow X_1'X_2' + X_2'X_3' = X_1'X_3' \leftrightarrow X_1'\text{-}X_2'\text{-}X_3'. \blacklozenge$$

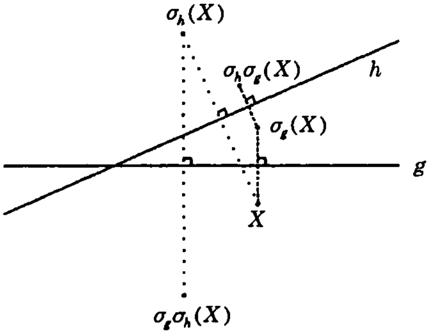

Figure 6.2.5
$\sigma_g\sigma_h(X) \neq \sigma_h\sigma_g(X)$

The critical idea of this proof is that you can define betweenness in terms of distance: X_1-X_2-X_3 $\leftrightarrow$ $X_1X_2 + X_2X_3 = X_1X_3$. You can use similar arguments to show that *any* property definable in terms of distance is invariant under isometries. At the end of section 6.1 you saw a long list of frequently used properties that are definable in terms of betweenness, hence in terms of distance. Invariance is frequently used implicitly in the rest of this chapter. For example, whenever you use a compound concept like the area of an isometric image of a triangle, you're alluding to two facts:

- The image of a triangle $\mathcal{T}$ is a triangle. (*Being a triangle* is in the list of properties definable in terms of betweenness.)
- It has the same area as $\mathcal{T}$. (You can define *area of a triangle* in terms of distance via Hero's formula, theorem 5.5.10.)

You can supply such arguments when they're needed.

Fixpoints; rigidity and uniqueness theorems

A *fixpoint* of a transformation φ is a point X that it leaves fixed: $\varphi(X) = X$. Often it's easier to analyze a transformation by considering its fixpoints than by studying how it changes other points. Translations, except for the identity, have *no* fixpoints. Rotations, except for the identity, have exactly *one*. The reflection in a line g has a whole *line* of fixpoints. And the fixpoints of the identity transformation constitute the whole *plane*. Are these the only possibilities for the fixpoint set of an isometry? The next two results—the *rigidity theorems*—answer that question.

Theorem 6. If an isometry $X \to X'$ has fixpoints $P \neq Q$, then every point X on $\overleftrightarrow{PQ}$ is fixed.

Proof. There are three cases: P-Q-X, Q-X-P, and X-P-Q. In the first case, where P-Q-X, theorem 5 implies P'-Q'-X', i.e. P-Q-X'. Thus X and X' are on the same side of Q in $\overleftrightarrow{PQ}$ and $QX = Q'X' = QX'$, so $X = X'$. You can prove the remaining cases similarly. ♦

Theorem 7. The only isometry with three noncollinear fixpoints is the identity.

Proof. Suppose an isometry $\varphi: X \to X'$ has noncollinear fixpoints A, B, and C. Then all edge points of ΔABC are fixed. For every point X you can find two distinct edge points P and Q with X on $\overleftrightarrow{PQ}$ —see figure 6.2.6. By theorem 6, X is fixed. Thus φ leaves every point fixed. ♦

Corollary 8 (Uniqueness theorem). If χ and ψ are isometries, and

$$\chi(A) = \psi(A) \qquad \chi(B) = \psi(B) \qquad \chi(C) = \psi(C)$$

for noncollinear points A, B, and C, then $\chi = \psi$.

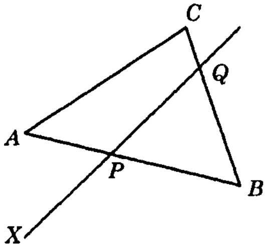

Figure 6.2.6
Proving theorem 7

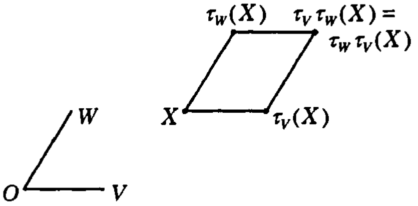

Figure 6.2.7
Translations commute

Proof. A, B, and C are fixpoints of $\varphi = \chi\psi^{-1}$, so φ is the identity. ♦

The uniqueness theorem is used often to prove that two isometries defined different ways are actually the same. Here's a typical example, which you can check by another method. Set up a coordinate system with origin O, and consider translations $\tau_V : X \to X + V$ and $\tau_W : X \to X + W$. Figure 6.2.7 shows that $\tau_V\tau_W(X) = \tau_W\tau_V(X)$ for the indicated point X. Often, such figures are valid only for a restricted set $\mathscr{X}$ of points X. But if $\mathscr{X}$ includes three noncollinear points, no matter how near each other, then by the uniqueness theorem, the equation holds for *all* points X. In this case, you can certainly pick three noncollinear points X for which the equation holds, so $\mathscr{X}$ is the entire plane and $\tau_V\tau_W = \tau_W\tau_V$. That is, any two translations commute. Of course, you could prove the same result algebraically:

$$\begin{aligned}\tau_V\tau_W(X) &= \tau_W(X) + V = (X + W) + V = (X + V) + W \\ &= \tau_V(X) + W = \tau_W\tau_V(X).\end{aligned}$$

But the uniqueness theorem is especially helpful when there are different cases to consider and no algebraic solution.

6.3 Reflections

Concepts
Mirror images
Triangle orientation
Reflections reverse orientation
Reflections in perpendicular lines
Half turns

Section 6.2 introduced the reflection $X' = \sigma_g(X)$ of a point X across a line g: If X lies on g, then $X' = X$, else $X' \neq X$ and g is the perpendicular bisector of $\overline{XX'}$. You saw that σ_g is a plane isometry. It's self-inverse: $\sigma_g^{-1} = \sigma_g$ because $\sigma_g\sigma_g(X) = X$ for each X. Why is it called a *reflection*? Stand with your eye at point Y on the same side of a mirror g as point X in figure 6.3.1. The mirror image of X appears to be at X', because light from X reflects from the mirror to Y so that the incidence and reflection angles $\angle XPO$ and $\angle YPQ$ are equal.[20]

The light ray reflected from X to Y strikes mirror g at the point P for which the path length $XP + PY$ is as short as possible. Figure 6.3.2 shows such a path for an arbitrary point P on g. Since $XP = X'P$, the shortest $XP + PY$ is the smallest sum $X'P + PY$, which occurs when P lies on $\overline{YX'}$ as in figure 6.3.1.

As a child you learned that a mirror reverses orientation; it reflects your right-hand gesture as one of your image's left hand. To learn some technological skills such as driving, you must develop intuition to process these reversed perceptions efficiently. This situation has a mathematical counterpart. Figure 6.3.3 should reinforce your intuition that if a figure $\mathcal{X}$ is oriented, then its image $\mathcal{X}' = \{X' : X \in \mathcal{X}\}$ under a reflection $\sigma_g : X \to X'$ has the opposite orientation.

What *is* an oriented figure? That concept is too general to formulate easily. In fact, it's more general than necessary; you need only consider triangles. Section 3.3 defined ΔABC as the *ordered* triple of its vertices. Thus, for example, ΔABC and ΔCBA are different, even though we use the same figure to represent them. Using figure 6.3.3, you can classify the six triangles with these vertices according to your intuitive notion of orientation:

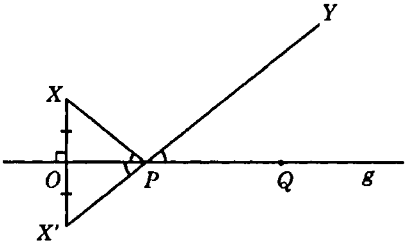

Figure 6.3.1 Mirror image X' of X as seen from Y

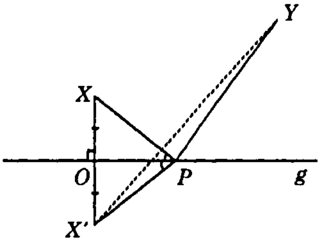

Figure 6.3.2 Path from X to Y via another point P on g

---

[20] The word *reflection* stems from the past participle of the Latin verb *reflexo*, which means *bend back*; the Greek σ in the traditional notation refers to the German word *Spiegel* for *mirror*.

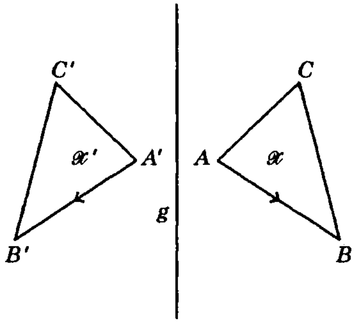

Figure 6.3.3
Reflection across g
reverses orientation.

Class (+): $\Delta ABC \quad \Delta BCA \quad \Delta CAB$
Class (-): $\Delta CBA \quad \Delta ACB \quad \Delta BAC$.

How can you distinguish these classes mathematically, without relying on figure 6.3.3 and your intuition? The determinant formula for triangle area derived in section 5.6 provides the tool. Choose a coordinate system, and regard the vertices as coordinate vectors. The triangles all have the same area; according to theorem 5.6.5, it's ± ½ times each of the determinants

$$\begin{array}{lll} \det[A-B,C-B] & \det[B-C,A-C] & \det[C-A,B-A] \\ \det[C-B,A-B] & \det[A-C,B-C] & \det[B-A,C-A]. \end{array}$$

Those in the first row are all equal. For example, by subtracting the right-hand column from the left, multiplying a column by -1, and interchanging columns, you get

$$\begin{aligned} \det[A-B,C-B] &= \det[(A-B)-(C-B),C-B] \\ &= \det[A-C,C-B] \\ &= -\det[A-C,B-C] \\ &= \det[B-C,A-C]. \end{aligned}$$

Moreover, each determinant in the second row is the negative of the one above it. Thus, all of the triangles in one row have the same *positive* determinant—they constitute class (+). The others have the same *negative* determinant—they constitute class (-). You can then call the triangles *positively* or *negatively* oriented, with respect to the chosen coordinate system. (The coordinate system for figure 6.3.3 evidently oriented ΔABC positively.)

To show that a reflection $\sigma_g : X \to X'$ reverses orientation, you could find equations for the coordinates of X' in terms of those of X, then show that $\det[A'-B', C'-B']$ and $\det[A-B,C-B]$ always differ in sign, so that $\Delta A'B'C'$ and ΔABC have opposite orientation. (In fact, these determinants always have the same magnitude; they differ *only* in sign!) Deriving the required equations for the reflection across an arbitrary line g is tedious. (See exercise 6.11.24.) Moreover, it's unnecessary, because a cleaner argument in section 6.9 will yield this general result. But you can check it easily for some special lines g. For example, if g is the first axis, then σ_g has equations $x_1' = x_1$, $x_2' = -x_2$, and you get $\det[A' - B', C' - B']$ from $\det[A - B, C - B]$ by changing the signs of the entries in its second row. If g is the second axis, change signs in the first row. If g is the diagonal line $x_1 = x_2$, then σ_g has equations $x_1' = x_2$, $x_2' = x_1$, and you get $\det[A' - B', C' - B']$ from $\det[A - B, C - B]$ by interchanging its rows. In each of these examples, the determinant merely changes sign.

The remainder of this section is concerned with the commutativity of reflections σ_g and σ_h across lines g and h. When does that occur? That is, for what lines g and h is $\sigma_g\sigma_h = \sigma_h\sigma_g$? Clearly, this equation holds if $g = h$. Figure 6.3.4 shows that if $g \perp h$, then $\sigma_g\sigma_h(P) = \sigma_h\sigma_g(P)$ for points P not on g or h. You can verify that it also holds for points P *on* the lines. Thus the reflections commute if the lines are equal or perpendicular. Conversely, suppose the reflections commute, but $g \neq h$. Find a point X on g but not h. Then

$$\sigma_g\sigma_h(X) = \sigma_h\sigma_g(X) = \sigma_h(X),$$

so $Y = \sigma_h(X)$ is a fixpoint of σ_g, and Y lies on g. Moreover, $X \neq Y$ because X isn't on h, so h is the perpendicular bisector of $\overline{XY}$ and $g = \overleftrightarrow{XY}$, hence $g \perp h$. This argument, and further inspection of figure 6.3.4, demonstrates

Theorem 1. σ_g and σ_h commute just when $g = h$ or $g \perp h$. If $g \perp h$, then $\sigma_g\sigma_h = \sigma_h\sigma_g$ is the half turn σ_O about the intersection $O = g \cap h$.

Corollary 2. A half turn σ_O commutes with a line reflection σ_h just when O lies on h. In that case, $\sigma_O\sigma_h = \sigma_h\sigma_O = \sigma_g$, the reflection across the line $g \perp h$ through O.

Proof. If O lies on h, then

$$\sigma_O\sigma_h = \sigma_g\sigma_h\sigma_h = \sigma_g = \sigma_h\sigma_h\sigma_g = \sigma_h\sigma_O$$

by theorem 1. Conversely,

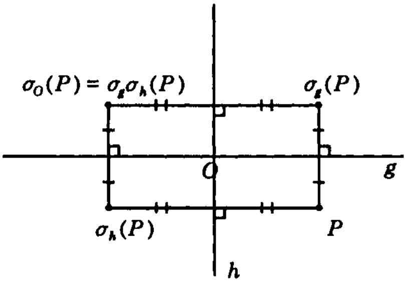

Figure 6.3.4 σ_g and σ_h commute if $g \perp h$.

$$\begin{aligned}
&\sigma_O\sigma_h = \sigma_h\sigma_O \\
&\quad\Rightarrow\ \sigma_O\sigma_h(O) = \sigma_h\sigma_O(O) = \sigma_h(O) \\
&\quad\Rightarrow\ \sigma_h(O) \text{ is a fixpoint of } \sigma_O \\
&\quad\Rightarrow\ \sigma_h(O) = O \text{ —the } \textit{only} \text{ fixpoint of } \sigma_O \text{ —} \\
&\quad\Rightarrow\ O \text{ is a fixpoint of } \sigma_h \\
&\quad\Rightarrow\ O \text{ lies on } h. \blacklozenge
\end{aligned}$$

You can complete this discussion of commutativity and reflections by verifying that two half turns σ_O and σ_P *never* commute unless $O = P$. In the next section, you'll see what kind of isometry $\sigma_O\sigma_P$ is in general.

6.4 Translations

Concepts

Definition of a translation
Equations for a translation
Compositions of translations and vector addition
Translation group
Compositions of reflections in parallel lines
Compositions of half turns
Translations preserve orientation

Section 6.2 presented two definitions of a translation: a purely geometric one using parallelograms and an equivalent formulation in terms of vector algebra. The latter is more convenient, but requires you to choose a coordinate system at the start of the discussion. Each translation is determined by the image V of the origin O; you can define the translation τ_V with vector V by setting $\tau_V(X) = X + V$ for each point X (regarded as a coordinate vector). This includes the case $\tau_V(O) = O + V = V$. As shown in figure 6.2.1, you can construct the point $X + V$ from V, O, and X using parallelograms, with no reference to coordinates. Therefore, the definition of τ_V depends only on V and O, not on other details of the coordinate system. Theorem 1 displays the *equations* for τ_V in terms of the coordinate system.

Theorem 1. The components of $X' = \tau_V(X)$ are

$$\begin{cases} x_1' = x_1 + v_1 \\ x_2' = x_2 + v_2 \,. \end{cases}$$

Not only do translations τ_V correspond one to one with their vectors V, but composition of translations corresponds to vector addition. Further, this analogy relates the inverse of a translation to the negative of its vector, and the identity, or *trivial*, translation corresponds to the zero vector:

Theorem 2. For any vectors V and W, $\tau_V \tau_W = \tau_{V+W} = \tau_W \tau_V$ and $\tau_V^{-1} = \tau_{-V}$. Moreover, τ_O is the identity transformation ι.

Proof. For all points X,

$$\begin{aligned}\tau_V \tau_W(X) &= \tau_V(X+W) = (X+W)+V = X+(W+V)\\ &= X+(V+W) = \tau_{V+W}(X)\\ \tau_O(X) &= X+O = X = \iota(X).\end{aligned}$$

Moreover,

$$\begin{aligned}&\tau_W \tau_V = \tau_{W+V} = \tau_{V+W} = \tau_V \tau_W\\ &\tau_V \tau_{-V} = \tau_{V+(-V)} = \tau_O = \iota = \tau_{(-V)+V} = \tau_{-V}\tau_V. \;\blacklozenge\end{aligned}$$

Corollary 3. The translations form a transformation group on the plane.

Proof. The composition $\tau_V \tau_W$ of two translations is the translation τ_{V+W}. The inverse τ_V^{-1} of a translation is the translation τ_{-V}. Finally, the identity transformation is a translation: $\iota = \tau_O$. ♦

The next results show how to build translations from reflections or half turns.

Theorem 4. The composition $\sigma_g \sigma_h$ of the reflections across equal or parallel lines g and h is a translation τ. With respect to any coordinate system, τ has vector $V = 2(P-Q)$, where P and Q are the intersections of g and h with a common perpendicular k.

Proof. If $g = h$, then V is the zero vector and $\sigma_g \sigma_h = \iota = \tau_V$. If $g \neq h$, as in figure 6.4.1, then

$$V = 2(P-Q) = \sigma_g \sigma_h(X) - X,$$

so $\tau_V(X) = \sigma_g \sigma_h(X)$ for any point X on the side of h opposite g. This equation holds for three noncollinear points—pick them near X in figure 6.4.1—so by the uniqueness theorem, $\sigma_g \sigma_h = \tau_V$. ♦

Corollary 5. The composition $\sigma_P \sigma_Q$ of half turns about points P and Q is a translation τ. With respect to any coordinate system, τ has vector $V = 2(P-Q)$.

Proof. Let g and h be the perpendiculars to $k = \overleftrightarrow{PQ}$ through P and Q. Then $\sigma_P \sigma_Q = \sigma_g \sigma_k \sigma_k \sigma_h = \sigma_g \sigma_h$. Now apply theorem 4. ♦

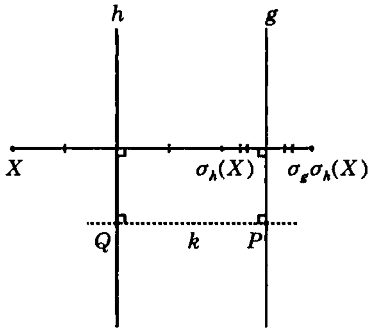

Figure 6.4.1 $\sigma_g\sigma_h$ is a translation when $g \parallel h$.

Given vector V and point P you can find a point Q, or given V and Q you can find P, such that $V = 2(P - Q)$. That yields

Corollary 6. Every translation τ is the composition $\sigma_P\sigma_Q$ of two half turns. You can choose P or Q arbitrarily; the other then depends on τ. If $P \neq Q$, then τ is the composition $\sigma_g\sigma_h$ of the reflections across the perpendiculars g and h to $\overleftrightarrow{PQ}$ through P and Q.

In section 6.5 you'll need to analyze all compositions of *three* reflections. The next result provides a start for that study.

Corollary 7. A composition $\sigma_g\sigma_h\sigma_k$ of reflections across parallel or equal lines g, h, and k is the reflection across a fourth line copencilar with these three.

Proof. A line l perpendicular to g, h, and k intersects them at points P, Q, and S. Choose a coordinate system, and find the point R on l such that $P - Q = R - S$. Let $V = 2(P - Q) = 2(R - S)$ and j be the perpendicular to l through R. By theorem 4, $\sigma_g\sigma_h = \tau_V = \sigma_j\sigma_k$, so $\tau_V(X) = \sigma_g\sigma_h(X)$ for any point X. ♦

Transformations correspond so closely to vectors that properties of vectors are often attributed to translations. For example, we refer to parallel translations or to the angle between them. By the *length* $|\tau|$ of a translation we mean the length of its vector: $|\tau| = P\tau(P)$ for any point P.

The last idea considered in this section is the effect of translation on orientation. Figure 6.4.2 should reinforce your intuition that any translation preserves orientation. You could deduce that from theorem 4 or corollary 5 if you'd shown already that every reflection reverses orientation or every half turn preserves it. However, neither of those results has been proved yet. Instead, you can use coordinates and determinants to construct the following argument, similar to the one devised for some special reflections in section 6.3.

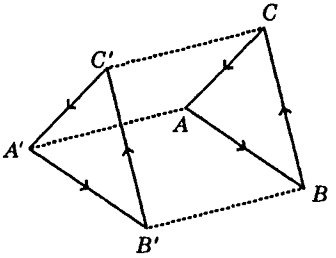

Figure 6.4.2 Translation preserves orientation.

Theorem 8. Suppose a translation τ_V maps ΔABC to $\Delta A'B'C'$. Then

$$\det[A - B, C - B] = \det[A' - B', C' - B'],$$

so τ_V preserves orientation.

Proof. $\det[A' - B', C' - B']$
$= \det[(A + V) - (B + V), (C + V) - (B + V)]$
$= \det[A - B, C - B]$. ♦

6.5 Rotations

Concepts

- Definition of a rotation
- Equation of a rotation about the origin
- Composition of rotations and angle addition
- Group of rotations about O
- Compositions of reflections in intersecting lines
- Compositions of rotations and translations

Section 6.2 defined the rotation $X \to X'$ about a point O that carries initial ray $\overrightarrow{OA}$ to terminal ray $\overrightarrow{OB}$ using an angular scale p at O as follows. Suppose p assigns those rays angle parameters α and β, and let $\theta = \alpha - \beta$. For any point $X \neq O$, find an angle parameter ξ corresponding to ray $\overrightarrow{OX}$, and let $X' = \rho_\theta(X)$ be the point on the ray with angle parameter $\xi + \theta$, such that $OX' = OX$. When you study a rotation in a broader context, you're often not free to choose the scale; some other aspect of your problem may have specified it already. Does it make any difference which angular scale you use? The answer is no. According to theorem 3.13.3, if p' is another scale at O, then there are constants ζ and n such that $n = \pm 1$ and for all ξ, $p(\xi) = p'(\zeta + n\xi)$. If you used scale p' to describe ρ, you'd find that the initial and terminal rays and ray $\overrightarrow{OX}$ correspond to parameters

$\alpha' = \zeta + n\alpha$, $\beta' = \zeta + n\beta$, and $\xi' = \zeta + n\xi$. To determine $\rho_\theta(X)$, you'd compute

$$\begin{aligned}\xi' + (\beta' - \alpha') &= (\zeta + n\xi) + (\zeta + n\beta) - (\zeta + n\alpha)\\ &= \zeta + n(\xi + \beta - \alpha) = \zeta + n(\xi + \theta),\end{aligned}$$

and you'd find that the corresponding ray is $p'(\zeta + n(\xi + \theta)) = p(\xi + \theta) = \vec{OX'}$, the same one you got with scale p.

Now choose a coordinate system with origin O. Use any angular scale at O. For any real number θ consider the rotation $\rho_\theta : X \rightarrow X'$ that carries the ray with parameter 0° to the one with parameter θ. Theorem 1 displays the *equations* for ρ_θ in terms of the coordinate system. Later, section 6.8 will derive equations for a rotation about a point different from the origin.

Theorem 1. The components of $X' = \rho_\theta(X)$ are

$$\begin{cases} x_1' = x_1 \cos\theta - x_2 \sin\theta \\ x_2' = x_1 \sin\theta + x_2 \cos\theta\,. \end{cases}$$

Proof. Suppose X has angle parameter ξ. Then $OX' = OX$ and X' has parameter $\xi + \theta$. Using the cosine and sine addition formulas (corollary 5.5.5) you get

$$\begin{aligned} x_1 &= OX \cos\xi \\ x_2 &= OX \sin\xi \\ x_1' &= OX' \cos(\xi + \theta) \\ &= OX[\cos\xi\cos\theta - \sin\xi\sin\theta] = x_1\cos\theta - x_2\sin\theta \\ x_2' &= OX'\sin(\xi + \theta) \\ &= OX[\cos\xi\sin\theta + \sin\xi\cos\theta] = x_1\sin\theta + x_2\cos\theta. \; \blacklozenge \end{aligned}$$

Not only do rotations ρ_θ about O correspond to angle parameters θ, but composition of these rotations corresponds to angle addition. Further, this analogy relates the inverse of a rotation to the negative of its parameter, and the identity rotation corresponds to parameter zero:

Theorem 2. $\rho_\eta\rho_\theta = \rho_{\eta+\theta} = \rho_\theta\rho_\eta$ and $\rho_\theta^{-1} = \rho_{-\theta}$ for any angle parameters η and θ. Moreover, ρ_{0° is the identity transformation ι.

Proof. First, $\rho_\eta\rho_\theta(O) = \rho_\eta(O) = O$. Consider a point $X \neq O$ for which ray $\vec{OX}$ has angle parameter ξ; let $\rho_\eta(X) = X'$ and $\rho_\theta(X') = X''$. Then $\vec{OX'}$ and $\vec{OX''}$ have parameters $\xi + \eta$ and $(\xi + \eta) + \theta = \xi + (\eta + \theta)$, so $\rho_{\eta+\theta}(X) = X''$. It follows that $\rho_\eta\rho_\theta = \rho_{\eta+\theta}$. Similarly, $\rho_\theta\rho_\eta = \rho_{\theta+\eta} = \rho_{\eta+\theta}$. Clearly, $\rho_{0^\circ} = \iota$. Finally, $\rho_\theta^{-1} = \rho_{-\theta}$ because $\rho_{-\theta}\rho_\theta = \rho_{-\theta+\theta} = \rho_{0^\circ} = \iota$. ♦

According to theorem 2, the composition of rotations about O, the inverse of any such rotation, and the identity transformation are all rotations about O:

Corollary 3. The rotations about O form a transformation group on the plane.

In section 6.4 you saw that a composition of reflections across parallel lines is a translation. The next result shows that if the lines intersect, the composition is a rotation. In fact, *every* rotation is such a composition of two reflections.

Theorem 4. If rays $\overrightarrow{OA}$ and $\overrightarrow{OB}$ have angle parameters α and β, then $\rho_{2(\alpha-\beta)}$ is the composition $\sigma_a\sigma_b$ of the reflections across lines $a = \overleftrightarrow{OA}$ and $b = \overleftrightarrow{OB}$.

Proof. If $a = b$, then $\rho_{2(\alpha-\beta)} = \iota = \sigma_a\sigma_b$. If $a \perp b$, the result is contained in theorem 6.3.1.

Now assume $\angle AOB$ is acute, as in figure 6.5.1. Select a point X on the side of b opposite A but on the same side of a as B, with $m\angle XOB < m\angle BOA$ as shown. Let $X' = \sigma_b(X)$ and $X'' = \sigma_a(X') = \sigma_a\sigma_b(X)$. Then rays $\overrightarrow{OX}$, $\overrightarrow{OB}$, $\overrightarrow{OX'}$, $\overrightarrow{OA}$, and $\overrightarrow{OX''}$ all fall in a single half plane as shown, and $m\angle XOX'' = 2m\angle BOA$, so $X'' = \rho_{2(\alpha-\beta)}(X)$. You can select three noncollinear points X that satisfy the same conditions, so $\sigma_a\sigma_b = \rho_{2(\alpha-\beta)}$ by the rigidity theorem.

If $\angle AOB$ is obtuse, replace A by a point $A' \neq O$ such that A-O-A'. Then $\angle A'OB$ is acute, $\overleftrightarrow{OA'} = a$, and $\overrightarrow{OA'}$ has parameter $\alpha + 180°$. By the previous paragraph, $\sigma_a\sigma_b = \rho_{2(\alpha+180°-\beta)} = \rho_{2(\alpha-\beta)+360°} = \rho_{2(\alpha-\beta)}$. ♦

Given an angle parameter θ and a ray $\overrightarrow{OA}$ with parameter α you can find a ray $\overrightarrow{OB}$ with parameter β, or given θ and $\overrightarrow{OB}$ you can find $\overrightarrow{OA}$, such that $\theta = 2(\alpha - \beta)$. Setting $a = \overleftrightarrow{OA}$ and $b = \overleftrightarrow{OB}$ yields

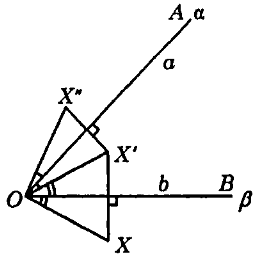

Figure 6.5.1
Proof of theorem 4

Corollary 5. Every rotation ρ about O is the composition $\sigma_a\sigma_b$ of two reflections across lines through O. You can choose either line a or b arbitrarily; the other then depends on ρ.

The next result continues the analysis of compositions of *three* reflections that you started with corollary 6.4.

Corollary 6. A composition $\sigma_g\sigma_h\sigma_k$ of reflections across lines through O is the reflection across a fourth line copencilar with these three.

Proof. Find points A, B, and $D \neq O$ on g, h, and k. Suppose rays $\vec{OA}$, $\vec{OB}$, and $\vec{OD}$ correspond to angle parameters α, β, and δ. Find the ray $\vec{OC}$ that corresponds to the parameter γ for which $\alpha - \beta = \gamma - \delta$, and let $j = \overleftrightarrow{OC}$. Then $\sigma_g\sigma_h = \rho_{2(\alpha-\beta)} = \rho_{2(\gamma-\delta)} = \sigma_j\sigma_k$, so $\sigma_g\sigma_h\sigma_k = \sigma_j$. ♦

Theorems 6.4.2 and 6.5.2 showed that the composition of two translations or of two rotations about the same center is a translation or rotation, respectively. Theorems 6.4.4 and 6.5.4 showed that the composition of two reflections is a translation or a rotation. The final two results in this section describe the composition of a rotation and a translation, and of rotations about different centers.

Corollary 7. The composition of a rotation $\rho \neq \iota$ and any translation τ is a rotation about some center.

Proof. By corollary 6.4.6, $\tau = \sigma_g\sigma_h$ for some line g through the center O of ρ and some line h parallel to g. By corollary 5, $\rho = \sigma_f\sigma_g$ for some line $f \neq g$ through O. Therefore $\rho\tau = \sigma_f\sigma_g\sigma_g\sigma_h = \sigma_f\sigma_h$, a rotation about the intersection P of f and h. You can supply a similar argument for $\tau\rho$. ♦

Corollary 8. Any composition of two rotations is a rotation or a translation.

Proof. By theorem 2 it's enough to consider rotations ρ and ρ' about distinct centers O and O'. Let $h = \overleftrightarrow{OO'}$. By corollary 5, $\rho = \sigma_g\sigma_h$ and $\rho' = \sigma_h\sigma_{g'}$ for some lines g and g' through O and O'. Therefore $\rho\rho' = \sigma_g\sigma_h\sigma_h\sigma_{g'} = \sigma_g\sigma_{g'}$. By theorem 6.4.4 or theorem 4, this composition is a translation or a rotation. ♦

Corollary 7 doesn't mention the relationship of the angle parameters of the constituent rotations to that of the composition. Corollary 8 doesn't show how the parameters of the constituent rotations determine whether the composition φ is a rotation or a translation, and in the former case how they are related to the angle parameter of φ. You can work out the connections in exercise 6.11.10 by analyzing the lines used in the proofs, or you can refer ahead to theorem 6.9.3, which derives these results through matrix algebra.

6.6 Structure theorem

Concepts

Congruent figures
Structure theorem
Even and odd isometries
Group of even isometries

Previous sections introduced the concept of a plane isometry, and described three familiar types in detail: reflections, translations, and rotations. You saw that all translations and rotations are compositions of two reflections. This section's main result is the structure theorem. It shows that *every* isometry is the identity transformation, or a reflection, or the composition of two reflections, *or the composition of three.* It's the fundamental tool for classifying plane isometries. Section 6.7 investigates the only type not yet introduced: the composition of three reflections. In section 6.8 the structure theorem plays a central role in connecting the study of isometries with matrix algebra.

The proof of the structure theorem proceeds via three preliminary results, which are arranged to make the argument as concise as possible. Lemma 2 and theorem 3 are hard to illustrate cleanly because each describes two or three different cases. You should work out separate figures for all cases.

Lemma 1. Suppose ΔABC and ΔABZ are congruent triangles. Then $C = Z$ or $\sigma_{\overleftrightarrow{AB}}(Z)$.

Proof. By theorem 3.12.5 case (2), the circles with centers A and B and radii $AC = AZ$ and $BC = BZ$ intersect at exactly two points Z and Z', and $\overleftrightarrow{AB}$ is the perpendicular bisector of $\overline{ZZ'}$. See figure 6.6.1. ♦

Lemma 2. Suppose ΔABC and ΔAYZ are congruent triangles. Then there exists an isometry χ such that $B = \chi(Y)$, $C = \chi(Z)$, and χ is the

(0) identity transformation,
(1) reflection across a line through A, or
(2) composition of the reflections across two lines through A.

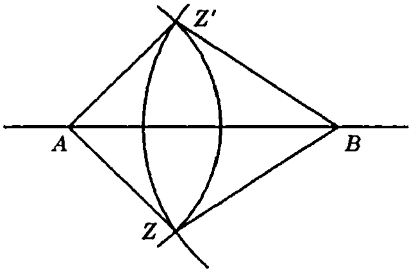

Figure 6.3.1
Proving lemma 1

Proof. If $B = Y$, lemma 1 yields the result with alternative (0) or (1). Otherwise, the perpendicular bisector h of $\overline{BY}$ passes through A because $AB = AY$. Then $B = \sigma_h(Y)$; let $Z' = \sigma_h(Z)$. By the SSS congruence principle, $\Delta ABZ' \cong \Delta AYZ \cong \Delta ABC$. By lemma 1 with Z' in place of Z, either

(1) $C = Z'$, or
(2) $C = \sigma_g(Z')$, where $g = \overleftrightarrow{AB}$.

In case (1), let $\chi = \sigma_h$; in case (2), $\chi = \sigma_g \sigma_h$. ♦

Theorem 3. Suppose ΔABC and ΔXYZ are congruent triangles. Then there exists an isometry φ such that $A = \varphi(X)$, $B = \varphi(Y)$, $C = \varphi(Z)$, and φ is

(0) the identity transformation,
(1) a reflection,
(2) the composition of reflections across two lines, or
(3) the composition of reflections across three lines.

Proof. If $A = X$, lemma 2 yields the result with alternative (0), (1), or (2). Otherwise, let k be the perpendicular bisector of $\overline{AX}$. Then $A = \sigma_k(X)$; let $Y' = \sigma_k(Y)$ and $Z' = \sigma_k(Z)$. By the SSS principle, $\Delta AY'Z' \cong \Delta XYZ \cong \Delta ABC$. By lemma 2 with Y' and Z' in place of Y and Z, there exists an isometry χ such that $B = \chi(Y')$, $C = \chi(Z')$, and χ is the

(1) identity transformation,
(2) reflection across a line through A, or
(3) composition of the reflections across two lines through A.

Let $\varphi = \chi \sigma_k$. ♦

According to theorem 3, congruent triangles are always related by some isometry. By the SSS congruence principle, triangles related by an isometry are always congruent. Thus, you should be able to *define* triangle congruence in terms of isometry in section 3.5. Some axiomatizations of geometry do exactly that. But this idea has more practical consequences, too. You can now easily *extend* the notion of congruence: Two figures $\mathcal{F}$ and $\mathcal{F}'$ are called *congruent*—in symbols, $\mathcal{F} \cong \mathcal{F}'$ —if $\mathcal{F}' = \varphi[\mathcal{F}]$ for some isometry φ. That's much more graceful than defining congruence separately for each interesting class of figure. You should check that this new definition is consistent with the section 3.5 definitions for segment and angle congruence, and with any other special cases you may have encountered earlier.

Theorem 4 **(*Structure theorem*).** The group of plane isometries consists of the identity, reflections, and compositions of two or three reflections.

Proof. Consider any isometry ψ, select any triangle ΔXYZ, and let $A = \psi(X)$, $B = \psi(Y)$, and $C = \psi(Z)$. By theorem 3, there exists an isometry φ such that $A = \varphi(X)$, $B = \varphi(Y)$, $C = \varphi(Z)$, and φ is

(0) the identity transformation,
(1) a reflection,
(2) the composition of reflections across two lines, or
(3) the composition of reflections across three lines.

By the uniqueness theorem, $\varphi = \psi$. ♦

To what extent do these isometry types overlap? The identity transformation ι is a composition of two reflections: $\iota = \sigma_g \sigma_g$ for any line g. Similarly, every reflection is a composition of three: $\sigma_g = \sigma_g \sigma_g \sigma_g$. You could write the structure theorem more tersely: Every plane isometry is a composition of two or three reflections. Is there any overlap between *these* two classes? The equation $\sigma_g \sigma_h = \sigma_j \sigma_k \sigma_l$ for lines g, h, j, k, and l leads to contradiction, as follows. Let $\varphi = \sigma_g \sigma_h$ and $\chi = \sigma_l \sigma_k$ so that $\varphi\chi = \sigma_j$. By theorems 6.4.4 and 6.5.4 and corollaries 6.5.7 and 6.5.8, each of φ and χ, and hence their composition, is a rotation or a translation. But the fixpoint set of a rotation or a translation is empty, a single point, or the entire plane, whereas that for a reflection is a line. Therefore, $\varphi\chi \neq \sigma_j$ —contradiction! *No* composition of two reflections is a composition of three.

Compositions of two reflections are called *even* isometries; compositions of three are called *odd*. By the previous paragraph, every isometry is even or odd, but none is both. The inverse of an even isometry—a translation or rotation—is also a translation or rotation, hence it's even. Summarizing these results about even isometries, here is

Theorem 5. The even isometries—the translations and rotations—constitute a group.

The notions of even and odd isometry are closely connected with that of orientation, mentioned several times in earlier sections. Since orientation was defined via coordinates and a determinant, that aspect of the theory is presented later, in section 6.8.

You've considered the reflections and the even isometries already in considerable detail. The next section investigates the remaining type: compositions of three reflections.

6.7 Glide reflections

Concepts

When do a translation and a reflection commute?
Glide reflections

In sections 6.4 and 6.5 you saw that the composition φ of reflections across three copencilar lines g, h, and k is a reflection across another line of the same pencil. This section investigates φ when g, h, and k aren't copencilar.

The first consideration seems unrelated, but it will provide the answer. When does a translation commute with a reflection?

Theorem 1. Let $\tau : P \to P'$ be a translation that's not the identity. Then τ and a reflection σ_g commute if and only if $\overleftrightarrow{PP'} \parallel g$ for some point P.

Proof. Figure 6.7.1 depicts the *if* argument. To verify the converse, suppose $\overleftrightarrow{PP'}$ and g intersect at a single point O. You'll find that $\tau\sigma_g(O)$ and $\sigma_g\tau(O)$ lie on different sides of g. ♦

When τ and σ_g commute, their composition φ is called a *glide reflection*. In that case, $\varphi\varphi = \tau\sigma_g\sigma_g\tau = \tau\tau$. This equation lets you determine τ if you know φ; for any point P, let $P'' = \varphi\varphi(P)$. Then $\tau(P)$ is the midpoint of $\overline{PP''}$. You can also determine g, since $\sigma_g = \varphi\tau^{-1}$. Thus you can call τ *the* corresponding translation and g *the* axis of φ. The vector corresponding to τ is often called the vector of φ.

When its translation is the identity, a glide reflection φ is just a reflection. Otherwise, you can see from figure 6.7.1 that φ has no fixpoint. In that case, φ is an odd motion, but not a reflection. Therefore, it's the composition of the reflections in three noncopencilar lines. Theorem 2 is the converse of this statement.

Theorem 2. If lines k, h, and g are not copencilar, then $\sigma_k\sigma_h\sigma_g$ is a glide reflection, but not a reflection.

Proof, case 1: k and h intersect at a point O, which may not lie on g. Find the line $h' \perp g$ through O; it intersects g at a point P. (See figure

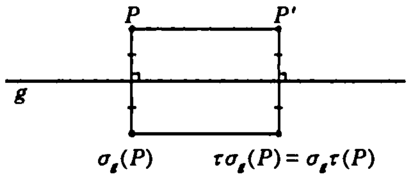

Figure 6.7.1
A commuting translation
τ and reflection σ_g

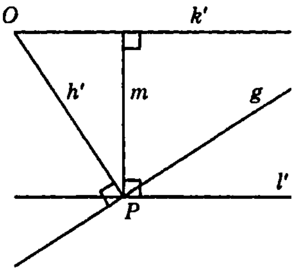

Figure 6.7.2
Case (1) of the proof
of theorem 2

6.7.2.) Let k' be the image of h' under the rotation $\sigma_k\sigma_h$, so that $\sigma_k\sigma_h = \sigma_{k'}\sigma_{h'}$. Find the line $m \perp k'$ through P, and the line $l' \perp m$ through P. Then $\sigma_{h'}\sigma_g = \sigma_P = \sigma_{l'}\sigma_m$ and $\iota \neq \sigma_{k'}\sigma_{l'} = \tau$, a translation. If $P' = \tau(P)$, then P' lies on m, hence $\tau\sigma_m$ is a glide reflection, but not a reflection. Finally,

$$\sigma_k\sigma_h\sigma_g = \sigma_{k'}\sigma_{h'}\sigma_g = \sigma_{k'}\sigma_P = \sigma_{k'}\sigma_{l'}\sigma_m = \tau\sigma_m .$$

Case 2: $k \nparallel h$. Then k and g intersect at a point. By case (1), $\sigma_g\sigma_h\sigma_k$ is a glide reflection $\tau\sigma_m$ with translation $\tau \neq \iota$ and axis m. Choose a point P, and set $O = \tau^{-1}(P)$ and $\tau(P) = Q$. Then $\overleftrightarrow{PO} = \overleftrightarrow{PQ}$, so τ^{-1} and σ_m commute and $\tau^{-1}\sigma_m$ is a glide reflection, but not a reflection. Finally,

$$\sigma_k\sigma_h\sigma_g = (\sigma_g\sigma_h\sigma_k)^{-1} = (\tau\sigma_m)^{-1} = \sigma_m^{-1}\tau^{-1} = \tau^{-1}\sigma_m . \blacklozenge$$

6.8 Isometries and orthogonal matrices

Concepts

- Orthogonal matrices A
- Inverses and products of orthogonal matrices are orthogonal
- Equation of a rotation about the origin O
- Equation of a reflection across a line through O
- Equations $X' = AX + V$ always represent isometries
- Every isometry has a unique equation $X' = AX + V$
- Angle parameters for arbitrary rotations
- Determinants of orthogonal matrices and parity of isometries

So far, your study of isometries has employed mostly synthetic methods. You've used coordinates only to formulate equations for translations, rotations about the origin, and a few special line reflections. And those have figured only in rudimentary discussions of orientation. It's time to use coordinates more seriously to derive equations for *all* plane isometries and to complete the discussion of orientation. Section 6.9 will then use equations to study various compositions of isometries.

For this section, use a fixed coordinate system with origin O, and the usual angular scale.

The most efficient way to formulate equations for arbitrary plane isometries uses matrix algebra. For example, you can restate as single matrix equations the pairs of equations derived in sections 6.5 and 6.3 for a rotation ρ_θ about O and a reflection σ_h across the first axis. For each of these isometries $X \to X'$ the components of X' are

$$\rho_\theta \begin{cases} x_1' = x_1 \cos\theta - x_2 \sin\theta \\ x_2' = x_1 \sin\theta + x_2 \cos\theta \end{cases} \qquad \sigma_h \begin{cases} x_1' = x_1 \\ x_2' = -x_2 \end{cases}$$

$$X' = A_\theta X \qquad\qquad X' = HX$$

$$A_\theta = \begin{bmatrix} \cos\theta & -\sin\theta \\ \sin\theta & \cos\theta \end{bmatrix} \qquad H = \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix}.$$

Orthogonal matrices

In this process, *orthogonal* matrices play a central role: matrices whose transposes are their inverses. That is, a square matrix A is orthogonal if A^tA is the identity matrix I. For example, the matrices A_θ and H are orthogonal:

$$A_\theta^t A_\theta = \begin{bmatrix} \cos\theta & \sin\theta \\ -\sin\theta & \cos\theta \end{bmatrix} \begin{bmatrix} \cos\theta & -\sin\theta \\ \sin\theta & \cos\theta \end{bmatrix}$$

$$= \begin{bmatrix} \cos^2\theta + \sin^2\theta & 0 \\ 0 & \sin^2\theta + \cos^2\theta \end{bmatrix} = I$$

$$H^t H = \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix} \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix} = \begin{bmatrix} 1 & 0 \\ 0 & (-1)^2 \end{bmatrix} = I.$$

These examples show that *some* isometries that fix the origin O correspond to orthogonal matrices. In fact, *every* orthogonal matrix A represents an isometry $X \to X' = AX$ that fixes O. To prove that, note that $X \to X'$

bijectively because A is invertible. Moreover, $O' = AO = O$ and for any points P and Q,

$$\begin{aligned}(P'Q')^2 &= (P' - Q')\cdot(P' - Q')\\ &= (P' - Q')^t\,(P' - Q')\\ &= (AP - AQ)^t\,(AP - AQ)\\ &= \big(A(P - Q)\big)^t A(P - Q)\\ &= (P - Q)^t A^t A(P - Q)\\ &= (P - Q)^t\,(P - Q) = (PQ)^2.\end{aligned}$$

Thus $P'Q' = PQ$; the transformation $X \to X'$ preserves distance.

For any vector V, the transformation $X \to X'' = X' + V = AX + B$ is also an isometry:

$$\begin{aligned}(P''Q'')^2 &= (P'' - Q'')\cdot(P'' - Q'')\\ &= \big((P' + V) - (Q' + V)\big)\cdot\big((P' + V) - (Q' + V)\big)\\ &= (P' - Q')\cdot(P' - Q') = (P'Q')^2 = (PQ)^2.\end{aligned}$$

You'll soon see that you can represent *every* plane isometry $X \to X''$ this way; there's always an orthogonal matrix A and a vector V such that $X'' = AX + V$ for every point X.

First, here are some simple and useful facts about orthogonal matrices. Clearly, the identity matrix I is orthogonal. The inverse of an orthogonal matrix A is orthogonal, for if $A^tA = I$, then $A^t = A^{-1}$ and

$$(A^{-1})^t A^{-1} = (A^{-1})^t A^t = (AA^{-1})^t = I^t = I.$$

Moreover, the product of orthogonal matrices A and B is orthogonal:

$$(AB)^t(AB) = B^tA^tA\,B = B^tB = I.$$[21]

Now consider a line $g = \overrightarrow{OP}$, where ray $\overrightarrow{OP}$ has angle parameter θ. Find the ray $\overrightarrow{OB}$ with parameter $\frac{1}{2}\theta$, and let $b = \overleftrightarrow{OB}$, as in figure 6.8.1. Consider the rotation $\rho_\theta = \sigma_b\sigma_h = \sigma_g\sigma_b$. This equation implies

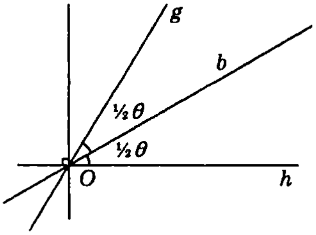

Figure 6.8.1
$\sigma_h\sigma_b = \sigma_b\sigma_g$

---

[21] This paragraph closely parallels the definition of a transformation group in section 6.1. Had this book defined the notion *matrix group*, it could speak in terms of the *group* of orthogonal matrices. But it avoids the more abstract group concepts because they're not so useful in this context.

$$\sigma_g = \sigma_b\sigma_h\sigma_b = \sigma_b\sigma_h\sigma_h\sigma_h\sigma_b = \rho_\theta\sigma_h\rho_\theta^{-1}.$$

Isometries ρ_θ and σ_h correspond to orthogonal matrices A_θ and H, so σ_g corresponds to the orthogonal matrix

$$\begin{aligned} A_\theta H A_\theta^{-1} &= A_\theta H A_{-\theta} \\ &= \begin{bmatrix} \cos\theta & -\sin\theta \\ \sin\theta & \cos\theta \end{bmatrix} \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix} \begin{bmatrix} \cos(-\theta) & -\sin(-\theta) \\ \sin(-\theta) & \cos(-\theta) \end{bmatrix} \\ &= \begin{bmatrix} \cos\theta & \sin\theta \\ \sin\theta & -\cos\theta \end{bmatrix} \begin{bmatrix} \cos\theta & \sin\theta \\ -\sin\theta & \cos\theta \end{bmatrix} \\ &= \begin{bmatrix} \cos^2\theta - \sin^2\theta & 2\sin\theta\cos\theta \\ 2\cos\theta\sin\theta & -(\cos^2\theta - \sin^2\theta) \end{bmatrix} = \begin{bmatrix} \cos 2\theta & \sin 2\theta \\ \sin 2\theta & -\cos 2\theta \end{bmatrix}. \end{aligned}$$

Theorem 1. Any isometry φ that fixes the origin has equation $\varphi(X) = AX$, for some orthogonal matrix A. Every orthogonal matrix A has the form $A = A_\theta$ or $A = A_\theta H A_\theta^{-1}$ for some angle parameter θ.

Proof. You've already seen that for any orthogonal matrix A the transformation $X \to AX$ is an isometry that fixes O. Now consider an arbitrary isometry φ that fixes O. According to sections 6.6 and 6.7, φ must be

(0) the identity,
(1) a reflection σ_g across a line g,
(2) a composition of two reflections, or
(3) a glide reflection.

A glide reflection with a fixpoint is a reflection, so case (3) is included in case (1). By sections 6.4 and 6.5, a composition φ of two reflections is

(2a) a translation, or
(2b) a rotation ρ.

A translation with a fixpoint is the identity, so case (2a) is included in case (0). Since ρ fixes only its center and σ_g fixes only the points on g, just these cases remain:

(0) φ is the identity, with orthogonal matrix I, or
(1) φ is a reflection σ_g across a line g through the origin, with orthogonal matrix $A_\theta H A_\theta^{-1}$, or
(2b) φ is a rotation ρ about the origin, with orthogonal matrix A_θ. ♦

Finally, consider an *arbitrary* isometry ψ. Let $B = \psi(O)$ and τ be the translation with vector $-B$. The isometry $\varphi = \tau\psi$ fixes the origin:

$$\varphi(O) = \tau\psi(O) = \tau(B) = B - B = O.$$

By the previous paragraph, there's an orthogonal matrix A such that $\varphi(X) = AX$ for every point X. Since τ^{-1} is the translation with vector $-(-B) = B$,

$$\psi(X) = \tau^{-1}\varphi(X) = \tau^{-1}(AX) = AX + B.$$

The transformation determines A and B uniquely; for if $AX + B = CX + D$ for every point X, then substituting $X = O$ yields $B = C$, and substituting the kth unit vector shows that the kth columns of A and C are equal. This discussion has proved

Theorem 2. The plane isometries are the transformations $\varphi : X \to X' = AX + B$ where A is an orthogonal matrix and B is an arbitrary vector. A and B are determined uniquely by φ.

A more concise argument for theorem 2 is presented in the proof of theorem 7.1.7. It doesn't refer to matrices A_θ and H, but uses the uniqueness theorem and some simpler matrix algebra. But that proof conveys little geometric insight; it's reserved until you've gained more experience.

A rotation $\varphi : X \to X'$ about a center $P \neq O$ has equation $X' = AX + B$ for some orthogonal matrix A. Let τ be the translation with vector $-B$. Then $\tau\varphi : X \to AX$ is an even isometry that fixes O —that is, a rotation ρ_θ about O with angle parameter θ. Thus $A = A_\theta$. Rotations with *any* center correspond to angle parameters just like the rotations about O!

Parity

If A is an orthogonal matrix, then

$$1 = \det I = \det A^tA = \det A^t \det A = (\det A)^2,$$

hence $\det A = \pm 1$. If φ is an isometry with matrix A, this determinant is called its *parity*, par φ. A rotation ρ_θ about O —an even isometry— has parity $\det A_\theta = \cos^2\theta + \sin^2\theta = 1$. In contrast, a reflection σ_g across a line g through O —an odd isometry—has parity $\det(A_\theta H A_\theta^{-1}) = (\det A_\theta)(\det H)(\det A_\theta)^{-1} = \det H = -1$. Theorem 3 shows that this pattern persists; parity provides an easy algebraic way to tell when φ is even or odd.

Theorem 3. φ is even if par $\varphi = +1$, and odd if par $\varphi = -1$.

Proof. A transformation $\varphi : X \to X' = AX + B$ preserves orientation of a triangle ΔPQR just in case $\det[P' - R', Q' - R']$ and $\det[P - R, Q - R]$ have the same sign. But

$$\begin{aligned}
&\det[P' - R', Q' - R'] \\
&\quad = \det[(AP + B) - (AR + B), (AQ + B) - (AR + B)] \\
&\quad = \det[AP - AR, AQ - AR] \\
&\quad = \det[A(P - R), A(Q - R)] \\
&\quad = \det A[P - R, Q - R] \\
&\quad = \det A \det[P - R, Q - R] \\
&\quad = \pm\det[P - R, Q - R]. \blacklozenge
\end{aligned}$$

Theorem 4. par $\varphi\chi$ = par φ par χ and par φ^{-1} = par φ for any isometries φ and χ.

6.9 Classifying isometries

Concepts

Compositions of reflections
Identity, reflections, translations, rotations, and glide reflections
Groups of even isometries
Rotations about arbitrary centers
Compositions of rotations and translations
Sets of fixpoints and fixed lines
Conjugacy
Transforming coordinate systems
Conjugacy classes

In previous sections you've seen that all plane isometries have simple matrix equations, and you've studied some particular isometries, their matrices, and their relationships in considerable detail. Parts of these analyses aren't yet complete. For example, although you've seen that the sets of all translations and of all rotations about a point O form groups, you haven't studied in detail the compositions of translations and rotations, nor of rotations about different centers. This kind of work often involves analyzing an isometry with a complicated definition, to fit it into the pattern of this chapter: Is it the identity, a translation, rotation, reflection, or glide reflection? What is its vector or center or axis? You've already started using the appropriate tools, without much attention to them. This section organizes them. They are employed to solve the example problems just mentioned, and to study in detail another kind of relationship—conjugacy—that's used to analyze symmetries in chapter 8.

Classification

The structure theorem in section 6.6 displayed a preliminary classification. A plane isometry is

the identity, or
a reflection, or
a composition of reflections across two lines g and h, or
a composition of reflections across three lines g, h, and k.

These classes aren't disjoint, since $\iota = \sigma_g \sigma_g$ and $\sigma_g = \sigma_g \sigma_g \sigma_g$ for any g. Clearly, $\sigma_g \sigma_h$ is the identity only when $g = h$. And by corollaries 6.4.7 and 6.5.6 and theorem 6.7.2, $\sigma_g \sigma_h \sigma_k$ is a reflection just when g, h, and k are copencilar. Therefore, a slight modification of the language just displayed yields a classification with disjoint classes:

Theorem 1. A plane isometry is

(0) the identity, or
(1) a reflection, or
(2) a composition of reflections across two distinct lines, or
(3) a composition of reflections across three noncopencilar lines.

For the rest of this heading, use a fixed coordinate system with origin O. Theorem 1 permits further refinement:

Corollary 2. A plane isometry is

(0) the identity ι, or
(1) a reflection σ_g across a line g, or
(2a) a translation τ_V with vector $V \neq O$, or
(2b) a rotation ρ_θ with center O and $\theta \bmod 360° \neq 0°$, or
(3) a glide reflection $\sigma_g \tau_V$ with $V \neq O$.

You can often use fixpoint information effectively to identify an isometry. This table shows the fixpoint sets of the isometry classes in corollary 2:

Class	*Isometry*		*Fixpoint set*
(0)	ι		the entire plane
(1)	σ_g		the line g
(2a)	τ_V	with $V \neq O$	empty
(2b)	ρ_θ	with $\theta \bmod 360° \neq 0°$	the center O
(3)	$\sigma_g \tau_V$	with $V \neq O$	empty

In exercise 6.11.12 you can work out an analogous description of the sets of fixed lines. You'll find several examples of the use of fixpoint information later in this section.

Classes (0) and (2) together form the group of *even* isometries. Those in (1) and (3) are called *odd.* By theorem 6.8.3, you can tell whether an isometry is even or odd by ascertaining whether its *parity*—the determinant of its matrix—is +1 or -1.

Rotations and translations

The group of even isometries has some interesting subgroups. Corollary 6.4.3 showed that the translations constitute a subgroup. In chapter 8 a yet smaller one is used to analyze ornamental patterns: the group of all translations τ_{cV}, where V is a specified nonzero vector. This set forms a group because it's closed under composition and inversion, and contains the identity:

$$\tau_{cV}\tau_{dV} = \tau_{(c+d)V} \qquad \tau_{cV}^{-1} = \tau_{-(cV)} = \tau_{(-c)V} \qquad \iota = \tau_O = \tau_{0V}.$$

You can allow c and d to be any scalars, or restrict them to be integers. You get two different groups, depending on your choice.

Theorem 6.5.3 showed that the rotations about a specified center also form a subgroup. For those about the origin, you've seen that composition corresponds to addition of angle parameters: $\rho_\eta\rho_\theta = \rho_{\eta+\theta}$. This is also true for other centers. If $\varphi : X \rightarrow A_\eta X + B$ and $\chi : X \rightarrow A_\theta X + C$ are rotations about a center P with angle parameters η and θ, then

$$\begin{aligned}\varphi\chi(X) &= \varphi(A_\theta X + C) = A_\eta(A_\theta X + C) + B\\ &= A_\eta A_\theta X + A_\eta C + B = A_{\eta+\theta}X + A_\eta C + B,\end{aligned}$$

so $\varphi\chi$ has angle parameter $\eta + \theta$. It follows that φ^{-1} has parameter $-\eta$.

You can use the matrix representation of a rotation $\varphi : X \rightarrow A_\eta X + B$ with angle parameter η to analyze compositions of φ with other isometries. For example, if $\tau : X \rightarrow X + V$ is any translation, then

$$\begin{aligned}\varphi\tau(X) &= \varphi(X + V) = A_\eta(X + V) + B = A_\eta X + A_\eta V + B\\ \tau\varphi(X) &= \tau(A_\eta X + B) = A_\eta X + B + V,\end{aligned}$$

so $\varphi\tau$ and $\tau\varphi$ are both rotations with the same angle parameter η, unless φ was the identity. For another rotation $\chi : X \rightarrow A_\theta X + C$ you get

$$\varphi\chi(X) = \varphi(A_\theta X + C) = A_\eta(A_\theta X + C) + B = A_{\eta+\theta}X + A_\eta C + B.$$

As in the previous paragraph, $\varphi\chi$ is a rotation with parameter $\eta + \theta$, unless $A_{\eta+\theta}$ is the identity matrix, in which case $\varphi\chi$ is a translation. This proves

Theorem 3. The composition of a rotation that's not the identity with any translation is a rotation with the same angle parameter. The composition of rotations with parameters χ and ψ is a rotation with parameter $\eta + \theta$ unless $(\eta + \theta) \bmod 360° = 0°$. In that case, it's a translation.

You can use theorem 3 to derive the equation of a rotation ψ with angle parameter θ but unknown center P if you can find $B = \psi(O)$. Consider $\rho = \tau_{-B}\psi$; since $\rho(O) = O$, ρ is a rotation about O with angle parameter θ. You know its equation, and from $\psi = \tau_B\rho$ you can derive the equation for ψ.

Conjugacy

In section 6.8, the isometry $\rho_\theta\sigma_h\rho_\theta^{-1}$ played a major role in deriving the matrix equation for a reflection across an arbitrary line g through O. This pattern occurs so commonly, particularly in studying symmetry, that it's studied in detail. For any transformations μ and φ, the composition $\varphi\mu\varphi^{-1}$ is called the *conjugate of* μ *by* φ. When λ is a conjugate of μ, we write $\lambda \sim \mu$. The next two theorems present some basic properties of conjugacy. They're used frequently, without mention, in later discussions.

Theorem 4. Conjugacy is an equivalence relation. That is, for any λ, μ, and ν,

$$\begin{array}{ll} \mu \sim \mu & \text{(reflexivity)} \\ \lambda \sim \mu \leftrightarrow \mu \sim \lambda & \text{(symmetry)} \\ \lambda \sim \mu \ \& \ \mu \sim \nu \Rightarrow \lambda \sim \nu & \text{(transitivity).} \end{array}$$

Conjugate isometries have the same parity.

Proof. μ is its own conjugate by ι. If λ is the conjugate of μ by φ, then μ is the conjugate of λ by φ^{-1}. If λ is the conjugate of μ by φ and μ is the conjugate of ν by χ, then λ is the conjugate of ν by $\varphi\chi$:

$$\lambda = \varphi\mu\varphi^{-1} = \varphi\chi\nu\chi^{-1}\varphi^{-1} = (\varphi\chi)\nu(\varphi\chi)^{-1}.$$

Finally, if $\lambda = \varphi\mu\varphi^{-1}$, then $\operatorname{par}\lambda = \operatorname{par}\varphi \operatorname{par}\mu \operatorname{par}(\varphi^{-1}) = (\operatorname{par}\varphi)^2 \operatorname{par}\mu = \operatorname{par}\mu$, by corollary 6.8.4. ♦

The equivalence classes generated by the conjugacy relation are called *conjugacy classes*.

Theorem 5. The only transformation that's conjugate with the identity ι is ι itself. Now consider any transformations φ, χ, and ψ, and let χ' and ψ' denote the conjugates of χ and ψ by φ. Then

(a) $\chi'\psi'$ is the conjugate of $\chi\psi$ by φ,
(b) $(\chi')^{-1}$ is the conjugate of χ^{-1} by φ, and
(c) χ' and ψ' commute just in case χ and ψ commute.

Proof. First, $\varphi\iota\varphi^{-1} = \varphi\varphi^{-1} = \iota$. Moreover,

(a) $\varphi\chi\psi\varphi^{-1} = \varphi\chi\iota\psi\varphi^{-1} = \varphi\chi\varphi^{-1}\varphi\psi\varphi^{-1}$.

(b) $(\chi')^{-1} = (\varphi\chi\varphi^{-1})^{-1} = (\varphi^{-1})^{-1}\chi^{-1}\varphi^{-1} = \varphi\chi^{-1}\varphi^{-1}$.

(c) $$\begin{aligned}\chi'\psi' = \psi'\chi' &\leftrightarrow \varphi\chi\varphi^{-1}\varphi\psi\varphi^{-1} = \varphi\psi\varphi^{-1}\varphi\chi\varphi^{-1}\\ &\leftrightarrow \varphi\chi\psi\varphi^{-1} = \varphi\psi\chi\varphi^{-1}\\ &\leftrightarrow \chi\psi = \varphi^{-1}\varphi\psi\chi\varphi^{-1}\varphi\\ &\leftrightarrow \chi\psi = \psi\chi.\ \blacklozenge\end{aligned}$$

Transforming coordinate systems

The conjugacy concept is even more closely connected to the equations of isometries than the section 6.8 examples suggest. The connection is based on the idea of transforming a coordinate system $\mathscr{C}$. All you need to describe $\mathscr{C}$ is the isosceles right triangle ΔOU_1U_2 in figure 6.9.1 that consists of the origin O and the axis points U_1 and U_2 with coordinate 1. An isometry φ transforms $\mathscr{C}$ into another system $\mathscr{D}$ defined by the image ΔPV_1V_2 of ΔOU_1U_2. What if you use *both* coordinate systems—for instance, to study different aspects of some geometric figure? How are a point's $\mathscr{C}$ and $\mathscr{D}$ coordinates related? Theorem 6 answers that question, and theorem 7 connects these considerations with conjugacy.

Theorem 6. If an isometry φ transforms coordinate system $\mathscr{C}$ into system $\mathscr{D}$, then the $\mathscr{C}$ coordinates of each point X are the same as the $\mathscr{D}$ coordinates of $Y = \varphi(X)$.

Proof. Consider figure 6.9.1. The figure formed by ΔOU_1U_2 and X is congruent to that formed by ΔPV_1V_2 and Y. ♦

Theorem 7. Isometries χ and ψ are conjugate if and only if there are coordinate systems under which they have the same matrix equation.

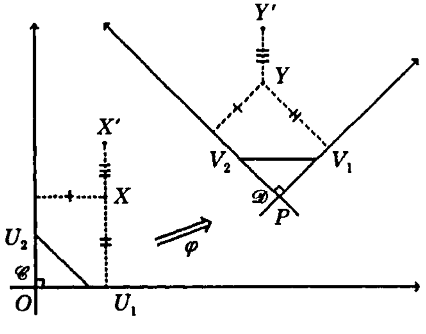

Figure 6.9.1
Transforming a coordinate system

Proof. Consider coordinate systems $\mathscr{C}$ and $\mathscr{D}$, points X and Y, and an isometry φ as in theorem 6. Suppose $\chi : X \to X'$ has equation $X' = AX + B$ with respect to $\mathscr{C}$. *Important: This equation treats X and X' as vectors of $\mathscr{C}$ coordinates!* By theorem 6, the $\mathscr{C}$ coordinates of X' are the same as the $\mathscr{D}$ coordinates of $Y' = \varphi(X')$. Thus

$$\begin{aligned} X' = AX + B &\leftrightarrow X' = \chi(X) \\ &\leftrightarrow \varphi^{-1}(Y') = \chi\varphi^{-1}(Y) \\ &\leftrightarrow Y' = \varphi\chi\varphi^{-1}(Y). \end{aligned}$$

If $\psi = \varphi\chi\varphi^{-1}$, then $X' = AX + B \leftrightarrow Y' = \psi(Y)$. Since the $\mathscr{D}$ coordinates of Y and Y' are the same as the $\mathscr{C}$ coordinates of X and X', you can conclude that

$$Y' = AY + B \leftrightarrow Y' = \psi(Y)$$

when you regard Y and Y' in the left-hand equation as vectors of $\mathscr{D}$ coordinates.

Conversely, suppose χ and ψ have the same equation with respect to coordinate systems $\mathscr{C}$ and $\mathscr{D}$. By theorem 6.6.3, $\mathscr{C}$ and $\mathscr{D}$ are related by an isometry φ as in figure 6.9.1. Since the $\mathscr{C}$ coordinates of X and X' are the same as the $\mathscr{D}$ coordinates of Y and Y',

$$\begin{array}{lclcl} X' = AX + B & \leftrightarrow & Y' = AY + B & \leftrightarrow & Y' = \psi(Y). \\ \text{with } X \text{ and } X' & & \text{with } Y \text{ and } Y' & & \\ \text{interpreted} & & \text{interpreted} & & \\ \text{as vectors of} & & \text{as vectors of} & & \\ \mathscr{C} \text{ coordinates} & & \mathscr{D} \text{ coordinates} & & \end{array}$$

But the first paragraph of this proof guaranteed $X' = AX + B \leftrightarrow Y' = \varphi\chi\varphi^{-1}(Y)$. Therefore $\psi(Y) = \varphi\chi\varphi^{-1}(Y)$ for all Y; having the same equation implies conjugacy. ♦

You now have *two* proofs of theorem 4; the word *same* in theorem 7 makes it *obvious* that conjugacy is an equivalence relation!

Conjugacy classes

By theorem 7, the half turns about any two points O and P are conjugate; with respect to coordinate systems with origins O and P, each has matrix form $X \to X' = -X$. By theorem 6.8.2, no other isometries have equations of this form, so the half turns constitute a single conjugacy class. But this result doesn't give complete information about the conjugate $\chi = \varphi\sigma_P\varphi^{-1}$ of σ_P by an isometry φ. Even without theorem 7, you can conclude that it's a half turn; χ is even and self-inverse. You can classify it completely by fixpoint analysis:

X is a fixpoint of χ
$\leftrightarrow \varphi\sigma_P\varphi^{-1}(X) = X$
$\leftrightarrow \sigma_P\varphi^{-1}(X) = \varphi^{-1}(X)$
$\leftrightarrow \varphi^{-1}(X)$ is a fixpoint of σ_P
$\leftrightarrow \varphi^{-1}(X) = P$
$\leftrightarrow X = \varphi(P)$.

Thus $\chi = \varphi\sigma_P\varphi^{-1} = \sigma_{\varphi(P)}$ because χ has exactly one fixpoint, $\varphi(P)$.

You can just as easily analyze reflections. By theorem 7, reflections across any two lines g and h are conjugate; with respect to coordinate systems with first axes g and h, each has the matrix form

$$X \to X' = \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix} X.$$

By theorem 6.8.2, no other isometries have equations of this form, so the reflections constitute a single conjugacy class. Again, this result doesn't give complete information about the conjugate $\psi = \varphi\sigma_g\varphi^{-1}$ of σ_g by an isometry φ. You can classify it completely by fixpoint analysis:

X is a fixpoint of ψ
$\leftrightarrow \varphi\sigma_g\varphi^{-1}(X) = X$
$\leftrightarrow \sigma_g\varphi^{-1}(X) = \varphi^{-1}(X)$
$\leftrightarrow \varphi^{-1}(X)$ is a fixpoint of σ_g
$\leftrightarrow \varphi^{-1}(X)$ lies on g
$\leftrightarrow X$ lies on the image set $\varphi[g]$.

The fixpoints of ψ constitute the line $\varphi[g]$, so ψ must be the reflection across that line. That is, $\varphi\sigma_g\varphi^{-1} = \sigma_{\varphi[g]}$. This paragraph and the previous one have proved

Theorem 8. The half turns constitute a single conjugacy class. Moreover, $\varphi\sigma_P\varphi^{-1} = \sigma_{\varphi(P)}$ for any point P and any isometry φ. Similarly, the reflections constitute a single conjugacy class, and $\varphi\sigma_g\varphi^{-1} = \sigma_{\varphi[g]}$ for any line g and any isometry φ.

Analyzing translations is a little more complicated. Consider a point O and translations τ and υ; let

$$T = \tau(O) \qquad t = OT$$
$$U = \upsilon(O) \qquad u = OU.$$

By theorem 7, τ and υ are conjugate just in case $t = u$. With respect to coordinate systems with origin O and with T and U on the positive rays of the first axes, they have matrix forms

$$X \to X' = X + \begin{bmatrix} t \\ 0 \end{bmatrix} \qquad X \to X' = X + \begin{bmatrix} u \\ 0 \end{bmatrix},$$

and these are the same just in case $t = u$. Theorem 9 provides complete information about the conjugate $\upsilon = \varphi\tau\varphi^{-1}$ of τ by an isometry φ:

Theorem 9. The conjugacy class of a translation τ whose vector has length t consists of all translations with vectors of that length. If τ and an isometry φ have equations $\tau: X \to X' = X + T$ and $\varphi: X \to X' = AX + B$ with respect to a single coordinate system, then $\upsilon = \varphi\tau\varphi^{-1}$ is the translation with vector AT.

Proof. The second sentence remains to be proved. Since $X = A^{-1}X' - A^{-1}B$, it follows that φ^{-1} has matrix form $X \to A^{-1}X - A^{-1}B$ and

$$\begin{aligned} \upsilon(X) &= \varphi\tau\varphi^{-1}(X) = \varphi\tau(A^{-1}X - A^{-1}B) = \varphi(A^{-1}X - A^{-1}B + T) \\ &= A(A^{-1}X - A^{-1}B + T) + B = X + AT. \blacklozenge \end{aligned}$$

The final results of this section provide analogous information for glide reflections and rotations. Their proofs differ. The argument for theorem 10 can use the concise techniques of function composition. But theorem 11 uses matrix computation, because that's convenient for handling angle parameters.

Theorem 10. Choose a coordinate system. The conjugacy class of a glide reflection χ with axis g and vector V consists of all glide reflections with vectors whose length is the same as that of V. The conjugate of χ by an isometry $\varphi: X \to X' = AX + B$ is the glide reflection with axis $\varphi[g]$ and vector AV.

Proof. Find points O and P on g with $V = P - O$, so that $\tau_V = \sigma_O\sigma_P$ and $\chi = \sigma_g\tau_V$. If φ is an isometry, then by theorems 8 and 9,

$$\varphi\chi\varphi^{-1} = \varphi\sigma_g\varphi^{-1}\varphi\tau_V\varphi^{-1} \qquad \varphi\sigma_g\varphi^{-1} = \sigma_{\varphi[g]} \qquad \varphi\tau_V\varphi^{-1} = \tau_{AV}.$$

Define $O' = \varphi(O)$, $P' = \varphi(P)$, and $V' = P' - O'$, so that O' and P' lie on $\varphi[g]$ and

$$\varphi\tau_V\varphi^{-1} = \varphi\sigma_O\varphi^{-1}\varphi\sigma_P\varphi^{-1} = \sigma_{O'}\sigma_{P'} = \tau_{V'}.$$

Thus $\varphi\chi\varphi^{-1}$ is the glide reflection with axis $\varphi[g]$ and vector V'.

Conversely, assuming that ψ is a glide reflection with axis g' whose vector V' has the same length as V, find points O' and P' on g' with $V' = P' - O'$, so that $\tau_{V'} = \sigma_{O'}\sigma_{P'}$ and $\psi = \sigma_{g'}\tau_{V'}$. By theorem 6.6.3, there's an isometry φ such that $\varphi(O) = O'$ and $\varphi(P) = P'$. It follows that $\varphi[g] = g'$. Then

$$\begin{aligned}
\sigma_{g'} &= \sigma_{\varphi[g]} = \varphi\sigma_g\varphi^{-1}\\
\tau_{V'} &= \sigma_{\varphi(O)}\sigma_{\varphi(P)} = \varphi\sigma_O\varphi^{-1}\varphi\sigma_P\varphi^{-1} = \varphi\sigma_O\sigma_P\varphi^{-1} = \varphi\tau_V\varphi^{-1}\\
\psi &= \varphi\sigma_g\varphi^{-1}\varphi\tau_V\varphi^{-1} = \varphi\sigma_g\tau_V\varphi^{-1} = \varphi\chi\varphi^{-1}. \ \blacklozenge
\end{aligned}$$

Theorem 11. Suppose χ is a rotation, not the identity, with angle parameter θ and center P. Its conjugate by an isometry φ is a rotation ψ with center $\varphi(P)$. Moreover, ψ has angle parameter θ or $-\theta$, depending on whether φ is even or odd.

Proof. $\psi = \varphi\chi\varphi^{-1}$ is a rotation with center $\varphi(P)$ because that's its only fixpoint:

$$\varphi\chi\varphi^{-1}(X) = X \leftrightarrow \chi\varphi^{-1}(X) = \varphi^{-1}(X) \leftrightarrow \varphi^{-1}(X) = P \leftrightarrow X = \varphi(P).$$

Suppose φ is even. From the matrix representations $\varphi : X \to A_\eta X + B$ and $\chi : X \to A_\theta X + C$, you get

$$\begin{aligned}
\varphi\chi\varphi^{-1}(X) &= A_\eta A_\theta A_\eta^{-1} X + \text{a constant vector}\\
&= A_\eta A_\theta A_{-\eta} X + \cdots\\
&= A_{\eta+\theta-\eta} X + \cdots\\
&= A_\theta X + \cdots,
\end{aligned}$$

so $\varphi\chi\varphi^{-1}$ is a rotation with parameter θ.

Now suppose ω is an odd isometry. Consider the even isometry $\varphi = \sigma_h\omega$, where h is the first axis. Then $\varphi\chi\varphi^{-1}$ is a rotation ρ with parameter θ:

$$\begin{aligned}
&\rho = (\sigma_h\omega)\chi(\sigma_h\omega)^{-1} = \sigma_h\omega\chi\omega^{-1}\sigma_h^{-1} = \sigma_h(\omega\chi\omega^{-1})\sigma_h\\
&\sigma_h\rho\sigma_h = \omega\chi\omega^{-1}.
\end{aligned}$$

From the matrix equation $\rho : X \to A_\theta X + B$, you see that

$$\omega\chi\omega^{-1}(X) = HA_\theta HX + \text{a constant vector,}$$

where H is the matrix corresponding to the reflection σ_h. Thus

$$H = \begin{bmatrix} 1 & 0\\ 0 & -1 \end{bmatrix}$$

$$\begin{aligned}
HA_\theta H &= \begin{bmatrix} 1 & 0\\ 0 & -1 \end{bmatrix}\begin{bmatrix} \cos\theta & -\sin\theta\\ \sin\theta & \cos\theta \end{bmatrix}\begin{bmatrix} 1 & 0\\ 0 & -1 \end{bmatrix}\\
&= \begin{bmatrix} \cos\theta & -\sin\theta\\ -\sin\theta & -\cos\theta \end{bmatrix}\begin{bmatrix} 1 & 0\\ 0 & -1 \end{bmatrix} = \begin{bmatrix} \cos\theta & \sin\theta\\ -\sin\theta & \cos\theta \end{bmatrix}\\
&= \begin{bmatrix} \cos(-\theta) & -\sin(-\theta)\\ \sin(-\theta) & \cos(-\theta) \end{bmatrix} = A_{-\theta}.
\end{aligned}$$

Therefore, $\omega\chi\omega^{-1}$ is a rotation with parameter $-\eta$. ♦

Corollary 12. Rotations with angle parameters η and θ are conjugate just in case $|\eta \bmod 360°| = |\theta \bmod 360°|$.

You can use theorem 11 to derive the equation of a rotation ψ with center P, as follows. Let ρ be the rotation about the origin with the same angle parameter, and let $\varphi = \tau_P$, so that $\psi = \varphi\rho\varphi^{-1}$. The equations of φ, ρ, and φ^{-1} are easy to find, and from those you derive the equation for ψ.

6.10 Similarities

Concepts

Similarities and their ratios
Contractions and dilations
Invariants
Similarity group
Uniqueness theorem
Classification theorem
Equation $X' = rAX + B$ of a similarity
Fixpoint theorem
Homothetic rotations and reflections
Even and odd similarities

Studying geometric transformations more general than isometries usually requires methods beyond those developed in this chapter. But one broader family of transformations, the similarities, needs little new. Let r be a positive real number. A *plane similarity with ratio* r is a plane transformation $\psi : P \to P'$ such that for all points P and Q,

$$P'Q' = r\,(PQ).$$

A similarity can't have two *different* ratios because $r\,(PQ) = r'\,(PQ)$ and $P \neq Q$ imply $r = r'$; so it makes sense to call r *the* ratio of ψ.

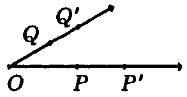

Figure 6.10.1 Dilation about O with ratio r

$$r = 1.7 \qquad OP' = r\,(OP)$$
$$OQ' = r\,(OQ)$$

Evidently, every isometry is a similarity with ratio 1. As another example, select any point O and consider the transformation $\varphi_{r,O} : P \rightarrow P'$ such that $O' = O$ and for $P \neq O$, P' is the point on $\overrightarrow{OP}$ with $OP' = r\,(OP)$. (See figure 6.10.1.) If O is the origin of a Cartesian coordinate system, so that you can regard points as vectors, then $P' = rP$ for every point P. If $r < 1$ or $r > 1$, then $\varphi_{r,O}$ is called a *contraction* or *dilation about* O.[22]

Theorem 1. $\varphi_{r,O}$ is a similarity with ratio r.

Proof. By theorem 3.11.2,

$$\begin{aligned}(P'Q')^2 &= (P' - Q')\cdot(P' - Q') = (rP - rQ)\cdot(rP - rQ)\\ &= r^2(P - Q)\cdot(P - Q) = r^2(PQ)^2. \blacklozenge\end{aligned}$$

You'll see soon, in the classification theorem, that *every* similarity is an isometry or the composition of an isometry with a dilation or contraction. That's why there's not much new in this section. First, though, theorems 2 and 3 record some general properties of similarities that you'll need for this analysis.

Theorem 2. A similarity $\psi : X \rightarrow X'$ with ratio r leaves angle measure and betweenness invariant. Thus any geometric property that you can define in terms of betweenness is invariant. In particular, ψ is a collineation. The image of a circle with radius t is a circle with radius rt. The image of a triangle with area s is a triangle with area $r^2 s$.

Proof. The equation $m\angle XYZ = m\angle X'Y'Z'$ follows from the SSS similarity principle. For betweenness, proceed as in the proof of theorem 6.2.5, taking into account ratio r:

$$\begin{aligned}X\text{-}Y\text{-}Z &\leftrightarrow XY + YZ = XZ\\ &\leftrightarrow r\,(XY) + r\,(YZ) = r\,(XZ)\\ &\leftrightarrow X'Y' + Y'Z' = X'Z'\\ &\leftrightarrow X'\text{-}Y'\text{-}Z'.\end{aligned}$$

If O is the center of circle Γ with radius t, then a point X lies on Γ if and only if $OX = t$. This condition is equivalent to $O'X' = rt$, so X lies on Γ if and only if X' lies on the circle with center O' and radius rt. The area result follows from theorem 3.9.7. ♦

Theorem 3. A composition of similarities with ratios r and s is a similarity with ratio rs. The inverse of a similarity with ratio r is a similarity with ratio r^{-1}. Therefore, the similarities form a transformation group that contains all isometries.

---

[22] Many authors also use the term *dilation* when $r < 1$. That jars, so this text uses *contraction* in that case. Don't confuse *dilation* with *dilatation*; the latter term has a different meaning —see the heading Dilatations in section 6.11.

Proof. If $P \to P'$ and $P' \to P''$ are similarities with ratios s and r, then for all points P and Q, $P''Q'' = r\,(P'Q') = rs\,(PQ)$, so the composition $P \to P''$ is a similarity with ratio rs. Moreover, $PQ = r^{-1}r(PQ) = r^{-1}(P'Q')$, so the inverse transformation $P' \to P$ is a similarity with ratio r^{-1}. ♦

Corollary 4 ***(Uniqueness theorem).*** Plane similarities χ and ψ coincide if $\chi(X) = \psi(X)$ for three noncollinear points X.

Proof. Suppose χ and ψ have ratios r and s, points X_1 and X_2 are distinct, $\chi(X_1) = \psi(X_1)$, and $\chi(X_2) = \psi(X_2)$. Then $r\,(X_1X_2) = \chi(X_1)\chi(X_2) = \psi(X_1)\,\psi(X_2) = s\,(X_1X_2)$, hence $r = s$. Since its ratio is $r/s = 1$, the similarity $\varphi = \chi\psi^{-1}$ is an isometry. Since φ fixes three noncollinear points, it's the identity, by theorem 6.2.7. ♦

Lemma 5 is a preliminary version of theorem 8. It's introduced now, to facilitate use of the equation of a similarity in the final version of theorem 8.

Lemma 5. Given any point O and any similarity ψ with ratio r, there's an isometry χ such that $\psi = \chi\varphi_{r,O}$.

Proof. The composition $\chi = \psi\varphi_{r,O}^{-1}$ is a similarity with ratio $rr^{-1} = 1$, hence it's an isometry. Moreover, $\psi = \chi\varphi_{r,O}$. ♦

Theorem 6. The similarities are the transformations $X \to X' = rAX + B$ where $r > 0$, A is an orthogonal matrix, and B an arbitrary vector. The transformation determines r, A, and B uniquely; r is the similarity ratio.

Proof. Every such equation defines a similarity: the composition of the isometry $X \to AX + B$ with $\varphi_{r,O}$. On the other hand, given a similarity $\psi : X \to X'$, lemma 5 provides an isometry χ such that $\psi = \chi\varphi_{r,O}$. By theorem 6.8.2 there's an orthogonal matrix A and a vector B such that $\chi(X) = AX + B$ for all X, so that ψ has the desired equation. If equations $X' = rA_1X + B_1$ and $X' = sA_2X + B_2$ represented the same transformation, it would be a similarity with ratio $r = s$. But then the transformation $X \to X'' = r^{-1}X'$ would be an isometry with equations $X'' = A_1X + r^{-1}B_1$ and $X'' = A_2X + r^{-1}B_2$, so $A_1 = A_2$ and $r^{-1}B_1 = r^{-1}B_2$ by theorem 6.8.2, hence $B_1 = B_2$. ♦

Theorem 7 ***(Fixpoint theorem).*** If $\psi : X \to X'$ is a similarity with ratio r, then $r = 1$ or ψ has exactly one fixpoint.

Proof. First consider the case $r < 1$. Select any point X_0 and define points $X_1, X_2, \ldots$ by the rule $X_{m+1} = X'_m$. Then

$$\begin{aligned} X_1X_2 &= X_0'X_1' = r\,(X_0X_1), \\ X_2X_3 &= X_1'X_2' = r\,(X_1X_2) = r^2\,(X_0X_1), \\ &\vdots \end{aligned}$$

so in general,

$$X_mX_{m+1} = r^m\,(X_0X_1).$$

Now let $m < n$ and consider the ith coordinates x_{mi} and x_{ni} of points X_m and X_n:

$$\begin{aligned} |x_{mi} - x_{ni}| &\le X_mX_n \le X_mX_{m+1} + X_{m+1}X_{m+2} + \cdots + X_{n-1}X_n \\ &= r^m\,(X_0X_1) + r^{m+1}\,(X_0X_1) + \cdots + r^n\,(X_0X_1) \\ &= r^m\,(1 + r + \cdots + r^{n-m})(X_0X_1). \end{aligned}$$

The sum in parentheses is the initial part of a convergent geometric series, so

$$|x_{mi} - x_{ni}| \le r^m\left(\sum_{n=0}^{\infty} r^n\right)(X_0X_1) = \frac{r^m\,(X_0X_1)}{1-r}.$$

Since $\lim_m r^m = 0$, you can make $|x_{mi} - x_{ni}|$ arbitrarily small by taking m sufficiently large and $n > m$. That is, $x_{0i}, x_{1i}, x_{2i}, \ldots$ is a Cauchy sequence; it has a limit x_i. Let X be the vector whose ith component, for each i, is x_i. Then X is a fixpoint. To see that, use the equation $X' = rAX + B$ provided by theorem 6:

$$\begin{aligned} i\text{th component of } X' &= i\text{th component of } rAX + B \\ &= (\textstyle\sum_j r a_{ij} x_j) + b_i \\ &= (\textstyle\sum_j r a_{ij} \lim_n x_{nj}) + b_i \\ &= (\lim_n \textstyle\sum_j r a_{ij} x_{nj}) + b_i \\ &= \lim_n ((\textstyle\sum_j r a_{ij} x_{nj}) + b_i) \\ &= \lim_n (i\text{th component of } rAX_n + B) \\ &= \lim_n (i\text{th component of } X_n') \\ &= \lim_n (i\text{th component of } X_{n+1}) \\ &= \lim_n x_{n+1,i} = x_i = i\text{th component of } X. \end{aligned}$$

Thus $X' = X$, as claimed.

Now consider the case $r > 1$. Since ψ^{-1} is a similarity with ratio < 1, it has a fixpoint X by the preceding paragraph. But then X is a fixpoint of ψ, too.

Finally, to prove uniqueness, suppose $r \ne 1$ and ψ has fixpoints X and Y. Then $X'Y' = r\,(XY) = r\,(X'Y')$, so $X'Y' = 0$, $X' = Y'$, and $X = Y$. ◆

The Cauchy sequence technique for proving the fixpoint theorem has a flavor different from that of the rest of this book. The only other part based on limits is the discussion of π in section 3.14. Cauchy sequences occur frequently in real analysis. In fact, similarities with ratio $r < 1$ are examples of the *contraction mappings* that you study in analysis: mappings such that $X'Y' \le r\,(XY)$ for all X and Y. And the proof of the fixpoint theorem is just an adaptation of a familiar proof of the contraction mapping theorem. That result[23] —*every* contraction mapping has a fixpoint—has several major applications. For example, it establishes the convergence of various iterative approximation methods such as the Newton–Raphson technique, and it implies the existence of solutions to first-order ordinary differential equations satisfying Lipschitz conditions. You can prove the fixpoint theorem without using analysis methods, but that proof will be less succinct, and may require different arguments for two and three dimensions.[24]

Compositions $\chi\varphi_{r,O}$ where χ is a rotation about O or a reflection across a line through O are called *homothetic rotations* or *reflections.*[25]

Theorem 8 ***(Classification theorem).*** A plane similarity is an isometry, a homothetic rotation, or a homothetic reflection.

Proof. By the fixpoint theorem, if a similarity ψ isn't an isometry, then it has a fixpoint O. Let r be its ratio, and define $\chi = \psi\varphi_{r^{-1},O}$, so that $\psi = \chi\varphi_{r,O}$. Then χ is an isometry with fixpoint O'. By the discussion following corollary 6.9.2, it's a rotation about O' or a reflection across a line g through O'. ♦

A similarity $\psi : X \to X' = rAX + B$ with $r > 0$ preserves orientation just in case the isometry $\chi : X \to AX + B$ does—that is, just in case $\det A = 1$. To see this, note that for any points P, Q, and R,

$$\begin{aligned}
&\det[P' - R', Q' - R'] \\
&\quad = \det[(rAP + B) - (rAR + B), (rAQ + B) - (rAR + B)] \\
&\quad = \det[rA(P - R), rA(Q - R)] \\
&\quad = (\det rA)\det[P - R, Q - R] \\
&\quad = r^2(\det A)\det[P - R, Q - R].
\end{aligned}$$

ψ is called *even* if orientation is preserved; *odd* if it's reversed.

---

[23] See Bartle 1964, 170 for the contraction mapping theorem.

[24] See Exercises 6.11.41–44 and Martin 1982, 141.

[25] *Homothetic* stems from the Greek prefix *homo-* and verb *tithenai,* which mean *same* and *put.* It's the opposite of *antithetic.*

6.11 Exercises

Concepts

- Curved mirrors
- Classifying isometries defined as compositions or by equations
- Constructions with isometries and similarities
- Billiards and dual billiards problems
- Equations of reflections
- Determining equations of isometries and similarities
- Coordinate transformations
- *Alias* and *alibi* interpretations of equations
- Reflection calculus
- Distance-preserving functions
- Dilatations

This section contains forty-five exercises related to earlier parts of the chapter. Like other exercises in this book, they're essential components of its development. A few—for example, exercises 1, 5, and 12—provide more experience with reasoning techniques introduced earlier. Others, particularly those on the classification and the equations of isometries, show you how to do the computations required to use the theorems derived in the text. The theory is streamlined into an efficient outline of the results important for applications. But those computations seem unwieldy at first. That would obscure the main points of the theory, so the computations are clustered here. Some may require awkward matrix arithmetic. There was no effort to avoid that. If you find a calculation too tedious, use mathematical software.[26]

This chapter's theory is often applied to analytic geometry problems. That work usually has a different flavor because it uses *coordinate* transformations. Those apply to the numbers used to locate points, not to the points themselves, like geometric transformations here. Exercise 31 shows how to make the transition. A few exercises introduce topics that could be developed much further. Those on reflection calculus, and on dilatations, for example, lead into deep studies in foundations of geometry. Chapter 7 extends the theory of isometries and similarities to three dimensions. Most of the exercises in this section can be extended as well. You'll see that in section 7.7.

Basic exercises

Exercises 1 and 2 present some important properties that apply to transformations in general, not just those in geometry. For instance, exercise 2, part 1, asks what you can say about functions φ and χ whose composition is surjective, and what you can *not* say, in general. To show that you can *not* claim that φ or χ has some property $\mathscr{P}$, you must provide a *counterexample*: specific functions whose composition is surjective, but for which $\mathscr{P}$ is not true. Searching for counterexamples for exercise 2, you should concentrate on functions whose domains and ranges are *very small* finite sets. You won't need more than that to make the required properties fail, and you'll avoid confusion by other phenomena that are really irrelevant. That kind of reasoning may seem nongeometric to you, but no—those tiny counterexamples are always contained in the larger ones that may seem closer to geometry, and they're much easier to understand.

---

[26] *X(Plore)* (Meredith 1993) is a good choice.

Exercise 1. Prove that two self-inverse transformations of a set D commute if and only if their composition is self-inverse.

Exercise 2. Consider functions $\varphi : S \to T$ and $\chi : D \to S$, so that $\varphi\chi : D \to T$.

Part 1. Prove that if $\varphi\chi$ is surjective, then φ must be surjective. Find an example where $\varphi\chi$ is surjective, but χ is neither surjective nor injective.

Part 2. Prove that if $\varphi\chi$ is injective, then χ must be injective. Find an example where $\varphi\chi$ is injective, but φ is neither injective nor surjective.

Part 3. Prove that if $\varphi\chi$ is bijective, then φ must be surjective and χ injective. Find an example where $\varphi\chi$ is bijective, but neither φ nor χ is.

Exercises 3 and 4 present some fundamental facts about linear functions. It wasn't necessary to state them in the text of chapter 6 or 7 because all linear functions considered there are isometries or similarities, and for those function classes these facts are evident. Had chapter 6 introduced isometries through their equations, however, the results in these exercises would have been incorporated in the text before that point. To prove them, use appendix C material about Gauss elimination, matrix invertibility, and determinants.

Exercise 3. Consider a matrix A, a vector B, and the linear function $X \to AX + B$ that maps $\mathbb{R}^n$ to itself, where $n = 2$ or 3. Show that these conditions are equivalent:

(a) A is invertible,
(b) $X \to AX + B$ is bijective,
(c) $X \to AX + B$ is injective,
(d) $X \to AX + B$ is surjective.

Exercise 4. Let $n = 2$ or 3. Show that the range of a linear function $X \to AX + B$ that maps $\mathbb{R}^n$ to itself is a point, line, plane, or the entire space. In which cases is φ bijective? *Suggestion*: First consider the function $\varphi : X \to AX$.

Theorem 6.6.3 shows that you can map any triangle onto any congruent one with an isometry; the uniqueness theorem, corollary 6.2.8, says that you can do that in only one way. The latter statement requires you to regard a triangle as an *ordered* triple of vertices. You'd lose the uniqueness if you defined a triangle as a mere *set* of vertices or as its boundary—the union of its edges—for there are several isometries that map the set of vertices and the boundary of an equilateral triangle onto themselves. You'll see much more detail on these considerations in chapter 8. In exercise 5 you can study the same question for a simpler example, a segment. As defined in section 3.2, a segment is the *set* of points between its vertices, *not* an ordered pair of vertices.

Exercise 5. Show that if Σ and Υ are segments of the same length, then there's a rotation ρ such that $\rho[\Sigma] = \Upsilon$. Could there be *another* isometry φ such that $\varphi[\Sigma] = \Upsilon$? Could there be another *rotation*?

At the beginning of section 6.3 you saw how to find the shortest path from one point to another via a point on a mirror line g by reflecting one of the points across g. And you saw how this relationship corresponds to the equality of incidence and reflection angles. Exercise 6 shows that the relationship holds for a smoothly curved mirror as well. You need differential calculus to work with the curve.

Exercise 6. Consider a smooth curve Γ and points A and B not on Γ. (See figure 6.11.1.) Suppose point O lies on Γ and

$$AO + OB \leq AX + XB$$

for every point X on Γ. Let g be the tangent to Γ at O and select points U and V on g such that U-O-V. Prove that $\angle UOA \cong \angle VOB$. *Suggestion*: Use a coordinate system with first axis g and origin O. Since Γ is smooth, there's a differentiable function f on an open interval $\mathscr{I}$ containing 0 such that for any $x_1 \in \mathscr{I}$, a point $X = \langle x_1, x_2 \rangle$ lies on Γ just in case $x_2 = f(x_1)$.

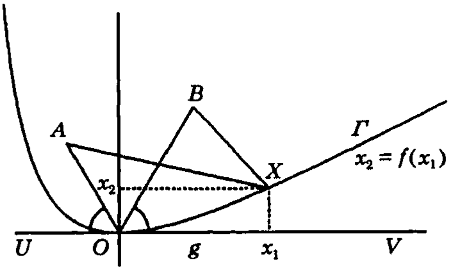

Figure 6.11.1
Exercise 6

The next exercise invites you to use a technique from section 6.3 to derive Fagnano's theorem, a morsel of triangle geometry mentioned in section 5.8.

Exercise 7. Show that of all triangles with vertices X, Y, and Z on the edges of an acute ΔABC, the orthic triangle has the shortest perimeter. *Suggestion*: Show first that for a given X on $\overline{BC}$ the shortest $XY + YZ + ZX$ is $\sigma_{\overleftrightarrow{AB}}(X)\,\sigma_{\overleftrightarrow{CA}}(X) = 2(AX)\sin \mathrm{m}\angle A$.

Classifying Isometries

Most exercises under this heading ask you to classify an isometry. That means decide whether it's the identity or one of these types of isometries, and provide the information in the right-hand column:

For a	*provide*
reflection	axis
translation	vector
rotation	center and an angle parameter
glide reflection	axis and vector.

Exercises 8 and 9 are aperitifs—you'll use this classification to verify some properties of isometries in general.

Exercise 8. Show that an isometry φ is even if and only if $\varphi = \chi\chi$ for some isometry χ.

Exercise 9. Show that every plane isometry is the composition of two self-inverse isometries.

Exercise 10. Prove a result like theorem 6.9.3 by continuing the proofs of corollaries 6.5.7 and 6.5.8 and analyzing the angles formed by the lines mentioned there, without referring to any equations of transformations. *Suggestion*: Be careful about the *signs* of the angle parameters. You don't need to get precisely the same result as the theorem. It was postponed from section 6.5 to section 6.9 because consistent assignment of angle parameters for different centers is so hard to describe.

Exercise 11 presents a nearly obvious result that you may use in several later exercises to find the axis of a glide reflection.

Exercise 11. Show that the axis of a glide reflection $\varphi : X \to X'$ consists of the midpoints of all segments $\overline{XX'}$.

Exercise 12. Construct a table analogous to the one following corollary 6.9.2, to show the possible sets of lines that are fixed by the various isometries. A fixed line might or might not consist entirely of fixed points. Lines that do are called *pointwise* fixed. What isometries have pointwise fixed lines? What isometries have fixed lines, *no* point of which is fixed?

The remaining exercises under this heading and some later ones require you to classify various isometries according to the scheme presented earlier. The main tools available are their fixpoints and parity—discussed in earlier sections—and exercises 11 and 12. *Use those tools!*

Exercise 13. Let $V_1V_2\cdots V_n$ be a convex polygon and $\theta_1, \theta_2, \ldots, \theta_n$ be the measures of the corresponding vertex angles. At each vertex V_i draw arc $\widehat{A_iB_i}$ with measure θ_i and radius $V_iA_i = V_iB_i$ small enough that no two of these arcs intersect. (See figure 6.11.2 for an example with $n = 4$.) Consider translations

τ_1 with vector $\overrightarrow{B_1A_2}$
τ_2 with vector $\overrightarrow{B_2A_3}$
$\vdots$ $\vdots$
τ_n with vector $\overrightarrow{B_nA_1}$

and for $i = 1, \ldots, n$ consider rotation ρ_i with center V_i and angle parameter θ_i. Classify the isometry $\tau_n\rho_n\tau_{n-1}\rho_{n-1}\cdots\tau_1\rho_1$.[27]

Exercise 14. Classify the composition of glide reflections with perpendicular axes g and h and vectors V and W.

Exercise 15. Classify the compositions of the reflection across the first coordinate axis and the translation with vector $<1, 2>$, in both orders.

Exercise 16. Let a, b, and c denote the lines containing the edges opposite vertices A, B, and C of ΔABC. Let D, E, and F denote the feet of

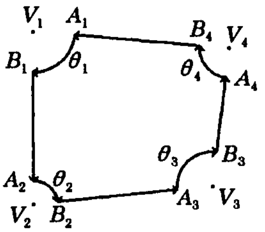

Figure 6.11.2
Exercise 13

---

[27] This exercise is due to Lawrence Levy (1970, 32).

the corresponding altitudes. Show that D and F lie on the axis of $\varphi = \sigma_a\sigma_b\sigma_c$. Classify φ when

(a) $m\angle A = m\angle B = 60°$ (c) $m\angle A = m\angle C = 45°$
(b) $m\angle A = m\angle B = 45°$ (d) $m\angle A = 30°$ and $m\angle C = 90°$.

Constructions

Following a more traditional approach to geometry, you'd have paid more attention to constructing the objects under study—probably with tools limited to straightedge and compasses. In fact, Euclid's axiomatization is sometimes viewed as a study of just those constructions, rather than of the space in which we live. This text has avoided them because they're no longer in the mathematical mainstream. The next seven exercises, however, merge transformational geometry into the older stream.[28] Each can be solved by traditional methods with no reference to transformations, but the isometries and similarities you've studied in this chapter shed more light on them. And if you seek the *simplest* constructions with straightedge and compasses, transformations may point the way.

Exercise 17. Suppose you want to carom ball A off the back, right, and front walls g, h, and k of a billiards table, to strike ball B, as in figure 6.11.3. How do you find the point P on g at which you must aim? *Suggestion*: Try more modest coups first.

Exercise 18. Consider nonparallel lines $g \nparallel h$ and three points P, Q, and R. Find a three-segment path beginning on g and ending on h, such that P, Q, and R are the midpoints of its segments. Can there be more than one such path? What if $g = h$ or $g \parallel h$?

Did your solution of exercise 17 require that the table be rectangular? Probably not. Could you extend it to apply to a convex polygonal table with any number of edges? Probably so—you can buy or build novelty billiards games like that. Exercise 18 didn't place any limitations on points

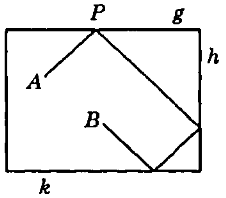

Figure 6.11.3
Exercise 17

---

[28] Several exercises under this heading are due to Max Jeger [1964] 1966.

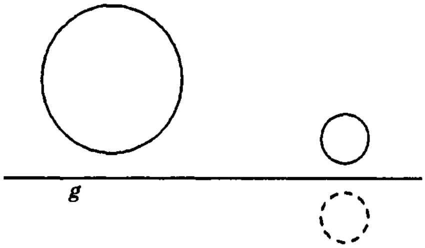

Figure 6.11.4
Exercise 19

P, Q, and R. Can you extend it to apply to any number of points? Exercises 34 and 35 consider *closed* polygonal paths of this sort.

Exercise 19. Consider two circles on the same side of line g. Find a point P on g such that tangents through P to the circles make equal angles with g. How many such points are there? *Suggestion*: Reflect one of the circles across g, as in figure 6.11.4.

Exercise 20. Consider two points A and B on the same side of line g. Find points O, P, and Q on g such that $2\text{m}\angle OPA = \text{m}\angle QPB$. *Suggestion*: Consider exercise 19.

Exercise 21. Consider a point P and concentric circles Γ and Δ. Look for points Q and R on Γ and Δ such that ΔPQR is equilateral. Under what condition on P, Γ, and Δ is a solution possible? How many solutions can there be? *Suggestion*: On which *two* circles must Q lie?

Exercise 22. Given ΔABC with $\text{m}\angle A < 90°$, find points C_1 and C_2 on the edge opposite C and points A_1 and B_1 on the edges opposite A and B such that $A_1B_1C_1C_2$ is a rectangle and $C_1C_2 = 2(B_1C_1)$.

Exercise 23. Consider a point B, two circles Γ and Δ, and any number $t > 0$. Find points C and D on Γ and Δ such that C-B-D and $BC/BD = t$. How many solutions could there be? Describe, as completely as you can, the set $\mathscr{B}$ of points B for which a solution is possible. *Suggestions*: On which *two* circles must C lie? Describing $\mathscr{B}$ is difficult; you may want to plot the points B corresponding to several thousand pairs of points C and D on Γ and Δ. The details of your description may vary depending on the situation of the circles.

Exercises on equations

Each exercise under this heading is concerned with the equation $X' = AX + B$ of a transformation $\varphi : X \to X'$. In exercises 24 to 26 the problem is simply to find the equation—that is, the entries of A and B.

Exercise 24. Two rotations about the point $Z = <1, 2>$ each map the line $2x_1 - x_2 = 0$ onto the line $x_1 - x_2 = -1$. Determine their equations, accurate to four decimal places.

Exercise 25. Consider a point $P = <p_1, p_2> \neq O$ and the line $g \perp \vec{OP}$ through O.

Part 1. Show that σ_g has matrix

$$A = I - \frac{2}{P^tP}K, \text{ where } K = PP^t = \begin{bmatrix} p_1^2 & p_1p_2 \\ p_2p_1 & p_2^2 \end{bmatrix}.$$

Part 2. Consider the line $h \perp \vec{OP}$ through a point Q. Show that $\sigma_h : X \rightarrow X'$ has equation

$$X' = AX + \frac{2}{P^tP}KQ.$$

Part 3. Find an equation for the reflection across the line h with equation $x_1 + 2x_2 = 3$.

Part 4. Find an equation for the glide reflection with axis h and vector $<2, -1>$.

Exercise 26. Consider points $A = <1, 0>$, $B = <2, 0>$, and $C = <0, 2>$, and the feet D and F of the altitudes of ΔABC through A and C. According to theorem 5.8.1, $\Delta ABC \sim \Delta DBF$.

Part 1. Find the equations of the similarity $\varphi : X \rightarrow X'$ that maps ΔABC onto ΔDBF.

Part 2. What's its ratio?

Part 3. Express φ as a composition of some or all of these: reflection, translation, rotation, glide reflection, dilation, and contraction.

Part 4. Find its fixpoint.

Suggestion: The entries of the matrix and vector for φ form the solution of a system of six linear equations in six unknowns. You might want to solve that for part (1), then work on (3). Or you could solve (3) first geometrically, then do (1).

Exercise 27 asks you to classify four transformations. First, show that they're isometries. Then you have the same tools at hand as for earlier classification exercises. Use them! The logic is the same, but now you compute with coordinates.

Exercise 27. Show that each of the following systems of equations represents an isometry φ, and classify it.

(a) $\begin{cases} x_1' = \frac{3}{5}x_1 + \frac{4}{5}x_2 \\ x_2' = -\frac{4}{5}x_1 + \frac{3}{5}x_2 \end{cases}$ (c) $\begin{cases} x_1' = \frac{3}{5}x_1 + \frac{4}{5}x_2 + 1 \\ x_2' = -\frac{4}{5}x_1 + \frac{3}{5}x_2 - 1 \end{cases}$

(b) $\begin{cases} x_1' = \frac{3}{5}x_1 - \frac{4}{5}x_2 \\ x_2' = -\frac{4}{5}x_1 - \frac{3}{5}x_2 \end{cases}$ (d) $\begin{cases} x_1' = \frac{3}{5}x_1 - \frac{4}{5}x_2 + 1 \\ x_2' = -\frac{4}{5}x_1 - \frac{3}{5}x_2 - 1 \end{cases}$

The next three exercises could have been placed under the earlier **Classifying isometries** heading. To solve them you don't really need to work with their equations. But that might be the simplest way.

Exercise 28. Classify the compositions of the 1° rotation about point <2, 3> and the translation with vector <4, 5>, in both orders.

Exercise 29. Classify the compositions of the 1° rotation about point <2, 3> and the 4° rotation about point <5, 6>, in both orders.

Exercise 30. Classify the compositions of the 10° rotation about the origin and the reflection across the line with equation $x_1 + x_2 = 1$, in both orders.

A geometric transformation φ associates with points of a figure those of a corresponding figure—its image—perhaps in another place. You could call this the *alibi* version of the concept—*alibi* is the Latin word for *elsewhere*. There's another version, often used in analytic geometry. Suppose the figure is a coordinate system; then so is its image. A point P with coordinates $<x_1, x_2>$ relative to the first system has coordinates $<x_1', x_2'>$ relative to the second. Associated with φ is a *coordinate transformation* that maps the coordinate pair $<x_1, x_2>$ to $<x_1', x_2'>$. Some texts regard *that* as the basic geometric transformation concept: Points of a figure Φ have two corresponding coordinate pairs. You could call it the *alias* version—*alias* is the Latin word for *otherwise*, to which we often add *known as*. Suppose you want to use two coordinate systems to model different aspects of some phenomenon. It's usually easy to find the isometry φ that transforms one into the other; it's part of the problem framework. Then you can derive an equation for φ. How do you use that to find equations that relate the corresponding coordinate pairs $<x_1, x_2>$ and $<x_1', x_2'>$ of a point P? (These considerations were introduced, with slightly different notation, under the heading **Transforming coordinate systems** in section 6.9.) Figures Φ in your model may be described by equations that relate the two coordinates of points P of Φ. How do you convert an equation that relates x_1 and x_2 to one for x_1' and x_2'? Exercise 31 provides some examples of this process. You'll have to decide when and how to use the equation of φ and that of its inverse. You'll see that how you transform equations that describe figures depends on whether they're single equations or pairs of parametric equations.

Exercise 31. Suppose that, in addition to your standard Cartesian coordinate system with origin O, you're using an auxiliary one with

- origin $O' = <3, 2>$,
- unit point U' for the first axis located below and left of O' on the line through O' with slope 1, and
- unit point V' for the second axis located above and left of O'.

A point $X = <x_1, x_2>$ has coordinates x_1' and x_2' relative to this coordinate system.

Part 1. Find formulas for x_1' and x_2' in terms of x_1 and x_2.

Part 2. Find the equation of the unit circle Γ with center O in terms of the auxiliary coordinate system: X must lie on Γ if and only if x_1' and x_2' satisfy the equation.

Part 3. $x_2 = x_1^2$ is the equation of a parabola Π. Find the equation of Π in terms of the auxiliary coordinate system.

Part 4. $x_1 = \cos t$ and $x_2 = 2 \sin t$ for $0 \le t < 2\pi$ are parametric equations for an ellipse Λ. Find parametric equations for Λ in terms of the auxiliary coordinate system.

Reflection calculus

During the 1920s Gerhard Thomsen discovered how to formulate many familiar properties of plane figures in terms of equations involving compositions of point and line reflections. The first few exercises under this heading introduce this method. You can solve them by manipulating equations involving reflections, half turns, translations, and occasionally vector algebra. You never have to use coordinates explicitly. You can call this method a *reflection calculus.*

Exercise 32. Show that for any points O, P, and Q, the composition $\sigma_O \sigma_P \sigma_Q$ is a half turn about point $R = O - P + Q$, and $OPRQ$ is a (possibly degenerate) parallelogram.

Exercise 33. Describe the figure formed by points A, B, C, and G for which $\sigma_A \sigma_G \sigma_B \sigma_G \sigma_C \sigma_G = \iota$. *Suggestion*: Reason with vectors.

Exercise 34. Construct a pentagon with given edge midpoints M_1 to M_5. Is it unique? Generalize your solution to apply to polygons with more edges.

Gerhard THOMSEN was born in Hamburg in 1899, the son of a physician. He served a year in World War I, then became one of the first students of the new university at Hamburg. Thomsen completed the Ph.D. in 1923 with a dissertation on differential geometry. He served as assistant in Karlsruhe and Hamburg, studied a year with Tullio Levi-Civita in Rome, then presented his Habilitationsschrift in Hamburg, on a problem in gravitational physics. In 1929 he became Ausserordentlicher Professor at Rostock. There he continued work on differential geometry, collaborating with Wilhelm Blaschke, and published as well in mathematical physics and foundations of geometry. In 1933, reacting to the Nazification turmoil in his university, he published an inflammatory lecture that seemed to support some Nazi aims but attacked Nazi suppression of education in the sciences. This evidently attracted the attention of the secret police. Thomsen died, an apparent suicide, on a Rostock railroad track in 1934.

Exercise 35. When can you construct a quadrilateral with given edge midpoints? When is it unique? How about a hexagon? *Suggestion*: What kind of figure is formed by the midpoints of the edges of a quadrilateral? Of a hexagon?

Exercises 34 and 35 are closely related to exercise 17 on billiards and to exercise 18. Can you imagine the pentagon and hexagon as *dual billiards* tables? You play on the outside, grazing the corners instead of rebounding from the sides!

A development of the reflection calculus and results obtained with it were published in Thomsen 1933a. Exercises 36 to 39 are selected from section 4 of that book.

Exercise 36. Consider points P and Q, lines g and h, and the isometry $\varphi = \sigma_g \sigma_P \sigma_h \sigma_Q$. Under what condition on the points and lines is $\varphi = \iota$? *Suggestion*: First, classify $\sigma_g \sigma_P$ and $\sigma_h \sigma_Q$.

Exercise 37. Prove that these conditions on lines g and h are equivalent:

(a) $g \parallel h$;
(b) for *every* point P, $\sigma_g \sigma_h \sigma_P \sigma_g \sigma_h \sigma_P = \iota$ but $\sigma_g \sigma_h \sigma_P \neq \iota$;
(c) for *some* point P, $\sigma_g \sigma_h \sigma_P \sigma_g \sigma_h \sigma_P = \iota$ but $\sigma_g \sigma_h \sigma_P \neq \iota$.

Exercise 38. Consider some lines a, b, and c and the isometry

$$\varphi = \sigma_c\sigma_a\sigma_b\sigma_a\sigma_b\sigma_a\sigma_c\sigma_b\sigma_a\sigma_c\sigma_a\sigma_c\sigma_a\sigma_b.$$

Prove that φ is the identity if and only if a, b, and c are copencilar or form an isosceles triangle with congruent edges on b and c. *Suggestion*: It's easy to show that copencilarity implies $\varphi = \iota$. When there's a triangle, consider the line g through the feet B^* and C^* of the altitudes perpendicular to b and c. When is $g \parallel a$? What isometry is $\gamma = \sigma_b\sigma_a\sigma_c$?

Exercise 39. Show that for any lines a, b, and c,

$$\sigma_a\sigma_b\sigma_c\sigma_a\sigma_b\sigma_c\sigma_b\sigma_c\sigma_a\sigma_b\sigma_c\sigma_a\sigma_c\sigma_b\sigma_a\sigma_c\sigma_b\sigma_c\sigma_b\sigma_a\sigma_c\sigma_b = \iota.$$[29]

Exercises on the definitions of isometry and similarity

The next two exercises are concerned with functions that map the plane to itself but satisfy (seemingly) weaker conditions than isometries or similarities.

Exercise 40. Show that any function $\varphi : X \to X'$ from the plane to itself that preserves distance is an isometry. That is, from the hypothesis that $X'Y' = XY$ for all X and Y, deduce that φ is injective and surjective. *Suggestion*: For surjectivity, given Y, you must find X such that $Y = X'$; select two points P and Q and observe the relationship of Y to P' and Q'.

Exercise 41. Let r be any positive number and φ be a function from the plane to itself such that $X'Y' = r\,(XY)$ for all X and Y. Prove that φ is a similarity with ratio r. *Suggestion*: Use exercise 40.

It's possible to weaken the definitions of isometry and similarity even further than these exercises suggest. For example, invariance of the property of separation by distance 1 —that is, the condition $XY = 1$ if and only if $X'Y' = 1$ —implies that φ is an isometry.[30]

---

[29] Responding to a question from Thomsen, Hellmuth Kneser (1931) showed that this equation is the shortest that's true for *all* lines a, b, and c, except for equations like $\sigma_a\sigma_a = \iota$ and others such as $\sigma_a\sigma_b\sigma_b\sigma_a = \iota$ that are derivable from it.

[30] Modenov and Parkhomenko [1961] 1965, appendix.

Dilatations

A *dilatation*[31] is a plane transformation $\varphi : X \rightsquigarrow X'$ such that the image $g' = \varphi[g]$ of any line g is a line parallel or equal to g. The last four exercises of this chapter develop the theory of dilatations, which plays a major role in some axiomatizations of geometry.[32] You should solve them without using any limit concepts from analysis. Your solutions will provide a proof of the fixpoint theorem for similarities, theorem 6.10.8, that, unlike the proof in the text, requires no analysis. In your solutions of exercises 43 to 45, you're expected to use the results in the preceding exercises.

Exercise 42. Prove that the dilatations form a transformation group. Of the various types of isometries and similarities considered in this chapter, which are dilatations and which not?

Exercise 43. Show that

(a) the only dilatation with two distinct fixpoints is the identity, and
(b) if φ and χ are dilatations and $\varphi(X) = \chi(X)$ for two distinct points X, then $\varphi = \chi$.

Suggestions: For (a) show first that a dilatation $\varphi : X \rightsquigarrow X'$ with distinct fixpoints P and Q fixes every point *not* on $\overleftrightarrow{PQ}$, then consider points *on* the line. Note that any line through a fixpoint is fixed and any point on two fixed lines is fixed.

Exercise 44. Show that every dilatation $\varphi : X \rightsquigarrow X'$ that's not a translation has a fixpoint. *Suggestion*: Find P and Q such that $PP'Q'Q$ is a quadrilateral, then show that it can't be a parallelogram.

Exercise 45. Prove that every dilatation that's not a translation is a contraction, a dilation, or the composition of a contraction or dilation with the half turn about its center.

---

[31] Be careful not to confuse the terms *dilation* and *dilatation*! The first stems from the Latin prefix *dis-*, meaning *apart*, with the past participle *latus* of the irregular Latin verb *fero*, which means *carry*. The second is from the related regular verb *dilato*, which means *broaden*.

Chapter

7

Three-dimensional isometries and similarities

Chapter 6 introduced plane transformational geometry. You studied plane isometries and similarities in depth. New concepts entered gradually, so that each new idea was related as closely as possible to basic geometry, where our visual intuition provides a clear guide. With that background, you've studied the effects of plane motions, and plane Cartesian coordinate transformations. You're prepared to analyze symmetries of plane ornamentation undertaken later, in chapter 8. And you're prepared to study more general types of plane transformations that fall beyond the scope of this book.

But you haven't many techniques yet to handle motions and coordinate transformations in three-dimensional space, where you live. Nor are you ready yet to analyze the three-dimensional symmetries of polyhedra and crystals. For that, this chapter provides a complete coverage of three-dimensional isometries and similarities. You'll see that it's a straightforward extension of the two-dimensional theory. Of course, there are more isometry types in three dimensions, but the algebra techniques you used in two dimensions apply without change in this chapter.

Because you've already met, in simpler form, most of the ideas discussed in this chapter, it's more streamlined. Concepts are introduced and studied in the order that leads most quickly to the main results of the theory. To that end, the chapter relies more heavily on algebra. Sometimes this is "brutally" efficient. For example, section 7.1 derives the matrix equation $X' = AX + B$ for an isometry $X \to X'$ directly from the uniqueness and rigidity theorems, before considering in detail *even one* particular type of isometry.

That plan makes various general techniques available for use earlier. But following it in chapter 6 would have prevented you from applying your geometric experience effectively in learning new concepts.

The greater reliance on algebra is also due to the greater complexity of three dimensions. Many problems to which we now apply algebraic plane transformational geometry methods could be solved without that theory. Algebra reveals its usefulness as it helps reduce the complexity in three dimensions.

7.1 Isometries

Concepts

- Definition
- The isometry group
- Invariance
- Rigidity theorem
- Uniqueness theorem
- Orthogonal matrices
- Equations of isometries
- Conjugacy
- Parity

This section extends to three dimensions the notion of isometry that you studied in chapter 6. It also presents various properties shared by all such isometries: the fixpoint, rigidity, and uniqueness theorems, representation of isometries $X \to X'$ by equations $X' = AX + B$ with orthogonal matrices A, the relationship of these equations to conjugacy, and the distinction between even and odd isometries. You'll study particular types of isometries in later sections.

The equations require a Cartesian coordinate system. Introduce a "standard" system $\mathscr{C}$ now, with origin O and unit vectors U_1 to U_3, and refer to it as necessary.

In the three-dimensional theory, an *isometry* is a distance-preserving transformation of the set of *all* points—not just those in some plane. As in two dimensions, you can show that the identity transformation ι is an isometry, the inverse φ^{-1} of an isometry φ is an isometry, and the composition $\varphi\chi$ of two isometries φ and χ is an isometry:

Theorem 1. The isometries form a subgroup of the symmetric group of the set of all points.

There's a whole catalog of properties of three-dimensional figures that are invariant under isometries: the invariant properties of plane figures that you've already considered—especially betweenness—plus

measure of a dihedral angle
volume of a tetrahedron
perpendicularity
parallelism, etc.

being a
- plane
- half space
- dihedral angle
- tetrahedron
- sphere

This text won't pursue those details. As necessary, you can supply invariance proofs like that of theorem 6.2.5, because you can define all these concepts in terms of distance (using betweenness if appropriate).

Rigidity and uniqueness theorems

The uniqueness theorem is a major tool in the plane theory. To see that an isometry under analysis is really a familiar one, you need only show that they agree at three noncollinear points. An analogous tool performs the same function in three dimensions. The plane version was derived from the *rigidity theorems* 6.2.6 and 6.2.7; its three-dimensional form requires analogs of those results. The first one is already valid in three dimensions:

Theorem 2. If an isometry $X \to X'$ has distinct fixpoints P and Q, then it fixes every point X on $\overleftrightarrow{PQ}$.

You can check that the original proof is valid, too. For the next result, you must edit the statement of theorem 6.2.7; its proof remains valid.

Theorem 3. If an isometry $X \to X'$ has noncollinear fixpoints P, Q, and R, then it fixes every point X on the plane PQR.

Three-dimensional geometry enters with a new rigidity result. Its proof, exercise 7.9.1, is merely a three-dimensional version of the proof of theorem 6.2.7.

Theorem 4. The only isometry with four noncoplanar fixpoints is the identity.

With this foundation, you can easily state the three-dimensional *uniqueness theorem*. Its proof is the same as that of the two-dimensional version, corollary 6.2.8.

Corollary 5 (Uniqueness theorem). If χ and ψ are isometries and $\chi(P) = \psi(P)$ for four noncoplanar points P, then $\chi = \psi$.

Orthogonal matrices

The entire analytic treatment of isometries with matrix algebra works in three dimensions just as it did in two. Appendix C presents an outline of the elementary features of vector and matrix algebra, independent of dimension. The notion of orthogonality, introduced in section 6.8, applies to square matrices A of *any* dimension: A is *orthogonal* if $A^tA = I$, i.e., its transpose is its inverse. As noted there, the identity matrix I is orthogonal, the inverse of an orthogonal matrix is orthogonal, and the product of two orthogonal matrices is orthogonal. That section also showed that for *any* orthogonal matrix A and vector B, the mapping $X \rightarrow AX + B$ is an isometry.

These analogies suggest that *every* three-dimensional isometry φ should have an equation $\varphi(X) = AX + B$ for some orthogonal matrix A and some vector B. The argument for the corresponding plane result, theorem 6.8.2, required the equations for two special types of isometries, including some rotations. You *could* take that approach in three dimensions, deriving analogs of those special equations. But that's difficult because equations of three-dimensional rotations are generally more complicated. The argument in the next proof, however, doesn't depend on individual equations nor on the dimension; so the desired result holds in three dimensions as well. The first step is to show that you can map your preselected coordinate system O, U_1, U_2, U_3 into *any* other one by applying a transformation of the form $X \rightarrow AX + B$ with an orthogonal matrix A.

Theorem 6. Given points B, V_1, V_2, V_3 such that $BV_j = 1$ for $j = 1$ to 3 and $\overrightarrow{BV}_1$ to $\overrightarrow{BV}_3$ are perpendicular, there's an orthogonal matrix A such that $AU_j + B = V$ for $j = 1$ to 3.

Proof. Construct the matrix A whose jth column is $A_j = V_j - B$. Then $AU_j + B = A_j + B = V_j$, as desired. Moreover, $A_j \cdot A_j = (BV_j)^2 = 1$. Now suppose $j \neq k$. Since $\overrightarrow{BV}_j \perp \overrightarrow{BV}_k$, Pythagoras' theorem implies

$$(OA_j)^2 + (OA_k)^2 = (BV_j)^2 + (BV_k)^2 = (V_jV_k)^2.$$

But $V_j - V_k = A_j - A_k$, so

$$(V_jV_k)^2 = (V_j - V_k)\cdot(V_j - V_k) = (A_j - A_k)\cdot(A_j - A_k) = (A_jA_k)^2.$$

The converse part of Pythagoras' theorem now yields $\overrightarrow{OA}_j \perp \overrightarrow{OA}_k$, and $A_j \cdot A_k = 0$ by theorem 3.11.10. It follows that A is orthogonal: $A^tA = I$. To see that, note that the j,kth entry of A^tA is the jth row of A^t times the kth column of A —that is, $A_j \cdot A_k$. According to the equations just derived, that's 1 if $j = k$ or 0 if $j \neq k$. It's the j,kth entry of I.[1] ♦

---

[1] The word *orthogonal*, a synonym for *perpendicular*, stems from the Greek words *orthos* and *gonia* for *upright* and *angle*. Matrices like A were termed orthogonal because their column vectors are perpendicular, as noted in this proof.

Theorem 7. The three-dimensional isometries are the mappings $X \to \varphi(X) = AX + B$, where A is an orthogonal matrix and B is an arbitrary vector. The isometry φ determines A and B uniquely.

Proof. You've already seen that this equation always defines an isometry. It remains to show that an arbitrary isometry φ has such an equation, and only one. First, φ maps your standard coordinate system O, U_1, U_2, U_3 into another system B, V_1, V_2, V_3. By theorem 6, there's an orthogonal matrix A such that $AU_j + B = V_j$ for $j = 1$ to 3. The isometry $X \to AX + B$ agrees with φ at four noncoplanar points O and U_1 to U_3. By the uniqueness theorem, the two isometries coincide: $\varphi(X) = AX + B$ for every X, as required. Finally, you can use the last paragraph of the proof of theorem 6.8.1 to show that φ determines A and B uniquely. ♦

The short algebraic argument in the proof of theorem 6 could have been used in chapter 6 to avoid some matrix calculations. But it has so little visual content that the longer argument was used instead. It's difficult to determine just how this material was originally discovered. In essence, it's already present in Euler [1775] 1968.

Conjugacy

Chapter 6 used the notion of conjugacy to classify plane isometries. It plays the same role in three dimensions. Its definition in section 6.9 applies to *any* transformations μ and φ; the composition $\varphi\mu\varphi^{-1}$ is the conjugate of μ by φ. We write $\lambda \sim \mu$ to indicate that a transformation λ is a conjugate of μ. The basic theorems 6.9.4 and 6.9.5 hold for three-dimensional isometries, too. In particular, conjugacy is an equivalence relation, and the equivalence class of an isometry is called its conjugacy class. Sections 7.2 to 7.5 use conjugacy to classify isometries.

The section 6.9 discussion of coordinate transformations, equations of isometries, and their conjugacy is essentially valid for three dimensions, too. An isometry φ transforms your standard coordinate system $\mathscr{C}$ into another system $\mathscr{D}$ defined by $P = \varphi(O)$ and $V_j = \varphi(U_j)$ for $j = 1$ to 3 as in figure 7.1.1. Theorem 9, the analog of theorem 6.9.6, shows how a point's $\mathscr{C}$ and $\mathscr{D}$ coordinates are related.

Theorem 9. If an isometry φ transforms coordinate system $\mathscr{C}$ into system $\mathscr{D}$, then the $\mathscr{C}$ coordinates of each point X are the same as the $\mathscr{D}$ coordinates of $Y = \varphi(X)$.

Proof. Consider figure 7.1.1. The figure formed by O, U_1 to U_3, and X is congruent to that formed by P, V_1 to V_3, and Y. ♦

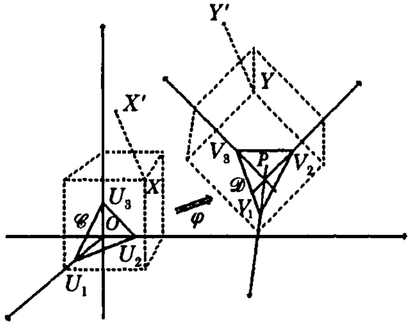

Figure 7.1.1
Transforming
a coordinate system

Theorem 10, the main result about conjugacy, is the analog of theorem 6.9.7; you can use its proof unchanged, if you cite theorem 6 of this section in place of theorem 6.6.3.

***Theorem 10* (*Conjugacy theorem*).** Two isometries are conjugate if and only if there are coordinate systems under which they have the same matrix equation.

Parity

As in two dimensions, the determinant par φ of the orthogonal matrix A corresponding to an isometry φ is called its *parity*. Since equation $A^tA = I$ implies $(\det A)^2 = (\det A^t)(\det A) = \det(A^tA) = \det I = 1$, the parity is ± 1. Isometries with parity 1 are called *even*. For example, the identity is an even isometry. The others are called *odd*. This section concludes with some simple facts about parity that you've already met in the plane theory. The connection between parity and orientation is discussed in the next section.

Theorem 11. par $\varphi\chi =$ par φ par χ and par $\varphi^{-1} =$ par φ for any isometries φ and χ.

Corollary 12. The even isometries constitute a subgroup of the isometry group.

Corollary 13. Conjugate isometries have the same parity.

Leonhard EULER was born in Basel in 1707. He was taught first by his father, a protestant minister, who had attended Jakob Bernouilli's lectures at the university there. In 1720 Euler entered the university. He studied with Johann Bernouilli, and received a degree in philosophy in 1723 with a comparison of Newton's and Descartes' ideas. He started theological studies, but dropped those for mathematics. Although he published some papers on mechanics, Euler could find no job at Basel. In 1727, however, Peter the Great's reign was ending, the Academy of Science at St. Petersburg was being formed, and the intelligentsia there was becoming dominated by Germans. On Bernouilli's recommendation, they offered Euler a job; he became Professor there in 1731. The Academy had scientific, educational, and technological assignments, and provided a very rich atmosphere. Euler produced about 90 papers on mathematics there during the period 1727–1741, and a treatise on mechanics. He worked on cartography, shipbuilding, and navigation as well.

Euler's brother also had an Academy position, as an artist. In 1733 Euler married the daughter of another Swiss artist at the Academy. Two sons were born in St. Petersburg. Later, in Berlin, they had another son and two daughters; eight other children died in infancy. In 1738, Euler contracted a disease that left him blind in one eye.

Political turmoil in Russia, particularly resentment against German influence, arose during the late 1730s, simultaneous with Frederick the Great's reorganization of the Academy of Science at Berlin. After prolonged negotiations, Euler moved there in 1741. However, he retained many connections with the St. Petersburg Academy, editing its mathematical publications and publishing there his own texts on calculus and navigation. Euler stayed in Berlin for 25 years. During that period he produced about 380 papers in pure and applied mathematics, and was elected to the Academies in London and Paris as well. Euler was very influential in the development and administration of the Berlin Academy, actually running it for many years. But he and the King were incompatible; Frederick wouldn't appoint him President.

In 1766, Euler returned to St. Petersburg. The long, stable reign of Catherine the Great had begun. One of Euler's sons became professor of physics there; another, an artillery officer. An illness in 1769–1771 led to Euler's total blindness. But his scientific output actually increased! Besides many research papers, he published texts on algebra, calculus, navigation, and life insurance, and treatises on optics and lunar theory. His first wife died in 1773; in 1776 he married her half-sister. Euler died of a brain hemorrhage in the midst of heavy work in 1783.

7.2 Reflections

Concepts

Reflections across planes
Conjugate reflections
Structure theorem
Even and odd isometries
Orientation

Reflections play a fundamental role in the theory of plane isometries. They provide components from which you can construct all other isometries, and they facilitate the distinction between even and odd isometries. Their three-dimensional counterparts are the *reflections across planes.* The reflection $X' = \sigma_\varepsilon(X)$ of a point X across a plane ε is X itself if X is on ε, else it's the point on the opposite side of ε such that ε is the perpendicular bisector of $\overline{XX'}$. The plane ε is called the *mirror* of σ_ε. To study these reflections, it's sometimes convenient to use the theory of plane isometries. Theorem 1 follows directly from the plane theory and the definition of σ_ε. (See figure 7.2.1.) You can supply the proof.

Theorem 1. σ_ε is self-inverse. Its fixpoints are the points in ε. It fixes any plane $\alpha \perp \varepsilon$, and its restriction to α is the (two-dimensional) reflection of the points on α across the intersection $g = \alpha \cap \varepsilon$.

Corollary 2. σ_ε is an isometry.

Proof. (See figure 7.2.1.) Any two points X and Y lie in some plane $\alpha \perp \varepsilon$, and σ_ε operates on X and Y just as the (two-dimensional) reflection of α across $g = \alpha \cap \varepsilon$. That preserves the distance XY. ♦

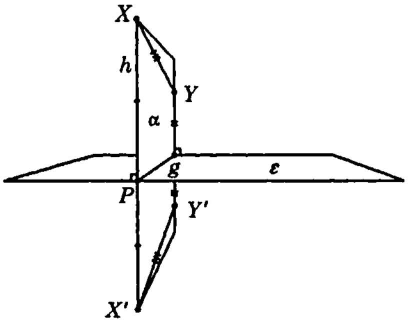

Figure 7.2.1
Reflection
$\sigma_\varepsilon: X \rightarrow X'$ across ε

Theorem 3. An isometry φ that leaves a plane ε pointwise fixed is the identity or σ_ε.

Proof. Select a point X not on ε, construct the line $h \perp \varepsilon$ through X, and let $P = h \cap \varepsilon$. (See figure 7.2.1.) Since φ fixes P and ε, it maps h to a line through P perpendicular to ε. That is, φ fixes h, so $\varphi(X)$ is one of the two points X and $\sigma_\varepsilon(X)$ on h whose distance from P is PX. Thus φ agrees either with ι or with σ_ε at four noncoplanar points: X and any three noncollinear points on ε. The uniqueness theorem yields $\varphi = \iota$ or σ_ε. ♦

Corollary 4. $\varphi\sigma_\varepsilon\varphi^{-1} = \sigma_{\varphi[\varepsilon]}$ for any isometry φ and any plane ε.

Proof. Use the argument under the section 6.9 heading **Conjugacy classes** to show that $\varphi\sigma_\varepsilon\varphi^{-1}$ leaves plane $\varphi[\varepsilon]$ pointwise fixed, but isn't the identity. ♦

The equation of the reflection $\sigma_\varepsilon : X \to X'$ across a plane ε is generally unwieldy—see exercise 7.9.20. But for some special planes it's very simple. For example, if ε is the plane through the first two coordinate axes, then σ_ε has equations

$$\begin{aligned} x_1' &= x_1 \\ x_2' &= x_2 \\ x_3' &= -x_3 \end{aligned} \qquad X' = AX \qquad A = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & -1 \end{bmatrix}.$$

This matrix A is orthogonal, with determinant -1.

Any plane ε contains the first two axes of some coordinate system, so any two reflections have the same equations with respect to suitably chosen coordinate systems. With the conjugacy theorem, corollary 4, and corollary 7.1.13, this implies

Theorem 5. The reflections constitute a single conjugacy class. All reflections are odd.

Structure theorem

According to the structure theorem in two-dimensional transformational geometry, every plane isometry is the identity, a reflection, or the composition of two or three reflections. That result is the basis for classifying plane isometries. An analogous one holds in the three-dimensional theory. You'll notice that its proof is organized just like that of theorem 6.6.4, the two-dimensional result.

Theorem 6 **(*Structure theorem*).** The three-dimensional isometry group consists of the identity, the reflections, and the compositions of two, three, and four reflections.

Proof. An isometry φ maps a tetrahedron Γ into a congruent tetrahedron Δ. If $\Gamma = \Delta$, then φ is the identity by the rigidity theorem. If Γ and Δ share three vertices but not four, then φ is the reflection across the plane δ through those vertices, by theorem 3.

If Γ and Δ share *two* vertices, then there's a plane γ through those vertices such that Γ and the tetrahedron $\sigma_\gamma[\Delta]$ share *three* vertices. (Make γ "bisect" a certain dihedral angle.) By the previous paragraph, $\sigma_\gamma \varphi$ is the identity or the reflection across a plane δ, so $\varphi = \sigma_\gamma$ or $\sigma_\gamma \sigma_\delta$.

If Γ and Δ share *one* vertex, then there's a plane β through it such that Γ and the tetrahedron $\sigma_\beta[\Delta]$ share *two*. By the previous paragraph, $\sigma_\beta \varphi = \sigma_\gamma$ or $\sigma_\gamma \sigma_\delta$ for some planes γ and δ, so $\varphi = \sigma_\beta \sigma_\gamma$ or $\sigma_\beta \sigma_\gamma \sigma_\delta$.

Even if Γ and Δ share *no* vertices, there's a plane α —the perpendicular bisector of any segment joining two corresponding vertices—such that Γ and the tetrahedron $\sigma_\alpha[\Delta]$ have at least *one* vertex in common. By the previous paragraph, $\sigma_\alpha \varphi = \sigma_\beta \sigma_\gamma$ or $\sigma_\beta \sigma_\gamma \sigma_\delta$ for planes β, γ, and δ, so φ is the composition of three or four reflections. ♦

Corollary *7.* An isometry is even or odd depending on whether it's a composition of an even or odd number of reflections.

Proof. Every isometry is a composition of reflections, which are odd. ♦
